24 Running Title: Community-weighted mean traits determines soil properties

25

26

27

28

29 **Abstract.** Climate change and human activities have caused a shift in vegetation
30 composition and soil biogeochemical cycles of alpine wetlands on the Tibetan Plateau.
31 The primary goal of this study was to test for associations between
32 community-weighted mean (CWM) trait and functional diversity, and soil properties
33 during wetland drying. We collected soil samples and investigated the above-ground
34 vegetation in swamp, swamp meadow and typical meadow; four CWM trait values
35 (specific leaf area, SLA; leaf dry matter content, LDMC; leaf area, LA; and mature
36 plant height, MPH) for 42 common species were measured across the three habitats;
37 three components of functional diversity (functional richness; functional evenness;
38 and functional divergence) were also quantified in these sites. Our results showed that
39 the drying of the wetland dramatically altered plant community and soil properties.
40 There was a significant correlation between CWM of traits and soil properties, but not
41 a significant correlation between functional diversity and soil properties. Our results
42 further showed that CWM-LA, CWM-SLA and CWM-LDMC had positive
43 correlations with soil readily available nutrients (available nitrogen, AN; available
44 phosphorus, AP), but negative correlations with total soil nutrients (soil organic
45 carbon, SOC; total nitrogen TN; and total phosphorus, TP). Our study demonstrated
46 that simple, quantitative plant functional traits, but not functional diversity, are
47 directly related to soil C/N properties, and likely play an important role in plant-soil
48 interactions, and our results also suggest that functional identity of species may be
49 more important than functional diversity in influencing ecosystem processes during
50 wetland drying.

59 **1 Introduction**

60 About one third of China's natural wetlands are situated on the Tibetan Plateau,
61 according to a state-of-the-art remote sensing-based classification (Gong et al., 2010).
62 The wetlands of Maqu on the Tibetan Plateau are one of the highest wetlands, and
63 they play very important role in water resources conservation, and in regulating the
64 river systems and regional climates across the entire Yellow River basin (Cai and Guo
65 2007). However, these wetlands are also climate-sensitive and have been gradually
66 shrinking and drying due to climate change and human activities, such as heavy
67 grazing and land use changes (Cai and Guo 2007; Peng et al., 2015; Wang et al.,
68 2016). Hence, it is imperative that we examine the changes of vegetation and soil, and
69 the relationships between them during this process of wetland drying for prediction
70 and conservation efforts.

71 Previous studies have suggested that there may be a secondary successional
72 change from swamp to swamp meadow and mature meadow, and that soil water
73 availability may be the main driver of this succession process (Ma et al., 2014; He and
74 Richards, 2015; Lin et al., 2015). At the same time, plant functional traits play an
75 important role in predicting the patterns of species composition, community structure,
76 and their responses to environment change, which has drawn substantial ecological
77 interest (e.g., Wright et al., 2004; McGill et al., 2006; Pérez et al., 2014; Li et al.,
78 2015); but it is not clear whether functional traits and functional diversity (i.e., the
79 identity, abundance and range of species in a given community) can reflect the
80 changes of soil properties during wetland drying on the Tibetan Plateau. A growing
81 body of evidence has shown that functional diversity is directly linked with ecosystem
82 processes (McGill et al., 2006; Flynn et al., 2011). However, recent studies have
83 shown that environmental disturbance (e.g., fertilization or grazing) did not influence
84 the value of functional diversity (Li et al., 2015; Niu et al., 2015), and functional traits
85 of species may be more important than functional diversity in influencing ecosystem
86 processes in an alpine meadow community (Li et al., 2015).

