Abstract. Electrical conductivity of gneiss samples with different chemical compositions (WA=Na2O+K2O+CaO=7.12%, 7.27% and 7.64% weight percent) were measured using a complex impedance spectroscopic technique at 623–1073 K and 1.5 GPa and a frequency range of 10⁻¹ to 10⁶ Hz. Simultaneously, a pressure effect on the electrical conductivity was also determined for the WA=7.12% gneiss. The results indicated that the gneiss conductivities markedly increase with total alkali and calcium ion content. The sample conductivity and temperature conform to an Arrhenius relationship within a certain temperature range. The influence of pressure on gneiss conductivity is weaker than temperature, although conductivity still increases with pressure. According to various ranges of activation enthalpy (0.35–0.52 eV and 0.76–0.87 eV) at 1.5 GPa, two main conduction mechanisms are suggested that dominate the electrical conductivity of gneiss: impurity conduction in the lower temperature region and ionic conduction (charge carriers are K⁺, Na⁺ and Ca²⁺) in the higher temperature region. The electrical conductivity of gneiss with various chemical compositions cannot be used to interpret the high conductivity anomalies in the Dabie–Sulu ultrahigh pressure metamorphic belt. However, the conductivity–depth profiles for gneiss may provide an important constraint on the interpretation of field magnetotelluric conductivity results in the regional metamorphic belt.
1 Introduction

According to magnetotelluric (MT) and geomagnetic depth sounding results, electrical conductivity of geological samples at high temperature and pressure can be used to extrapolate the mineralogical composition and thermodynamic state in the Earth’s interior (Maumus et al., 2005; Manthilake et al., 2015; Li et al., 2016; Dai et al., 2016; Hu et al., 2017). High conductivity anomalies are widely distributed in the middle to lower crust and upper mantle, and there are various causes of these anomalies in different regions (Xiao et al., 2007, 2011; Pape et al., 2015; Novella et al., 2017). Hence, it is crucial to comprehensively measure the electrical conductivities of minerals and rocks that are distributed in the deep Earth. A series of electrical conductivity results of the main minerals and rocks have been reported in previous studies under high temperature and pressure conditions (Fuji-ta et al., 2007; Hu et al., 2011, 2013; Dai et al., 2012; Yang et al., 2012; Dai and Karato, 2014; Sun et al., 2017). However, electrical conductivity of most metamorphic rocks have not been explored at high temperature and pressure, and thus the interpretation for high conductivity anomalies distributed in representative regional metamorphic belts is still not comprehensive.

A regional metamorphic ultrahigh pressure belt for the Dabie–Sulu orogen is a complexly giant geotectonic unit in central-eastern China. Geophysical exploration results confirmed that a large quantity of high conductivity anomalies have been observed in metamorphic belts (Xiao et al., 2007; Wannamaker et al., 2009; Zeng et al., 2015). Metamorphic rocks (e.g., slate, schist, gneiss, granulite and eclogite) with different degrees of metamorphism play an important role because of their widespread distribution in regional metamorphic belts. Dai et al. (2016) measured the electrical conductivity of dry eclogite at 873–1173 K, 1.0–3.0 GPa and different oxygen partial pressures (using Cu+CuO, Ni+NiO and Mo+MoO₂ solid oxygen buffers), and found that the hopping of small polaron is the dominant conduction mechanism for dry eclogite at high temperature and pressure. The electrical conductivity of natural eclogite is much lower than the high conductivity anomaly in the Dabie–Sulu ultrahigh pressure metamorphic (UHPM) belt of eastern China. Granulite is another important
metamorphic rock distributed in a majority of regional metamorphic belts. The
electrical conductivity of granulite is lowered by repetitive heating cycles with a
conductivity range about $10^{-7}$–$10^{-2}$ S/m at 1.0 GPa and up to about 900 K (Fuji-ta et al.,
2004). Due to granulite’s complicated mineralogical assemblage and rock structure, the
features of the electrical conductivity values over heating cycles have not been
explained, and the conduction mechanism for granulite not definitively stated. Gneiss
is formed at middle to lower crustal pressure and temperature conditions, and widely
distributed in regional metamorphic belts. The main rock-forming minerals of gneiss
are feldspar, quartz and biotite. The electrical conductivity of gneiss increases with
temperature, and the conductivity values range from about $10^{-4}$–$10^{-2}$ S/m at up to 1000
K and 1.0 GPa (Fuji-ta et al., 2007). On the basis of the dominant rock-bearing
mineralogical assembly of the metamorphic rock, gneiss can generally be divided into
types, such as plagioclase gneiss, quartz gneiss and biotite gneiss. Therefore, it is crucial
to investigate the electrical conductivity of gneisses with various chemical
compositions and mineralogical constituents. Gneiss is formed by the metamorphism
of granite, and the mineralogical assemblage of gneiss is similar to granite. The
electrical conductivity of granite dramatically increases with alkaline and calcium ion
content at 623–1173 K and 0.5–1.5 GPa (Dai et al., 2014). Impurity conduction has
been proposed to be the dominant conduction mechanism for granite in the lower
temperature region, and alkaline ions, including K⁺, Na⁺ and Ca²⁺, are probable charge
carriers at higher temperatures.

