### Abstract

28           This study was designed to examine the fixation patterns and kinetics of zinc (Zn) in  
29 chelated (Ethylene diamine tetraacetic acid, EDTA) and non-chelated mixed micronutrient  
30 systems in semi-arid alkaline soils of the Southern High Plains, US. Soils were characterized  
31 for a suite of chemical and physical properties and data obtained from extraction experiments  
32 fitted to various kinetic models. About 30% more plant-available Zn was fixed in the non-  
33 chelated system within the first 14 d with only about 18% difference observed between the  
34 two systems by day 90, suggesting that the effectiveness of the chelated compounds tended to  
35 decrease over time. The strengths of the relationships of change in available Zn with respect  
36 to other micronutrients (copper, iron, and manganese) were higher and more significant in the  
37 non-chelated system ( $R^2$ : 0.68-0.94), compared to the chelated ( $R^2$ : 0.20-0.77). Fixation of  
38 plant-available Zn was best described by the power function model ( $R^2 = 0.94$ , SE = 0.076) in  
39 the non-chelated system, and was poorly described by all the models examined in the chelated  
40 system. Reaction rate constants and relationships generated from this study can serve as  
41 important tools for micronutrient management and for future micronutrient modeling studies  
42 in these soils and other semi-arid regions of the world.

The soil, a subject of interdisciplinary study (Brevik, et al., 2015), has numerous ecological functions, among which is the storage and cycling of plant needed nutrients (Smith et al., 2015). Micronutrient fixation, a process that leads to the reduction of plant-available portion of micronutrients through its interactions with other soils constituents, limits crop productivity in most part of the world (WHO, 2000). Plant available portion of micronutrient is generally controlled by a number of factors such as soil organic matter (OM), clay, calcium carbonate ( $\text{CaCO}_3$ ), and iron (Fe) oxides contents, as well as pH, aeration status, and interaction with other micronutrients (Dimkpa, et al., 2013; Bindraban et al., 2015). Reduction in the availability of micronutrient could be more pronounced in calcareous or alkaline soils due to their inherently high pH (Alloway, 2008; Havlin et al., 2013) which often results in decrease in solubility of most metals, leading to increased fixation of most micronutrients such as copper (Cu), Fe, manganese (Mn), and zinc (Zn) in soil systems (Sparks, 2003). For Zn, apart from high pH; free  $\text{CaCO}_3$ , low OM, and texture could also influence the plant-available portion (Fageria et al., 2002; Alloway, 2008; Alloway, 2009). Climatic and/or environmental conditions such as flooding, temperature variation (cool or wet season) could also affect Zn availability to plants (Slaton et al., 2005; Alloway, 2008; Alloway, 2009; Havlin et al., 2013).

Given the ease of fixation in soil, micronutrients such as Zn are often recommended to be applied in the forms of organic or synthetic chelates to enhance their availability to plants. The chemistry and effectiveness of chelated micronutrient compounds have also been previously documented under certain soil conditions and types (Sekhon, 2003; Luo et al.,

72 2005; Chiu et al., 2005; Lucena et al., 2008). However, due to the heterogeneous nature of  
73 soils, it could be misleading to apply findings from one soil type and region to another, thus  
74 the need for soil- and site-specific studies.

75 As with other arid to semi-arid regions of the world, the Southern High Plains (SHP)  
76 of the US is currently facing numerous environmental challenges such as drought, soil  
77 salinization, and wind erosion that limit agricultural productivity (Mehta et al., 2000; Stout,  
78 2001; Allen et al., 2005). This region is typified by semi-arid climatic conditions with soil  
79 types which are characteristically alkaline in nature. Thus, the characteristically high pH soils  
80 and climatic conditions of this region favor micronutrient deficiency. Recent field  
81 observations have also confirmed cases of limited crop productivity resulting from low level  
82 of micronutrients, particularly Zn in some important agricultural soils in Texas High Plains.  
83 Unfortunately, in spite of the agronomic significance of the soils of this region, there is still  
84 little information on the chemistry of micronutrients in the semi-arid alkaline soils of this  
85 regions (Udeigwe et al., 2016). Examining the fixation kinetics of micronutrients in these  
86 soils are vital for understanding micronutrient dynamics for further development of nutrient  
87 management tools for long-term agricultural and environmental sustainability. Kinetic  
88 parameters obtained from such efforts can be used for comparisons among micronutrients as  
89 well as among soil types. A more systematic approach to study micronutrients in soil systems  
90 will encompass examining their chemistry in a mixed system of a number of other  
91 micronutrients. Simple relationships developed from such examination could be used for  
92 future predictive purposes.