87 As the relationships between the plant community and environmental factors are
88 dynamic, certain traits may be used to predict the changes of environmental factors

89 (Lavorel and Garnier, 2002; Suding et al., 2008). At the species scale, some leaf traits
90 that respond to water or nutrient availability (e.g. leaf dry matter content (LDMC) and
91 leaf nitrogen content (LNC)) also affect leaf palatability and litter decomposability
92 (Diaz et al., 2004). Similar to this, at the community scale, the community-level
93 means of some functional traits (e.g. specific leaf area (SLA), leaf area (LA), LDMC
94 or plant height) weighted by their relative abundances can respond to environmental
95 change in grasslands, and affect nutrient cycling and dynamics (Garnier et al., 2004;
96 Quétier et al., 2007).

97 The “mass ratio hypothesis” proposed by Grime (1998) implies that the
98 functioning of ecosystems is determined to a large extent by the trait values of the
99 dominant species. This hypothesis was confirmed by some studies that account for
100 ecosystem functions such as primary productivity (Garnier et al., 2004) and
101 nitrification (Laughlin, 2011). Conversely, the “diversity hypothesis” postulates that
102 the traits diversity within a community can affect ecosystem processes (Tilman, 1997).
103 The high functional diversity may allow for a more complete use of resources among
104 species, thereby improving biomass production and nutrient cycling in ecosystems
105 (Loreau, 2000; Díaz and Cabido, 2001; Villéger et al., 2008; Mouchet et al., 2010).

106 The plant functional traits selected therefore pertain to the processing of resources
107 at the species level, with the underlying assumption that this would scale up to
108 ecosystem functioning (Lavorel and Garnier, 2002). We chose four functional traits,
109 known to affect nutrient cycles at the leaf, whole-plant, and ecosystem levels
110 (Cornelissen et al., 1999; Lavorel and Garnier, 2002): specific leaf area (SLA, the
111 ratio of water-saturated leaf area to leaf dry mass), leaf dry matter content (LDMC,
112 the ratio of leaf dry mass to water-saturated fresh mass), leaf area (LA) and mature
113 plant height (MPH). SLA is an important variable in comparative plant ecology
114 because it is closely related with relative growth rate (Wright et al., 2001) and leaf net
115 assimilation rate (Shipley and Lechowicz, 2000); it is also a good predictor of plant
116 response to resource availability (Grime, 1977). LDMC is tied to plant nutrient
117 retention and water (Poorter and Garnier, 1999). LA has important consequence for
118 the leaf energy and water balance (Cornelissen et al., 2003). MPH has been associated

119 with competitive ability in herbaceous plant communities, with the general idea that
120 light competition becomes more intense at high soil fertility when above-ground
121 biomass or vegetation stature increases (Hautier et al., 2009). Fast growing species
122 from nutrient-rich habitats usually have high SLA, high LNC and low LDMC, while
123 opposite trends characterize species from nutrient-poor habitats (Diaz et al., 2004).
124 These responses reflect a fundamental trade-off (leaf economics spectrum) between
125 traits related to nutrient conservation and traits related to nutrient acquisition and
126 turnover (Wright et al., 2004).

127 In this study, we investigate whether soil properties are affected by plant
128 functional traits and functional diversity during wetland drying. Ongoing
129 extensification of human activities has affected the functional composition and
130 structure of wetlands on the Tibetan Plateau (Cai and Guo, 2007; Peng et al., 2015).
131 At the same time, the soil nutrient availability has also been modified (Robson et al.,
132 2007), and this has been directly linked to community-level trait changes in response
133 to environmental dynamics (Diaz et al., 2007). The aim of this study was to answer
134 the following questions: (1) How do community composition and structure, and soil
135 nutrient characteristics, change following wetland drying on the Tibetan Plateau? (2)
136 Can the community weighted mean (CWM) trait values and functional diversity be
137 regarded as predictors of soil properties during wetland drying?