In the present study, we measured the electrical conductivity of gneiss samples in
situ under 0.5–2.0 GPa, 623–1073 K and three different chemical compositions. The
influences of temperature, pressure and chemical composition on the gneiss electrical
conductivity were determined, and the dominant conduction mechanism for gneiss is
discussed in detail. On the basis of the conductivity results, the geophysical implications
for the high conductivity anomalies of the Dabie–Sulu UHPM belt were explored in
depth.
2 Experimental procedures

2.1 Sample preparation

Three relatively homogeneous natural gneiss samples with parallel to foliation direction were collected from Xinjiang, China. The sample surfaces were fresh, non-fractured and non-oxidized, without evidence of alteration before and after the experiments. To determine the gneiss mineralogical assemblage, we used optical microscopy and scanning electron microscopy (SEM) at the State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China. The major elemental content of the gneiss samples was analyzed by X-ray fluorescence spectrometry (XRF) at Australian Laboratory Services, Shanghai, China. The main rock-forming minerals of three gneiss samples were feldspar, quartz and biotite (Fig. 1). The volume percentage varied for each corresponding rock-forming mineral in different gneiss samples (Table 1). Three gneiss samples had the same mineralogical assemblage, and all of them belong to the biotite-bearing felsic gneiss. Table 2 shows the results of whole rock analysis by XRF for the three gneiss samples. We found that the total alkali, such as K⁺ and Na⁺, and the divalent cationic calcium metal ion content varied for each sample (Table 2). Therefore, in the present study, we carried out a series of experiments to determine the influence of chemical composition on the electrical conductivity of gneiss at high temperature and pressure by changing the total alkali and calcium ion content.

2.2 Impedance measurements

High temperatures and pressures for the experiments were generated in a YJ-3000t multi-anvil apparatus, and the impedance spectra were collected using a Solartron-1260 impedance/gain-phase analyzer at the Key Laboratory of High-Temperature and High-Pressure Study of the Earth’s Interior, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China. All components of the experimental assemblage (ceramic
tubes, pyrophyllite, Al₂O₃ and MgO sleeves) were previously baked at 1073 K for 12 h in a muffle furnace to avoid the influence of absorbed water on the electrical conductivity measurements. The sample was then loaded into a MgO insulation tube (Fig. 2). Two nickel disks (6.0 mm in diameter and 0.5 mm in thickness) were applied to the top and bottom of sample to act as electrodes. To shield against external electromagnetic and spurious signal interference, a layer of nickel foil with a thickness of 0.025 mm was installed between the alumina and magnesia sleeves. These sleeves have good insulating properties for current and transmitting pressure. A pyrophyllite cube (edge length: 32.5 mm) was used as the pressure medium, and the heater was composed of three-layer stainless steel sheets with a total thickness of 0.5 mm. The sample assembly was placed in an oven at 330 K to keep it dry before the experiment.