93 A major limitation to previous studies (Manouchehri et al., 2006; Reyhanitabar and

94 Gilkes, 2010; Abbas and Salem, 2011) on micronutrient fixation was that the experimental  
95 conditions (e.g. sample size, reaction times, experimental duration) limits the application of  
96 findings to field settings. Extensive literature search on these semi-arid soils indicates that  
97 limited resources are available to address: (i) how much of applied plant-available Zn will be  
98 present at a specific time, (ii) the reaction rates and mechanism of Zn fixation, and (iii) how  
99 these compare to those of other micronutrients, and (iv) how they vary among chelated and  
100 non-chelated micronutrient compounds. The objective of this study was to examine the  
101 fixation pattern and kinetics of plant-available Zn in chelated (Ethylene diamine tetraacetic  
102 acid, EDTA) and non-chelated mixed systems of selected agriculturally-important soils of the  
103 SHP, US. The experimental conditions of this study will facilitate the easier application of  
104 findings to field settings. Findings are intended to enhance the understanding of Zn chemistry  
105 and management in the semi-arid regions.

## 106 **2 Materials and Methods**

### 107 **2.1 Site and soil sampling description**

108 Soil samples of interest were collected from three different crop production sites in  
109 West Texas. These soils were identified using the Web Soil Survey (WSS) of the Natural  
110 Resources Conservation Services (NRCS). Surface (0-15 cm) and subsurface (15-30 cm) soils  
111 were collected from three important soil series in the SHP. The soil series include the  
112 Amarillo (A), Pullman (P), and Mansker (M) and their descriptions are presented in Table 1.  
113 The selected depths are the typical ones examined in most soil fertility and nutrient  
114 management studies (Havlin et al., 2013). Soil samples were randomly collected from  
115 approximately 12-15 spots at each representative site, using a digging spade marked at 0-15

116 cm and 15-30 cm depths. Samples from the same depth at each site were combined to get a  
117 composite sample of about 10 kg. Samplings were sometimes restricted to a defined area of  
118 approximately 5-7 ha to avoid crossing into a different soil series.

## 119 **2.2 Soil property characterization**

120 From each original (untreated) soil sample, a subsample of approximately 2 kg was  
121 ground, passed through a 2-mm sieve and stored in plastic bags at a room temperature of  
122 approximately 23°C. The samples were then analyzed for a suite of chemical and physical  
123 properties. Soil pH<sub>1:2</sub> and EC<sub>1:2</sub> were determined on a 1:2 soil/water ratio following the  
124 procedure described by Sparks et al. (1996). Soil OM content was determined using the loss  
125 on ignition (LOI) method (Nelson and Sommers, 1996). Calcium carbonate content was  
126 determined using the tensimeter method 4E and 4E1 of the United State Department of  
127 Agriculture NRCS-Soil Survey Investigation Report (Soil Survey Staff, 2014). Particle size  
128 determination was conducted using the modified hydrometer method (Gee and Bauder, 1986).  
129 Estimation of plant-available micronutrients (Cu, Fe, Mn, and Zn) was conducted using DTPA  
130 extraction following the procedure by Lindsay and Norvell (1978). Soil-test P determination  
131 was conducted using the Mehlich 3 procedure (Mehlich, 1984). Total elemental content was  
132 determined following USEPA Method 3050B using the DigiPREP Digestion System.

133 Measurement of elements in all extracts was conducted using the inductively coupled plasma-  
134 optical emission spectroscopy (ICP-OES) (iCAP 7400, Thermo Scientific, Waltham, MA).