138 **2 Materials and methods**

139 **2.1 Study site**

140 This study was conducted at the Research Station of Alpine Meadow and Wetland
141 Ecosystems of Lanzhou University (N 33°58', E101°53') (Fig. 1). The site is located
142 on the eastern Tibetan Plateau. The mean annual temperature is 1.2 °C, ranging from
143 -10 °C in January to 11.7 °C in July, and the mean annual precipitation (calculated
144 from 1975 to 2010) was 620 mm, occurring mainly during the short, cool summer (Li
145 et al., 2011). The annual duration of cloud-free solar radiation is about 2580 h, and
146 there are on average 270 frost days per year. The soil type of the study area is alpine
147 meadow soil. Parent materials are from a variety of glacial deposits, alluvial deposits,
148 residual deposits, residual slope deposits, etc. (Chen and Wang, 1999). The

149 experiment was carried out in typical mature meadow, swamp meadow and swamp
150 which are adjacent to each other in our study area. These habitats have different
151 community compositions, structures and dominant species (Table 1).

152 **2.2 Experimental design and community measurements**

153 Twenty five sampling plots (10 m × 8 m) were selected in each meadow type.
154 Each plot was separated from the others by a 2-m buffer strip. Each plot was
155 separated into two subplots: a 4m × 8 m subplot for community investigation and soil
156 collection, and a 6 m × 8 m subplot for individual plant sampling. Community
157 measurements were conducted from 5 to 8 Sept 2010. One 0.25 m² quadrat was
158 harvested from the 4 m × 8 m subplot in each plot. The quadrat location was randomly
159 selected with the constraint that it was at least 0.5 m from the margin to avoid edge
160 effects. We estimated the cover of each species and vegetation before it was clipped
161 and brought to the lab. For clonal species, an individual plant was defined as a group
162 of tillers connected by a crown (Luo et al., 2006). The cover of each species in each
163 plot was estimated as a percentage using a canopy interception technique based on
164 cardboard cut-outs of various shapes and sizes as visual guides. All samples were
165 dried at 80 °C for 48 h, and weighed to the nearest 0.01 g. Above-ground biomass was
166 calculated by summing all dried biomass of harvested individuals within a quadrat.

167 **2.3 Soil collection and processing**

168 Soil samples (0–15 cm depth) were collected from each quadrat in each sampling
169 plot of each habitat, after the above-ground material was harvested. In each quadrat,
170 soil was randomly collected from three points (3.8 cm in diameter) using a bucket
171 auger and mixed into a single soil sample. All of the soil samples were brought into
172 the laboratory in airtight plastic bags. All of the soil samples were air-dried and then
173 filtered through a 0.2-mm sieve, discarding the visible roots and other plant debris.
174 Soil pH was measured using a pH meter with a glass electrode (soil/KCl ratio 1:2.5).
175 Soil water content was obtained by the oven-drying method. Soil organic carbon was
176 determined by wet oxidation with potassium dichromate (K₂Cr₂O₇), both dichromate
177 oxidation and dry combustion, using a carbon analyser with the Mebius method for
178 the Walkley-Black acid digestion (Kalembasa and Jenkinson, 1973). The soil total

179 nitrogen, available nitrogen, total phosphorus and available phosphorus were
180 measured by the methods of Miller and Keeney (1982).

181 Plant functional trait measurements

182 Following Perez-Harguindeguy et al. (2013), we measured four functional traits
183 (SLA, LDMC, LA and MPH) of 42 common species for three habitats in early
184 September 2010. These species represented 85-95% of the peak standing biomass and
185 80–90% of the vegetation cover of the total plant community in the studied plots. We
186 randomly sampled 1 individuals and 3 mature leaves at flowering time for each of the
187 42 species in each 6m × 8 m subplot. That is, 25 individuals and 75 mature leaves
188 were measured for each of the 42 species in each habitat. Mature plant height is the
189 shortest distance between the upper foliage boundary and ground level. Leaves were
190 scanned to measure leaf area in the field, and fresh weight of leaves was determined
191 with a balance (Acculab Lt-320; Acculab, Measurement Standards Inc., Danvers, MA,
192 USA). Following these measurements, leaves were placed in paper bags and dried in
193 the sun. Leaf samples were oven-dried at 80 °C for 48 h in the laboratory, and their
194 dry masses were measured on a semianalytical balance with an accuracy of 10⁻⁴ g
195 (Sartorius AG, Goettingen, Germany).