In the experiments, the pressure was slowly increased to the desired value at a rate of 1.0 GPa/h, and then the temperature was increased at a rate of 300 K/h to the designated values. The Solartron-1260 impedance/gain-phase analyzer with an applied voltage of 3 V and frequency range of 10⁻¹–10⁶ Hz was used to collect impedance spectra when the pressure and temperature were stable. At the desired pressure, the spectra were measured at a certain temperature, which was changed in 50 K intervals. The impedance spectra of gneiss samples with Wₐ (Na₂O+K₂O+CaO)=7.12% were collected under conditions of 0.5–2.0 GPa and 623–1073 K. The spectra of the other two gneiss samples (Wₐ=7.27% and 7.64%) were measured at 623–1073 K and 1.5 GPa. To confirm the data reproducibility, we measured the electrical conductivity of gneiss over two heating and cooling cycles at a constant pressure. The errors of temperature and pressure were ±5 K and ±0.1 GPa, respectively.

### 3 Results

The typical complex impedance spectra for the run DS12 gneiss samples at 1.5 GPa and 623–1073 K are shown in Figure 3. All of these obtained spectra are composed of an almost ideal semicircle in the high frequency domain and an additional tail in the lower frequency domain. Other complex impedance spectra of the gneiss samples at
other pressures displayed the same characteristics of those shown in Figure 3. Figure 4 displays the real and imaginary parts of complex impedance for the runs DS13 and DS14 gneiss samples as a function of the measured frequency at 1.5 GPa and 623–1073 K. The real part values almost remain unchanged over a frequency range of $10^6$–$10^4$ Hz, and sharply increased at $10^4$–$10^2$ Hz; these values then slowly increased within the $10^2$ to $10^1$ Hz lower frequency region. The values of imaginary parts almost remain unchanged within a frequency range of $10^6$–$10^3$ Hz, the values gradually increased at $10^3$–$10^1$ Hz; and these values then slowly increased in the $10^1$ to $10^{-1}$ Hz lower frequency region. Roberts and Tyburczy (1991) and Saltas et al. (2013) have suggested that the ideal semicircle represents the bulk electrical properties of a sample, and the additional tail is characteristic of diffusion processes at the sample–electrode interface. Hence, the bulk sample resistance can be obtained by fitting the ideal semicircle in the high frequency domain. A series connection of resistance and constant phase elements ($R_s$-CPE$_s$) and the interaction of charge carriers with the electrode ($R_e$-CPE$_e$) was applied to be the equivalent circuit. All fitting errors of the electrical resistance were less than 5%. Based on the sample size and electrical resistance, the electrical conductivity of the sample was calculated:

$$\sigma = \frac{L}{SR}$$  \hspace{1cm} (1)

where $L$ is the height of the sample (m), $S$ is the cross-sectional area of the electrodes ($m^2$), $R$ is the fitting resistance ($\Omega$) and $\sigma$ is the electrical conductivity of the sample ($S/m$).

The logarithmic electrical conductivities of the gneiss samples were plotted against the reciprocal temperatures under conditions of 623–1073 K and 0.5–2.0 GPa. The electrical conductivities of gneiss with $X_A=7.12\%$ were measured in two sequential heating and cooling cycles at 1.5 GPa (Fig. 5). After the first heating cycle, electrical conductivities of the gneiss at the same temperature were close to each other in other cycles. We confirmed that our experimental data were reproducible, and the gneiss sample was kept at a steady state after the first heating cycle. Two different linear relationships of logarithmic electrical conductivity and reciprocal temperature were separated by an inflection point. The electrical conductivity of gneiss with $W_A=7.12\%$
significantly increased with temperatures above 723 K at 0.5–1.0 GPa, and this phenomenon occurred after 773 K at 1.5–2.5 GPa (Fig. 6). The electrical conductivity of the samples increased with pressure, but the effect of pressure on conductivity was weaker than temperature. For other gneiss samples (W_A=7.27% and 7.64%), the inflection points appeared at 773 K under all designated pressures (Fig. 7). In a specific temperature range, the relationship between electrical conductivity and temperature fits the Arrhenius formula:

\[ \sigma = \sigma_0 \exp\left(\frac{-\Delta H}{kT}\right) \]

where \( \sigma_0 \) is the pre-exponential factor (K·S/m), \( k \) is the Boltzmann constant (eV/K), \( T \) is the absolute temperature (K), and \( \Delta H \) is the activation enthalpy (eV). All fitting parameters for the electrical conductivities of three gneiss samples are listed in Table 3.