## 135 **2.3 Soil sample preparation and treatment application**

136 Soil sample from each depth was thoroughly mixed and a representative portion taken  
137 to fill a 4-L plastic pot. Each pot was planted with sorghum (*Sorghum bicolor*) and grown in

138 the greenhouse with no nutrients added for about 35 d, an optional practice primarily aimed  
139 at further depleting the original micronutrient nutrient level of the soils prior to the  
140 micronutrient treatment application. After this practice, samples were crushed, air dried,  
141 ground, mixed, and passed through a 2-mm sieve. From each soil sample, two subsets of 250  
142 g samples were weighed. One set was treated with a mixture of non-chelated micronutrients  
143 and the other with a mixture of chelated micronutrients. This was accomplished by using 80  
144 ml solution of each fertilizer compound mixture prepared to deliver 5 mg of each  
145 micronutrient (Cu, Mn, Zn, and Fe) to 1 kg of each soil. The non-chelated micronutrient  
146 compounds used were  $\text{CuSO}_4 \cdot 5 \text{H}_2\text{O}$ ,  $\text{MnSO}_4 \cdot \text{H}_2\text{O}$ ,  $\text{ZnSO}_4 \cdot \text{H}_2\text{O}$ , and  $\text{FeSO}_4 \cdot 7 \text{H}_2\text{O}$ , while  
147 the chelated compounds were Cu-EDTA, Mn-EDTA, Zn-EDTA, and Fe-EDTA. Twelve  
148 soil-fertilizer treatments were obtained from six soil samples (three soil series by two depths)  
149 and two sets of micronutrient amendments (non-chelated mixture and chelated mixture) and  
150 each replicated twice for a total of 24 experimental samples. These experimental samples  
151 were left in an open space in the laboratory under room temperature of approximately 23°C.  
152 Subsamples were taken from each experimental sample at 2, 5, 7, 14, 21, 28, 35, 49, 63, 77,  
153 and 90 d and analyzed for plant available-micronutrients using DTPA extraction technique  
154 (Lindsay and Norvell, 1978). Following each subsampling event, the remaining soil samples  
155 were wetted with water to approximately field capacity. The soils were wetted after each  
156 subsampling event within the first 7 d, however, after the first 7 d, sampling was conducted  
157 at 7-14 d intervals, thus, the soil samples were wetted every 7 d. The periodic wetting and

158 drying was to simulate field conditions and also provide a medium that will facilitate soil  
159 chemical reactions.

#### 160 **2.4 Extraction procedure**

161 Preparation of the DTPA extractant and the extraction procedure used followed the  
162 method described by Lindsay and Norvell (1978). The DTPA extraction technique is the most  
163 commonly and broadly used approach for estimating plant-available micronutrient cations  
164 such as Fe, Mn, Cu, and Zn (Liang and Karamanos, 1993). In brief, 20 ml of DTPA extracting  
165 solution was added to 10 g of air-dried soil sample in a 50-mL plastic tube. All tubes were  
166 shaken on a reciprocal shaker for 2 h at approximately 25°C and 180 oscillations per min.  
167 Following shaking, the suspensions were centrifuged for 10 min at 4000 rpm and the resulting  
168 solutions filtered using Whatman 2 filter papers into 16-mm borosilicate glass tubes. All  
169 extractions were conducted in duplicate. All filtrates were analyzed for Fe, Cu, Zn, and Mn  
170 using inductively coupled plasma-optical emission spectroscopy (ICP-OES) (iCAP 7400,  
171 Thermo Scientific, Waltham, MA) following USEPA Method 200.7 (USEPA-ICP Users  
172 Group, 1982). The calibration of the ICP-OES instrument was performed using calibration  
173 standards and routinely checked using a set of second source standards from a different  
174 manufacturer. As part of the quality control/quality assurance measures, check samples were  
175 inserted after every 20-25 samples and also the relative percentage difference (RPD) between  
176 duplicates were examined and 10% set as the acceptance criterion.

#### 177 **2.5 Statistical analyses**

178 Statistical analyses were performed using the Statistical Analysis Software (SAS 9.4,  
179 SAS Institute, Cary, NC). Differences among means, where applicable, were examined using

180 PROC GLM and mean comparison conducted using Fisher's Least Significance Difference at  
181  $\alpha$  level of 0.05. The PROC REG procedure was used to conduct single linear regression  
182 analyses used in examining changes in available Zn with respect to other micronutrients in  
183 each system (chelated and non-chelated). The data obtained from the kinetic experiment were  
184 fitted to selected kinetic models (Table 4) to derive the needed parameters using the PROC  
185 NLIN procedure.