196 **2.4 Statistical analysis**

197 From the vegetation harvest data, we calculated the species richness (Pielou, 1969)
198 represented by the number of species recorded in each quadrat. Following Garnier et
199 al. (2004), the community-weighted mean (CWM) trait values for each trait were
200 calculated for every sample using species mean trait values and species relative
201 cover: $CWM = \sum_{i=1}^S P_i \times trait_i$, and $trait_i$ is the trait value of species i .

202 Although various indices have been proposed to measure the functional diversity
203 of a community, there is still no consensus on which are most suitable. Villéger et al.
204 (2008) suggested that some of functional diversity are redundant and they
205 recommended using three independent components of functional diversity - functional
206 richness (FRic), functional evenness (FEve) and functional divergence (FDiv). In this
207 study, we chose FRic, FEve and FDiv to examine how different components of
208 functional diversity responded to different habitat types. We used the FDiversity

209 software program to calculate FRic, FEve and FDiv after the traits were standardized
210 to ensure equal contribution of each trait.

211 We used one-way ANOVA to test the effect of different habitat types on plant
212 taxonomic diversity (species richness), the CWM traits, functional diversity (FRic,
213 FEve and FDiv) and soil properties. Correlations between the CWM traits and soil
214 properties were tested using Pearson correlation coefficients, and a principal
215 component analysis (PCA) on standardized data was conducted to analyze the overall
216 pattern of correlations between soil properties, functional diversity and aggregated
217 trait values. These statistical analyses were performed using the R 3.2.3 software (R
218 Development Core Team, 2011).

219 **3 Results and Analysis**

220 **3.1 Vegetation response**

221 Wetland drying had obvious effects on vegetation composition and structure, and
222 our study demonstrated that the species richness, vegetation cover and above-ground
223 biomass significantly increased with wetland drying (Table 1). Species richness
224 increased approximately 120.8% from swamp meadow to typical meadow relative to
225 swamp (Table 1). Vegetation cover increased approximately 10.7% in swamp meadow
226 and typical meadow relative to swamp (Table 1). Above-ground biomass increased
227 approximately 36.3% in swamp meadow and typical meadow relative to swamp
228 (Table 1). There was also significant difference in species composition among the
229 community types (Table 1). Many typical wetland plants gradually disappeared from
230 the vegetation after wetland drying occurred; these included *Carex meyeriana*,
231 *Blysmus sinocompressus*, *Rumex patientia*, *Nardostachys jatamansi*, *Caltha palustris*,
232 *Sanguisorba filiformis*, and *Cremanthodium lineare*. Others greatly decreased in
233 abundance, mainly *Deschampsia caespitosa*. Meanwhile, many other new species
234 emerged from the typical meadow, such as *Kobresia capilifolia*, *Poa poophagorum*,
235 *Festuca ovina*, and *Anemone rivularis*, all adapted to a high drought environment.

236 **3.2 Community-weighted means of traits and functional diversity response**

237 Community-weighted means of traits differed greatly between the three habitats.
238 The CWM-LA, CWM-SLA and CWM-LDMC significantly increased with the

239 wetland drying (Fig.2a ,b, and c), however, the CWM-MPH of swamp (Fig2d) was
240 significantly higher than the swamp meadow and typical meadow. Functional richness
241 (Fig.3a), functional evenness (Fig.3b) and functional divergence (Fig.3c) had not
242 obvious changes with the wetland drying. These results also further showed that
243 community-level traits responses (community-weighted means of traits and functional
244 diversity) were totally different, and the single-trait level responses may be more
245 sensitive than multi-trait level responses in the process of wetland drying.