The activation enthalpy values (\( \Delta H \)) for the gneiss samples are 0.35–0.58 eV in the lower temperature region and 0.71–1.05 eV in the higher temperature region, respectively. In addition, the logarithms of pre-exponential factor values (Log \( \sigma_0 \)) were transformed from negative to positive from the correspondent lower to the higher temperature ranges.

The total alkali and calcium ion content of K_2O, Na_2O and CaO is a remarkable influence on the electrical conductivities of the gneiss samples. As shown in Figure 7, the electrical conductivity of the gneiss samples increased with the total weight percent of K_2O, Na_2O and CaO. It reflects the fact the electrical conductivity of the gneiss samples is controlled mainly by minerals that contain abundant K_2O, Na_2O and CaO. The cations of feldspar are K\(^+\), Na\(^+\) and Ca\(^2+\), and K\(^+\) is also the main cation of biotite. Furthermore, impurity ions (K\(^+\), Na\(^+\) and Al\(^{3+}\)) have been suggested to be the charge carriers for quartz samples (Wang et al., 2010). In addition, the electrical conductivity of the gneiss samples do not regularly change with variations in biotite-bearing content (Fig. 7, Table 1). Based on all of the experimental results, the biotite content is not the main influential factor on the electrical conductivity of gneiss. Therefore, we cannot distinguish the specific mineral that controls the electrical conductivity of the gneiss samples. However, it was reasonable to consider the gneiss sample as a complex whole, and analyze the electrical conductivity of gneiss with various chemical compositions at
4 Discussion

4.1 A comparison with previous studies

As three constituent minerals of gneiss, feldspar, biotite and quartz dominated the electrical conductivity of the whole rock at high temperature and pressure. Due to their sophisticated mineralogical assemblage and rock structure, the gneiss samples were unstable in the first heating cycle. In this process, the impurity ions may have been distributed, the grain size slightly changed and the microfractures gradually closed. After the first cycle, the electrical conductivity of the gneiss samples had good repeatability. This suggested that the gneiss samples were in a stable state. The electrical conductivity range of the gneiss samples with various chemical compositions was about $10^{-5} - 10^{-1}$ S/m at 623–973 K and 0.5–2.0 GPa. The electrical conductivity was slightly related to pressure, and conforms to previous conclusions that the influence of pressure on mineral and rock conductivity is much weaker than temperature (Xu et al., 2000; Hu et al., 2011). The possible reason is that the effect of pressure on the activity of the charge carriers is weaker than temperature. The total alkaline ion content of K$_2$O, Na$_2$O and CaO has crucial influence on the electrical conductivity of gneiss. Previous studies have investigated the electrical conductivity of minerals and rocks with various chemical compositions, and the conclusions were similar to ours (Dai et al., 2014). Fuji-ta et al. (2007) performed the electrical conductivity of gneiss perpendicular and parallel to foliation at up to 1000 K and a constant pressure of 1.0 GPa. The conductivity of gneiss measured perpendicular to foliation was one order of magnitude lower than the value measured parallel to foliation. However, the influence of pressure and chemical composition on the electrical conductivity of gneiss has not been studied. In the present work, we investigated the electrical conductivity of gneiss parallel to foliation. As shown in Figure 8, the electrical conductivity of gneiss from Fuji-ta et al. (2007) was higher than our results in the lower temperature range, and values were
lower than the conductivity of gneiss with $W_\Lambda = 7.27\%$ and 7.64\% in this study. This discrepancy is probably caused by varying chemical compositions of the gneiss samples. Dai et al. (2014) measured the electrical conductivity of granite at 0.5–1.5 GPa and 623–1173 K, and the main rock-forming minerals were also quartz, feldspar, and biotite. They found that the content of calcium and alkali ions significantly affected the electrical conductivity of granite under conditions of high temperature and high pressure. Electrical conductivities of granite and gneiss increased with calcium and alkali ion content. However, the electrical conductivity of granite was much lower than gneiss (Fig. 8). This difference may be caused by the various chemical compositions and rock structures between granite and gneiss. Feldspars are important rock-forming minerals in gneiss, and thus it is important to compare the electrical conductivity of feldspar. The electrical conductivity of K-feldspar is one order of magnitude lower than albite, and $K^+$ and $Na^+$ ions are the charge carriers of K-feldspar and albite, respectively (Hu et al., 2013). As shown in Figure 8, the electrical conductivity of alkali feldspar is much higher than the gneiss samples. This may be because the concentration of alkali ions in feldspar is higher than gneiss. In addition, granulite is another significant metamorphic rock, and usually coexists with gneiss. The electrical conductivity of granulite is moderately higher than gneiss. The electrical conductivity of quartz at 1.0 GPa is slightly lower than gneiss with $X_\Lambda = 7.27\%$ at 1.5 GPa, and the slope of the linear relationship between the logarithm of electrical conductivity and the reciprocal of temperature for quartz is close to gneiss in a lower temperature range (Fuji-ta et al., 2004). The conductivity of phlogopite is higher than gneiss with $X_\Lambda = 7.64\%$ at higher temperatures ($>773$ K), and lower than gneiss samples at lower temperatures ($<773$ K). Furthermore, the slope of the linear relationship between the logarithm of electrical conductivity for the phlogopite and the reciprocal temperature is much higher than the slope of the gneiss samples (Li et al., 2016). Compared with Ferri et al. (2013), the electrical conductivity of the garnet–biotite–sillimanite residual enclave (JOY2-X4) was very close to our conductivity results for the run DS13 and DS14 gneiss samples in the lower temperature and higher temperature regions, respectively. The electrical conductivity of sample JOY2-X4 was slightly lower than the run DS12 gneiss sample.
In addition, the electrical conductivity of natural metapelite (PP216) from Hashim et al. (2013) was close to the values of the run DS12 gneiss sample in the lower temperature region, and the slope between logarithmic conductivities and reciprocal temperature for the PP216 metapelite was higher than the gneiss samples in the higher temperature region.