### 186 **3 Results and discussion**

#### 187 **3.1 Soil properties**

188  
189 The description and selected properties of the soils used in the study are summarized  
190 in Table 1. The average soil pH was 8.05 and pH tended to be higher in the subsurface depth  
191 (15-30 cm) of each of the soil series (Mansker, Amarillo, and Pullman). Soil OM ranged from  
192 0.93 to 1.57% among depth with an average of 1.33%. This average value is typical of the  
193 soils of the area (Udeigwe et al., 2015). The soil EC was within a narrow range of 0.22-0.27  
194  $\text{dS m}^{-1}$  with an average of 0.24  $\text{dS m}^{-1}$ , indicating the studied soils are not salt impacted.  
195 Percent  $\text{CaCO}_3$  varies from 0.13 to 5.59% among depths and was almost two folds higher in  
196 the subsurface depths in the Amarillo and Pullman soils. The average clay content within the  
197 0-15 cm and 15-30 cm depths were 26.2 and 32.9%, respectively, and the textural classes vary  
198 from sandy loam (Amarillo) to clay (Mansker) (Table 1).

199 The results of the total elemental analysis are summarized in Table 2. The observed  
200 total content of Fe, Cu, Mn, and Zn were within the typical levels found in most non-polluted  
201 agricultural soils or those not receiving excessive amount of organic/inorganic amendments  
202 (Adriano, 2001; Kabata-Pendias, 2010), likewise, the levels of Ca, Mg, Na, K, and P

203 (Adriano, 2001; Udeigwe et al., 2009). There appeared to be no consistent trend in the  
204 concentration of the elements with depth in each soil series and none of the soils was  
205 consistently higher in all the elements measured. Estimated background levels of available  
206 nutrients are presented in Table 3. The mean DTPA-extractable Fe, Mn, Cu, and Zn are 5.18,  
207 5.09, 0.76, and 0.35 mg kg<sup>-1</sup>, respectively, likely suggesting an insufficient level of these  
208 nutrients (Havlin et al., 2013) in the studied semi-arid soils. Soil-test P varied more widely,  
209 ranging from 8.93 to 123 mg kg<sup>-1</sup>, and was generally higher in the top soil. Phosphorus, a  
210 macronutrient could possibly be added through fertilization to these soils.

### 211 **3.2 Short and long-term zinc fixation pattern**

212       Percent estimates of fixed plant-available Zn determined after the first 14 d  
213 (designated as short term), and 90 d (long term) are presented in Table 4. Individual soils and  
214 depths were examined, however, findings reveal no justifiable differences among the soils  
215 worth discussing, thus, the findings are summarized as averages of all soils within a given  
216 depth and for both depths. The percent amount fixed was approximated using the differences  
217 between days 2 and 14, and days 2 and 90 for the 14 d and 90 d examinations Comparison  
218 was made between the chelated and non-chelated micronutrient treatments. Average values  
219 from the three soil series examined revealed that within the non-chelated system,  
220 approximately 31.3 and 41.3% of the added Zn was fixed in the 0-15 cm and 15-30 cm  
221 depths, respectively, after the first 14 d. When compared to the chelated system, these  
222 numbers were drastically reduced to 5.1 % and 6.8 % in the 0-15 and 15-30 cm depths,  
223 respectively. After the first 14 d, the averages for both depths were 36.3 % and 6.0 % for non-  
224 chelated and chelated systems, respectively. The findings clearly indicate that chelating with

225 EDTA reduced the amount of plant-available Zn fixed by soil constituents (Lopez-Valdivia et  
226 al., 2002; Chiu et al., 2005; Alvarez and Gonzalez, 2006). This observed difference between  
227 the chelated and non-chelated partly supports the high fixation of Zn encountered in most  
228 alkaline soil, particularly when applied non-chelated and why Zn is often the most deficient  
229 micronutrient in most alkaline soils (Alloway, 2008).