246 **3.3 Soil response**

247 Wetland drying had obviously different effects on different soil characteristics.
248 Soil organic carbon (SOC) (Fig. 4a), soil total nitrogen (TN) (Fig. 4b), soil total
249 phosphorus (TP) (Fig. 4c), and soil moisture (SM) (Fig. 4f) of the swamp were
250 significantly higher than the swamp meadow and the typical meadow. However, soil
251 available nitrogen (AN) (Fig 4d), soil available phosphorus (AP) (Fig. 4e) and soil pH
252 (Fig. 4g) of the swamp were significantly lower than that of the swamp meadow and
253 the typical meadow. These results clearly demonstrated that the changes of soil readily
254 available nutrients (AN and AP) and total soil nutrients (SOC, TP and TP) may be
255 habitat-dependent and the soil water content may be the first driving factor with the
256 wetland drying.

257 **3.4 Relationships between CWM traits, functional diversity and soil properties**

258 Simple correlations and a PCA combining data on soil properties, community
259 functional diversity and the community-weighted means of traits (CWM) were
260 conducted. The analyses revealed a significant correlation between soil properties and
261 CWM of traits, but not a significant correlation between soil properties and functional
262 diversity (Table 2). Fig. 5 further shows that there was a significantly positive
263 correlation between SOC, TN, TP, and SM and CWM-MPH, but a significantly
264 negative correlation between AN, AP, and pH and CWM-MPH (Table 2, Fig. 5). In
265 contrast, there was a significantly negative correlation between SOC, TN, TP, and SM
266 and CWM-SLA, CWM-LDMC and CWM-LA, but a significantly positive correlation
267 between AN, AP, pH and CWM-SLA, CWM-LDMC and CWM-LA (Table 2, Fig. 5).
268 In addition, the functional richness (FRic) had a positive relationship with functional

269 divergence (FDiv), but negative relationship with functional evenness (FEve) (Fig. 5).
270 Thus, these results showed that community responses of single-functional trait level
271 may play crucial role in influencing soil properties during wetland drying.

272 4 Discussions

273 4.1 Responses of above-ground community composition and functional traits

274 Our study demonstrated that the species richness, vegetation cover and
275 above-ground biomass significantly increased with wetland drying, and there was also
276 significant difference in species composition among the community types. Many
277 typical wetland plants disappeared from the community after wetland drying occurred,
278 and many other new species (adapted to a high drought environment) emerged from
279 the typical meadow.

280 Previous studies have shown that SLA and LA are often closely positively
281 correlated with photosynthesis and transpiration rate (Reich et al., 1999; Westoby et
282 al., 2002), and plants with an exploitative strategy (e.g. high SLA and transpiration
283 rate) are often drought intolerant (Reich et al., 1999; Diaz et al., 2004). Our results
284 also demonstrated that some forbs species (e.g. *C. palustris*, *N. jatamansi*, and *R.*
285 *patientia*; usually with higher SLA and LA) dominated in the swamp meadow. These
286 forbs species tended to deplete soil moisture more quickly than grass species,
287 therefore further aggravating the trend of drying of the entire community. Following
288 this, some grass species (e.g. *E. nutans*, *P. poophagorum*, and *K. cristata*) with high
289 LDMC would dominate in the typical meadow. Although forb species account for less
290 total biomass than the grass species, they formed the bulk of the species diversity in
291 this community, as in most herbaceous communities (Grime, 1998). Plant height has
292 been associated with competitive ability for light interception in herbaceous plant
293 communities, with the general idea that light competition becomes more intense when
294 above-ground biomass or vegetation stature increases (Hautier et al., 2009). In the
295 present study, our results showed that taller plants dominated (e.g., *D. caespitosa*) in
296 the swamp, due to accumulated standing water in summer, but shorter plants
297 dominated in the swamp meadow and typical meadow due to light not being a
298 limiting factor in these communities.