4.2 Conduction mechanism

The logarithm of electrical conductivities and reciprocal temperatures showed linear relationships at the lower and higher temperature ranges, respectively. This implies that the dominant conduction mechanism for our gneiss samples in the lower temperature range is different from the higher temperature range. The mineral assemblage and chemical composition of gneiss samples are very complicated, and thus the conduction mechanisms for gneiss samples are difficult to determine. Feldspar, quartz and biotite are the dominant minerals in the gneiss samples. Previous studies have suggested that the conduction mechanism for feldspar minerals is ionic conduction and the charge carriers are $K^+$, $Na^+$ and $Ca^{2+}$ (Hu et al., 2013). The conduction mechanism for biotite has not been studied, whereas the charge carriers of phlogopite were proposed to be $F^+$ and $K^+$ (Li et al., 2016). For quartz, the conduction mechanism was impurity ionic conduction, and the dominant charge carriers migrate by moving the alkali ions in channels (Wang et al., 2010). Therefore, we deduced that the conduction mechanism for gneiss samples may be related to ions. The activation enthalpy is one crucial evidence for the conduction mechanism of minerals and rocks (Dai et al., 2016). The activation enthalpies for gneiss samples are 0.35–0.58 eV in the lower temperature region, and 0.77–0.87 eV in the higher temperature region (Table 3). Dai et al. (2014) studied the electrical conductivity of granite that had the same mineralogical assemblage as the gneiss samples. They proposed that the conduction mechanism at the lower temperature range was the impurity conduction owing to the low activation enthalpy (0.5 eV), whereas the mechanism was ionic conduction with a high activation enthalpy (1.0 eV) at the higher temperature range. The activation enthalpy for gneiss
was close to the values for granite at the lower and higher temperature ranges. The activation enthalpies for albite and K-feldspar were 0.84 and 0.99 eV, respectively (Hu et al., 2013). With increasing pressure, the electrical conductivity of gneiss increased accordingly. The activation volumes for one gneiss sample (DS12) were -7.10 cm³/mole and -2.69 cm³/mole in the low and high temperature regions, respectively. We can compare gneiss with the electrical conductivity of eclogite, another representative metamorphic rock. Recently, Dai et al. (2016) measured the electrical conductivity of dry eclogite and the negative activation volume for eclogite was -2.51 cm³/mole under 1.0–3.0 GPa and 873–1173 K. It was proposed that the main conduction mechanism for dry eclogite is intrinsic conduction (Dai et al., 2016). In addition, Figure 7 shows that the increasing content of alkali and calcium ions significantly enhances the electrical conductivity of gneiss samples. Therefore, the impurity conduction (possible charge carriers: K⁺, Na⁺, Ca²⁺, H⁺) and ionic conduction (possible charge carriers: K⁺, Na⁺ and Ca²⁺) are suggested to be the conduction mechanisms at lower and higher temperature ranges, respectively.