230 The amount of Zn fixed by the end of the experimental period of 90 d (long-term  
231 fixation) was also examined. About 51.1% and 61.4% of available Zn was fixed after 90 d in  
232 the non-chelated system within the 0-15 and 15-30 cm depths, respectively. These numbers  
233 when compared to the chelated system were 30.7% and 45.1% for the 0-15 and 15-30 cm  
234 depths, respectively. Average fixation for both depths in these semi-arid soils after 90 d were  
235 56.2% for non-chelated system and 37.9% for chelated system, a difference of approximately  
236 18% compared to the 30% observed in the short term fixation (14 d). The narrower  
237 differences in Zn fixation observed on the long term could be attributed to the half-life of the  
238 chelating agent, EDTA. A half-life of 39 to 59 d for EDTA in doses of 0.8 to 1.6 mmol in a  
239 heavy metal phytoextraction study was estimated by Meers et al. (2005), suggesting that the  
240 effectiveness of EDTA on micronutrient mobilization will decrease over time, causing more  
241 micronutrient to be fixed by other soil constituents. Although not significant, the slightly  
242 higher fixation of Zn observed in the subsurface soil could be partly attributed to higher clay  
243 content. Clay interaction with metal cations such as Zn, which could reduce the amount of  
244 plant-extractable Zn, has been widely documented (Sparks, 2003; Eze et al., 2010; Udeigwe et  
245 al., 2015).

### 246 3.3 Changes in available zinc with respect to other micronutrients

247           The changes in the concentration of plant-available Zn over the experimental period of  
248 90 d was compared to those of other micronutrients in both the chelated and non-chelated  
249 systems (Table 5). The relationships were examined among individual soil and depth,  
250 however, there was no remarkable differences among soils worth discussing, thus, the  
251 findings are summarized as averages for the soils at each depth and for both depths combined  
252 within each Zn system (chelated and non-chelated). The strengths of the relationships and  
253 slope of change between Zn and each of the other micronutrient elements (Cu, Fe, and Mn)  
254 were examined using regression analyses. Within each depth, the amount of available Zn  
255 positively and significantly changes with each of the other micronutrients, although to a  
256 varying degree within the chelated and non-chelated micronutrient systems. Overall, the  
257 strengths of the relationships were higher in the non-chelated systems ( $R^2$ : 0.68-0.94)  
258 compared to the chelated ( $R^2$ : 0.20-0.77), suggesting less linearity in changes in Zn  
259 concentration to those of the other micronutrients in the chelated system. The slopes were also  
260 generally higher in the non-chelated systems for each of the relationships examined,  
261 suggesting that more Zn will be fixed for each unit of the other micronutrient fixed in the non-  
262 chelated system. Within each depth in the non-chelated system, the change in available Zn  
263 with respect to change in Cu (Zn-Cu) was higher than those of Zn-Fe, and Zn-Mn as  
264 evidenced from the slopes of the equation. When both depths were combined for each  
265 element, within the non-chelated system, the slopes were 0.90 (Zn-Cu), 0.37 (Zn-Fe), and  
266 0.29 (Cu-Zn). Similar relationships were also evidenced in the non-chelated system, although  
267 to a lesser strength and some were not significant (Table 5). Within the non-chelated system,

268 the findings suggest that a  $1 \text{ mg kg}^{-1}$  change in the concentration of available Cu, Fe, and Mn,  
269 will be associated with 0.90, 0.37, and  $0.29 \text{ mg kg}^{-1}$  change in available Zn respectively, in  
270 these semi-arid alkaline soils of the SHP. The strong association of Zn and Cu fixation  
271 evidenced here could be attributed to the fact these are the two most-limiting micronutrients  
272 in these soils with estimated plant-available averages  $0.38$  and  $0.81 \text{ mg kg}^{-1}$ , respectively.  
273 These relationships provide an estimation of how Zn changes with the other micronutrients in  
274 both the chelated and non-chelated systems in this semi-arid alkaline soils. Such information  
275 is currently not available for soils of this region and as such little comparisons could be made  
276 between the findings here and existing literature.

### 277 **3.4 Kinetics of zinc fixation**

278 Fixation kinetics of chelated and non-chelated Zn fixation in these soils were further  
279 examined by fitting the data obtained from kinetic experiments to various kinetic models. A  
280 number of kinetic models (Table 6) were examined, based on the experimental conditions of  
281 this study and evidence gathered from previous related studies (Dang et al., 1994;  
282 Reyhanitabar and Gilkes, 2010). The criteria used for evaluating best fit among the models  
283 were coefficient of determination ( $R^2$ ) and standard error (SE) (Dang et al., 1994;  
284 Reyhanitabar and Gilkes, 2010). Fixation kinetics were studied within soils and depths,  
285 however, the individual examination of soils however did not show justifiable reasons to  
286 focus the discussion on the comparison among them, thus, for further examinations, average  
287 data points for all three soils were used.