299 In contrast, the functional diversity (FRic, FEve, and FDiv) (Fig. 3a ,b, and c)
300 did not show any significant change among the three habitats (Fig. 3). We speculated
301 that these changes in functional diversity would primarily be determined by the
302 balance between competitive exclusion and stabilizing niche differences (Chesson,
303 2000; Hille Ris Lambers et al., 2012). First of all, functional diversity may decrease
304 when stabilizing niche differences are smaller than is needed to overcome competitive
305 exclusion. Second, functional diversity may increase when stabilizing niche
306 differences of species are greater than competitive exclusion. In addition, the
307 responses of functional diversity can be constrained by close functional linkages to
308 any number of traits determining performance at the whole plant level (Reich, 2014).
309 Trade-offs in the responses within a suite of traits can create approximately equal
310 performance at the whole plant level and hence a low value for change in functional
311 diversity (Shiply et al., 2006). These results are consistent with many recent
312 observations that the response of functional diversity to fertilization and grazing is
313 relative stable (Niu et al., 2015; Li et al., 2015) and highlights the potential
314 complexity of community responses to environmental change.

315 **4.2 Response of below-ground soil properties**

316 Our results showed that the soil of the swamp had significantly higher moisture,
317 organic carbon, total phosphorus, and total nitrogen, but lower pH, available nitrogen,
318 and available phosphorus than the swamp meadow and typical meadow. These results
319 indicates that the soil total nutrient content had a decreasing trend with wetland drying.
320 The wetlands can accumulate a large amount of soil organic matter because of lower
321 decomposition rates of litter, due to permanent or temporary anaerobiosis associated
322 with waterlogged conditions (Nieder and Benbi, 2008). However, the drying of
323 wetlands can stimulate microbial activity and increase mineralization of soil organic
324 matter (Denef et al., 2001), therefore leading to an increase of soil readily available
325 nutrients, such as nitrogen, and phosphorus. However, other studies have reported that
326 a reduction in mineralization with drying could be caused by reduced microbial
327 activity and mobility (Pulleman and Tietema, 1999). In swamp meadow and typical
328 meadow, certain factors can contribute to reduced soil total nutrient content. First,

329 trampling by livestock (yak and Tibetan sheep) can lead to compaction and changes in
330 infiltration rates, bulk density, and decline of edaphon activity (Li et al., 2011; Yu and
331 Jia, 2014); Second, under the long-term pressure of grazing, some energy and
332 nutrients are transferred to livestock (Li et al., 2011; Lu et al. 2015). In addition, the
333 available forms of nitrogen and phosphorus in the wetland are lower than in the
334 typical meadow, because they are very water-soluble and move rapidly in the wetland
335 environment.

336 **4.3 Relationships between CWM traits, functional diversity and soil properties**

337 Simple correlations and a PCA analyses strongly support the idea that
338 fast-growing plant species can promote the rates of soil C, N and P cycling, which in
339 turn results in high nutrient availability, but relatively low C and N sequestration. A
340 striking result of the present study is that above-ground plant traits can determine the
341 changes of below-ground soil properties during wetland drying. There are two likely
342 reasons to explain this phenomenon. First, it is possible that high-quality litter results
343 in high decomposition rates in suitable environmental conditions, whereas
344 lower-quality litter might result in a more consistent level of microbial activity due to
345 the longer residence time of the litter in soil. For the swamp, the accumulation of SOC,
346 TN, and TP was greater than in swamp meadow and typical meadow, because primary
347 production exceeds the slow mineralization rates, caused by permanent or temporary
348 anaerobiosis associated with waterlogged conditions (Nieder and Benbi, 2008).
349 Second, other factors that co-varied with leaf and litter quality may have been more
350 important drivers of soil properties. For example, the results of our study support that
351 greater litter diversity associated with species diversity (in typical meadow) can
352 stimulate a large and active soil microbial community, which further results in higher
353 rates of litter decomposition and higher soil nutrient availability (Wardle et al., 2006).
354 In addition, in this study, fast growing species (with higher SLA and LA) that produce
355 high-quality litter may exceed slow-growing species (with higher LDMC) which
356 produce a litter of lower quality, therefore remained the higher rates of litter
357 decomposition in swamp meadow and typical meadow. Some models study such as
358 BIOME-BGC (Running and Hunt, 1993) or CENTURY (Parton et al., 1993) also