4.3 Effect of chemical composition on electrical conductivity

The influence of chemical composition (Na₂O+K₂O+CaO) on the electrical conductivity of the gneiss samples was very significant, as shown in a previous study that the electrical conductivity of granite samples is closely related to the alkali and calcium ion content (Dai et al., 2014). The electrical conductivity of granite samples at high temperature and pressure can be fitted as a function of (Na₂O+K₂O+CaO)/SiO₂ (Dai et al., 2014). However, the electrical conductivity of gneiss samples does not regularly change with variations in (Na₂O+K₂O+CaO)/SiO₂. This shows that the dependence of electrical conductivity of gneiss on chemical composition is not identical to granite. This may be due to the more complicated mineralogical assemblage and chemical composition of gneiss. Hu et al. (2013) demonstrated that the electrical conductivity of alkali feldspar significantly depends on the value of Na/(Na+K). This suggests that the electrical conductivity of gneiss is affected by the total content of alkali
and calcium ions, as well as the ratios between various ions.

5 Geophysical implications

As a typical metamorphic rock in the present research region, gneiss is widespread in the UHPM zone (Zheng et al., 2003; Liu et al., 2005; Hashim et al., 2013). The geological map of the Dabie–Sulu orogenic belt and its corresponding lithological distribution in the southern Dabie–Sulu region are displayed in Figure 9. As one of the largest UHPM belts in the world for Dabie–Sulu orogen, gneiss is the outcropping rock directly in contact with eclogite, and occupies up to 90% of the exposed metamorphic rock area. Therefore, the in situ laboratory-based electrical conductivity of gneiss at high temperature and pressure is very significant to interpret the conductivity structure in the Dabie–Sulu belt, deep in the Earth’s interior. The Dabie terrane is a major segment bounded by the Tan–Lu fault to the east and separated into a series of continuous zones by several large-scale E–W trending faults; the Sulu terrane is segmented into a number of blocks by several NE–SW trending faults subparallel to the Tan–Lu fault (Zheng, 2008; Xu et al., 2013). The discovery of coesite and/or diamond inclusions in various types of rock (e.g., gneiss, eclogite, amphibolite, marble and jadeite quartzite) through the Dabie–Sulu orogen indicates that continental crust has been subducted at a depth of 80–200 km and subsequently exhumed to the Earth’s surface. During subduction, dehydration reactions of some hydrous minerals (e.g., lawsonite, phengite and chlorite) and partial melting of other regional metamorphic rocks (e.g., gneiss and eclogite) occur at high temperature and pressure (Xu et al., 2013; Liu et al., 2014). Previous field MT results have found that high conductivity anomalies with magnitudes of $10^{-1}$ S/m are widely distributed at 10–20 km in the Dabie–Sulu UHPM belt (Xiao et al., 2007). In addition, the slab-like high velocity anomaly results have also confirmed a depth of $\geq 110$ km for the uppermost mantle beneath the Dabie–Sulu orogen, which represents a remnant of the subducted Yangtze block after Triassic continent–continent collision (Xu et al., 2001). However, the origin and causal mechanisms of these high conductivity anomalies for the Dabie–Sulu UHPM belt are
still unknown. Together with the two main constituent rocks (natural eclogite and
granulite) in the UHPM belt, it is crucial to explore whether the gneiss electrical
conductivity can be used to interpret the high conductivity anomalies distributed in the
Dabie–Sulu tectonic belt. The relationship between temperature and depth in the Earth’s
stationary crust can be obtained by a numerical solution of the heat conduction equation
(Selway et al., 2014):
\[ T = T_0 + \left( \frac{Q}{k} \right) Z - \left( \frac{A_0}{2k} \right) Z^2 \] (3)
where \( T_0 \) is the surface temperature (K), \( Q \) is the surface heat flow (mW/m²), \( Z \) is the
lithosphere layer depth (km), \( k \) is thermal conductivity (W/mK), and \( A_0 \) is the
lithospheric radiogenic heat productivity (μW/m³). Based on previous studies, the
corresponding thermal calculation parameters for the Dabie–Sulu orogen are \( Q=5\)
mW/m² (He et al., 2009), \( A_0=0.31 \) μW/m³ and \( k=2.6 \) W/mK (Zhou et al., 2011).