288 The data from Zn kinetic experiments were fitted to the zero, first, second order, and  
289 power function models and findings summarized in Table 7. In all the models, **qt** represents

290 the amount of DTPA extractable (plant-available) micronutrient in  $\text{mg kg}^{-1}$  remaining at time  
291  $t$ , in d. Discussions will be concentrated on models derived using data points from both depths  
292 averaged across soils because there was no difference of interest between the 0-15 and 15-30  
293 cm depths that worth focusing the discussion on. Employing more data points will also  
294 enhance the statistical reliability of the evaluation. In the non-chelated system, fixation of  
295 available Zn was poorly described by the zero, first, and second order models ( $R^2$ : 0.66 - 0.82)  
296 but better described by the power function model ( $R^2 = 0.95$ ,  $SE = 0.076$ ) (Fig. 1). This better  
297 fit to the power function model suggest that the fixation of plant-available Zn in this mixed  
298 system of non-chelated micronutrients is not linear over the experimental period of 90 days  
299 (Fig. 1), an indication of a more complex reaction type This finding can be related those of  
300 Reyhanitabar et al. (2010) who reported the kinetics of DTPA extraction of zinc from  
301 calcareous soils was better described by the power function model. Same was the case when  
302 Zn was examined in a single system (data not shown). Within the chelated system (Fig. 2),  
303 none of the models examined was able to reasonably describe the reduction of plant-available  
304 Zn in these semi-arid soils ( $R^2$ : 0.66 to 0.70), a finding suggesting that the reduction of  
305 chelated Zn did not perfectly follow the speculated decay trend in these soils over the 90-day  
306 period. Literature search did not yield much information on the fixation kinetics of chelated  
307 Zn, thus, further justifying the need for this study.

### 308 **3.5 Significance of findings to zinc management**

309 The fixation kinetics of non-chelated Zn following the power function model over the  
310 zero, first, and second order models, is an indication of a more complex reaction type.  
311 Inferences drawn from the short and long-term experiments substantiate the need to apply Zn

312 micronutrient in the chelated form on these semi-arid soils as significantly less chelated Zn  
313 was fixed particularly within the first 14 d. Findings also highlighted the importance of timing  
314 in Zn micronutrient management in these soils even when chelated micronutrient compounds  
315 are used. The simple linear relationships of change in plant-available Zn relative to other  
316 micronutrients (Cu, Mn, and Fe) could be used as predictive tools. The kinetic parameters  
317 obtained from the kinetic experiments could be used for approximating how much of added  
318 Zn micronutrient will be available at a given time, particularly for the non-chelated Zn  
319 materials which its fixation was reasonably described by the power function model.

320 Findings from this study provide a basis for developing applications for comparing  
321 fixation pattern of Zn to those of other micronutrients in a given soil and also among soils. Of  
322 interest, the applications developed from this study provide a basis for a more mechanistic  
323 approach to evaluating and comparing the fixation patterns and effectiveness of different  
324 micronutrient compounds in any given soil system. A database of the reaction rate constants  
325 derived for different Zn micronutrient compounds could be used as a tool for making a more  
326 informed decision on Zn management on these semi-arid soils, an application that can be  
327 extended to soils of other regions.

#### 328 **4 Conclusions**

329 The application of kinetic models to Zn fixation could be used to further the  
330 understanding of its chemistry and behavior in the soils of the semi-arid to arid climates. The  
331 reduction of plant-available Zn more closely followed the power function models over the  
332 zero, first, and second order models in these soils, suggestion a more complex reaction type.  
333 Timing is an important practice in Zn management in these semi-arid soils, even when

334 chelated compounds are used. Evidence gathered from this study suggest that kinetic model  
335 application to Zn fixation provide a sound basis for evaluating Zn dynamics among soil types  
336 and for comparing different Zn micronutrient compounds. The experimental setup and  
337 conditions of this study will facilitate the easier application of findings to field settings. This  
338 study provides useful background information that will enable future studies on the  
339 examination of the reaction mechanisms involved in zinc fixation in chelated and non-  
340 chelated systems of these semi-arid soils.