359 suggest that some key functional traits, such as SLA, LDMC, LA and MPH, can
360 directly affect ecosystem properties. Additionally, positive effects of plant functional
361 traits on soil properties may also result in positive or negative feedback effects, which
362 influence plant community dynamics and composition (McLaren, 2006). In this study,
363 higher soil available nutrients changed plant community structure and productivity to
364 favor graminoid species, which have greater competitive and colonization abilities
365 (e.g. *K. capilifolia*, *E. nutans*, *P. poophagorum*) over forb species in typical meadow
366 (Moretto & Distel 1997; Van der Wal et al., 2004; Li et al., 2015).

367 Our results showed that functional diversity had no measurable effect on soil
368 properties. Many studies have found that functional diversity does not influence litter
369 decomposition and nutrient cycling (Barantal et al., 2011; Schindler and Gessner,
370 2009). However, these studies typically use only one metric of functional diversity.
371 Functional diversity is complex, and single metrics may not capture its effects (Mason
372 et al., 2005). In this study, we used three metrics of functional diversity (FRic, FEve
373 and FDiv), yet we still did not find evidence for a relationship between functional
374 diversity and soil properties. We found little evidence to support the diversity
375 hypothesis, which predicted that trait diversity would perform better in litter mixtures
376 because those mixtures would better provision the variety of nutrients that plants need.
377 These results also suggested functional diversity (traits taken in aggregate) may not
378 directly related to with ecosystem functioning (Li et al., 2015). Zuo et al. (2016)
379 directly measured the relationship between plant functional traits and the C and N
380 storage in plant, litter, root, and soil along a restoration gradient of sandy grassland in
381 northern China, and their results showed that ecosystem C and N pools are primarily
382 associated with the traits of the most abundant species in communities, thereby also
383 supporting the biomass ratio hypothesis. Overall, these results suggest soil properties
384 are likely to be predictable based on plant functional traits and/or litter quality, but not
385 functional diversity. However, predicting soil properties from plant functional traits is
386 likely to be a complex process.

387 **5 Conclusions**

388 Our study has demonstrated that simple, quantitative plant functional traits, but

389 not functional diversity, could provide relevant information on key aspects of
390 ecosystem functioning. We have also shown that the particular traits selected here,
391 specific leaf area, leaf dry matter content, leaf area, and mature plant height could be
392 used to capture the functioning of plant species and communities. Our observations
393 also promote a better understanding of plant–soil feedbacks for plant functional traits
394 in plant communities, but long-term monitoring is needed, especially in different
395 times of the year in future research, because the cycling and sequestration of soil
396 nutrients may be “fast-out, slow-in” processes with high variation due to regulation by
397 environmental factors (Schulze, 2006).

628 Table 1 Brief descriptions for vegetation properties (species richness, vegetation cover, above-ground biomass, and dominant species), grazing
 629 intensity and standing water status during the wetland drying. S, swamp; SM, swamp meadow; TM, typical meadow. Significant differences
 630 across treatments within each variable were determined using Tukey's Honest Significant Difference test ($P < 0.05$) after one-way analysis of
 631 variance and are indicated by dissimilar letters.