Based on the heat conduction equation (Eq. 3) and thermal calculation parameters,
the conductivity–temperature results of gneiss with various chemical compositions
\((W_A=Na_2O+K_2O+CaO=7.12\%, 7.27\% \) and 7.64%) can be converted to a conductivity–
depth profile for the Dabie–Sulu orogen (Fig. 10). A similar transformation was also
conducted for granulite by Fuji-ta et al. (2004) and eclogite with different oxygen
fugacity (Cu+CuO, Ni+NiO, and Mo+MoO₂) by Dai et al. (2016). Figure 10 makes
clear that the high conductivity anomaly of \( 10^{-1.5} \)–\( 10^{-0.5} \) S/m from the field MT results
in the Dabie–Sulu UHPM belt occurs at 12–21 km, compared with three dominant
constituent rock conductivities of gneiss, granulite and eclogite in the region. Although
our obtained electrical conductivity of gneiss with different chemical compositions is
moderately higher than granulite and eclogite, it is not high enough to explain the high
conductivity anomaly observed in field MT results in the Dabie–Sulu orogen. In other
words, three dominant outcrops of metamorphic rocks, including gneiss, eclogite and
granulite, are not substances that produce the high conductivity anomalies of the Dabie–
Sulu orogen. However, the conductivity–depth profile for gneiss with various chemical
compositions may provide an important constraint on the interpretation of field
magnetotelluric conductivity results in the regional UHPM belt.
Aside from the chemical composition, other available alternative causes for high conductivity anomalies can be considered, such as water in nominally anhydrous minerals (Wang et al., 2006; Yang, 2011; Dai et al., 2014), interconnected saline (or aqueous) fluids (Hashim et al., 2013; Shimojuku et al., 2014; Sinmyo and Keppler, 2017), partial melting (Wei et al., 2001; Maumus et al., 2005; Gaillard et al., 2008; Ferri et al., 2013; Laumonier et al., 2015, 2017; Ghosh and Karki, 2017), interconnected secondary high-conductivity phases (e.g., FeS, Fe₃O₄) (Jones et al., 2005; Bagdassarov et al., 2009; Padilha et al., 2015), dehydration of hydrous minerals (Wang et al., 2012, 2017; Manthilake et al., 2015, 2016; Hu et al., 2017) and graphite films on mineral grain boundaries (Freund, 2003; Pous et al., 2004; Chen et al., 2017). In consideration of the similar formation conduction and geotectonic environments, the Himalaya–Tibetan orogenic system was compared with the Dabie–Sulu UHPM belt, and explains high electrical conductivity anomalies. Previous evidence from magnetotelluric and elastic seismic velocity data in the southern Tibet and northwestern Himalaya zones have confirmed that the high conductivity and low seismic velocity anomalies widespread exist at 10–25 km in the Himalaya–Tibetan orogenic system (Wei et al., 2001; Unsworth et al., 2005; Arora et al., 2007; Caldwell et al., 2009). Some studies have hypothesized that partial melting is the cause of the high conductivity anomalies in the Himalaya–Tibetan orogenic system (Wei et al., 2001; Gaillard et al., 2004; Hashim et al., 2013). Nevertheless other researchers think they are closely related with interconnected aqueous fluid (Makovsky and Klempere, 1999). As argued by Li et al. (2003), five possible hypotheses could explain the cause for the high conductivity anomalies in the INDEPTH magnetotelluric data of the southern Tibet mid-crust. The authors found that the high conductivity anomalies may be a result of interconnected melt and fluids. Recently, Naif et al. (2018) suggested that the high conductivity anomaly at 50–150 km can be explained by either a small amount of water stored in nominally anhydrous minerals or interconnected partial melts. In the present study, the electrical conductivity of gneiss with various chemical compositions at high temperature and pressure cannot be used to interpret the high conductivity anomalies of the Dabie–Sulu UHPM belt. Therefore, we propose that it is possibly caused by interconnected fluids or melts that
result in high conductivity anomalies for the Dabie–Sulu UHPM belt.

6 Conclusions

The electrical conductivity range of gneiss samples with various chemical compositions was about $10^{-5} - 10^{-1}$ S/m at 623–1073 K and 0.5–2.0 GPa. Electrical conductivity of the gneiss samples significantly increased with temperature, and weakly increased with pressure. The total alkaline ion content of K$_2$O, Na$_2$O and CaO is a remarkable influence on the electrical conductivity of the gneiss samples. Based on various activation enthalpy ranges (0.35–0.52 eV and 0.76–0.87 eV), corresponding to higher and lower temperature regions at 1.5 GPa, two main conduction mechanisms are suggested to dominate the conductivity of gneiss: impurity conduction in the lower temperature region and ionic conduction (charge carriers are K$^+$, Na$^+$ and Ca$^{2+}$) in the higher temperature region. Because of the much lower conductivity of gneiss samples at high temperature and pressure, we confirmed that gneiss with various chemical compositions cannot cause the high conductivity anomalies in the Dabie–Sulu UHPM belt.

Acknowledgements. We thank the editor of Professor Ulrike Werban and three anonymous reviewers for their very constructive comments and suggestions in the reviewing process, which helped us greatly in improving the manuscript. We appreciate Dr Kara Bogus from Edanz Group (www.edanzediting.com/ac) Scientific Editing Company for their helps in English improvements of the manuscript. This research was financially supported by the Strategic Priority Research Program (B) of the Chinese Academy of Sciences (XDB 18010401), Key Research Program of Frontier Sciences of CAS (QYZDB-SSW-DQC009), “135” Program of the Institute of Geochemistry of CAS, Hundred Talents Program of CAS and NSF of China (41474078, 41774099 and 41772042).

Fig. 7 Logarithm of the electrical conductivities versus the reciprocal temperatures of the gneiss samples with various chemical compositions at 1.5 GPa and 623–1073 K.

Fig. 8 Comparisons of the electrical conductivities of the gneiss samples measured at 1.5 GPa in this study and in previous studies. The dashed blue and green lines represent the electrical conductivities of gneiss and granulite at 1.0 GPa from Fuji-ta et al. (2004) and Fuji-ta et al. (2007), respectively, the dashed violet line represents the electrical conductivity of quartz at 1.0 GPa from Wang et al. (2010), the dashed brown line represents the electrical conductivity of alkali feldspars at 1.0 GPa from Hu et al. (2013), the dashed deep pink line represents the electrical conductivity of natural PP216 metapelite at 0.3 GPa from Hashim et al. (2013), the dashed maroon line represents the electrical conductivity of the residual JOY2-X4 enclave at 0.3 GPa from Ferri et al. (2013), the dashed red line represents the electrical conductivity of granite at 0.5 GPa from Dai et al. (2014), and the dashed
light pink line represents the electrical conductivity of phlogopite at 1.0 GPa from Li et al. (2016).

**Fig. 9** Geological sketch map of the Dabie-Sulu orogenic belt (a) and its correspondent lithological distribution diagram in the southern counterpart of Dabie-Sulu region (b) (modified after Xu et al., 2013; Liu et al., 2014).

**Fig. 10** Laboratory-based conductivity–depth profiles constructed from data of the gneiss samples, and the thermodynamic parameters, and comparison with geophysically inferred field results from Dabie–Sulu UHPM belt, China. The red solid lines represent the conductivity–depth profiles based on the conductivities of the samples described in Fig. 3 and based on a surface heat flow of 75 mW/m² in Dabie–Sulu UHPM belt. The dashed blue lines represent the conductivity–depth profiles based on the conductivities of eclogite, and the dashed brown line represents the conductivity–depth profiles based on the conductivities of granulite (Fuji-ta et al., 2004; Dai et al., 2016). The green region represents the MT data derived from high conductivity anomaly in Dabie–Sulu UHPM belt (Xiao et al., 2007; He et al., 2009).