Types	Species richness (no. 0.25m ⁻²)	Vegetation cover (%)	Above-ground biomass (g 0.25m ⁻²)	Dominant species	Grazing intensity	Standing water status
S	7.9(1.85)c	72.3%(13.12%)b	56.9(10.84)c	<i>Deschampsia caespitosa</i> , <i>Carex meyeriana</i> , <i>Blysmms</i> <i>sinocompressus</i> , <i>Nardostachys jatamansi</i> , <i>Caltha palustris</i>	Lightly grazed by livestock (yak and Tibetan sheep).	It was dry for most of the whole year, with about four months (July to October) having standing water during the rainy season.
SM	14.2(1.98)b	71.3%(9.23%)b	97.6(8.66)b	<i>Nardostachys jatamansi</i> , <i>Deschampsia caespitosa</i> , <i>Caltha palustris</i> , <i>Rumex</i> <i>patientia</i> , <i>Sanguisorba</i> <i>filiformis</i> , <i>Cremanthodium</i> <i>lineare</i> <i>Kobresia capitifolia</i> , <i>Elymus nutans</i> , <i>Poa</i>	Grazing disturbance by Tibetan sheep and yak was higher than that in swamp.	No standing water at any time for the whole year.
TM	20.7(1.77)a	88.5%(12.17%)a	124.4(11.27)a	<i>poophagorum</i> , <i>Koeleria</i> <i>cristata</i> , <i>Anemone rivularis</i> , <i>Trollius farreri</i> , <i>Festuca</i> <i>ovina</i>	Grazing disturbance was similar with swamp meadow.	No standing water at any time for the whole year.

632 Table 2 Relationships between CWM trait and soil properties from a Pearson's correlation analysis.

	Soil organic carbon (g kg ⁻¹)	Soil total nitrogen (g kg ⁻¹)	Soil total phosphorus (g kg ⁻¹)	Soil available nitrogen (mg kg ⁻¹)	Soil available phosphorus (mg kg ⁻¹)	Soil moisture (%)	Soil pH value

Functional richness	-0.331	-0.274	-0.321	0.216	0.187	-0.377	0.038
Functional evenness	-0.272	-0.283	-0.367	0.239	0.221	-0.339	0.201
Functional divergence	-0.318	-0.248	-0.379	0.313	0.312	-0.299	0.04

633 Notes: CWM, community-weighted mean trait values; SLA, leaf area per unit dry mass; LDMC, leaf dry matter content; LA, leaf area; MPH,
 634 mature plant height. *, p<0.05; **, p<0.01.

635 **Figure legends**

636 **Fig. 1** The location of the Tibetan Plateau in China and our study site (the Research
637 Station of Alpine Meadow and Wetland Ecosystems of Lanzhou University) at the
638 Tibetan Plateau..

639 **Fig. 2** The changes of CWM trait across three habitats. CWM, community-weighted
640 mean trait values; SLA, leaf area per unit dry mass; LDMC, leaf dry matter content;
641 LA, leaf area; MPH, mature plant height; S, swamp; SM, swamp meadow; TM,
642 typical meadow; Significant differences indicated by dissimilar letters above each bar
643 were determined using Tukey's honestly significant difference (HSD) test ($P < 0.05$)
644 after one-way ANOVA.

645 **Fig. 3** The changes of functional diversity (functional richness, functional evenness,
646 and functional divergence) across three habitats. Significant differences indicated by
647 dissimilar letters above each bar were determined using Tukey's honestly significant
648 difference (HSD) test ($P < 0.05$) after one-way ANOVA.

649 **Fig. 4** The changes of soil properties across three habitats. S, swamp; SM, swamp
650 meadow; TM, typical meadow; Significant differences indicated by dissimilar letters
651 above each bar were determined using Tukey's honestly significant difference (HSD)
652 test ($P < 0.05$) after one-way ANOVA.

653 **Fig. 5** Principal components analysis combining data on soil properties, CWM trait
654 and functional diversity. Only the first two axes (PC1 and PC2), which account for
655 80% of the total variation, are retained here. The first axis, which can account for 71%
656 of the total inertia, and it differentiates communities according to soil moisture: the
657 communities of higher soil moisture showed higher SOC, TN, TP and CWM-MPH
658 while the communities of lower soil moisture showed higher AN, AP, pH, CWM-LA,
659 CWM-SLA and CWM-LDMC. The second axis, which can account for 9% of the
660 total inertia, and it showed that functional richness (FRic) had a positive relationship
661 with functional divergence (FDiv), but negative relationship with functional evenness
662 (FEve).
