15
16
17 **Abstract.** The switching in deformation mode (from distributed to localized) and mechanisms (viscous
18 versus frictional) represent a relevant issue in the frame of crustal deformation, being also connected
19 with the concept of the brittle-“ductile” transition and seismogenesis. In subduction environment,
20 switching in deformation mode and mechanisms may be inferred along the subduction interface, in a
21 transition zone between the highly coupled (seismogenic zone) and decoupled deeper aseismic domain
22 (stable slip). On the other hand, the role of brittle precursors in nucleating crystal-plastic shear zones
23 has received more and more consideration being now recognized as fundamental in the localization of
24 deformation and shear zone development, thus representing a case in which switching deformation
25 mode and mechanisms interact and relate to each other. This contribution analyzes an example of a
26 crystal plastic shear zone localized by brittle precursor formed within a host granitic-protomylonite
27 during deformation in subduction-related environment. The studied structures, possibly formed by
28 transient instability associated with fluctuations of pore fluid pressure and episodic strain rate variations
29 may be considered as a small scale example of fault behaviour associated with a cycle of interseismic
30 creep and coseismic rupture or a new analogue for episodic tremors and slow slip structures. Our case-
31 study represents, therefore, a fossil example of association of fault structures related with stick-slip
32 strain accomodation during subduction of continental crust.

41 1. Introduction

42 The study of deformation fabric of fault rocks has been the base to develop a general model for crustal
43 scale fault zones (Sibson, 1977; Sibson, 1983; Scholz, 1988; Scholtz, 2002; Handy et al., 2007; Cooper
44 et al. 2010; Platt and Behr, 2011). In this model, the increasing PT conditions determine the transition
45 from a seismogenic frictional regime, dominated by pressure-sensitive deformation and involving
46 cataclasis and frictional sliding, to a viscous regime (Rutter, 1986; Schimid and Handy, 1991; Handy
47 and Brun, 2004), where dominantly aseismic, mainly crystal-plastic and continuous shearing is
48 localized within mylonitic shear zones. In quartzo-feldspathic rocks, this transition is primarily
49 determined by temperature-related quartz response to change in deviatoric stress, with dislocation creep
50 becoming the principal deformation mechanism at $T > 270$ °C (Sibson et al., 2002 and references).

51 Rock deformation experiments (Rutter, 1986; Shimamoto and Logan 1986; Bos and Spiers 2002;
52 Scholz 2002) have shown that the shear strength of simulated faults at the brittle-viscous transition may
53 depend on normal stress (as by faulting dominated by cataclastic mechanisms) although strain is
54 achieved through crystal plasticity and/or solution transfer. These results support the hypothesis that
55 some mylonitic shear zones are produced by coupled frictional and viscous mechanisms under semi-
56 brittle conditions (Shimamoto and Logan, 1986; Shimamoto, 1989; Chester, 1989; Scholz, 2002; Pec et
57 al., 2012 and references). Studies on semi-brittle behaviour leave several open questions regarding
58 natural fault zones including micromechanisms controlling bulk-rock deformation, the degree of
59 interdependence of active deformation mechanisms, their cyclicity and the associated bulk rock style of
60 deformation (Sibson, 1980; White and White, 1983; Takagi et al., 2000; Handy and Brun, 2004; Pec et
61 al., 2012). Complex transitional behaviour involving mixed continuous and discontinuous, distributed
62 vs. localized, and cyclic switching in deformation mechanisms over large variations in strain rates is
63 inferred at the transition between frictional and viscous domains, a zone which includes the typical
64 hypocentres and rupture depths for large earthquakes in continental crust (Sibson, 1983; Kohlstedt et
65 al., 1995; Scholz, 2002; Handy and Brun, 2004).

66 In convergent subduction settings, similarly, the transition zone, located between 10 and 35 km depth
67 depending on slab dip and thermal structure (i.e., between temperatures of 150 °C and 350–450 °C),
68 along subduction interfaces is recognized as the site of megathrust earthquake nucleation and
69 concentrated postseismic afterslip, as well as the focus site of episodic tremor and slow slip events
70 (Seki et al., 2003; Vannucchi et al., 2008; Meneghini et al., 2010; Angiboust et al., 2012; Andersen et
71 al., 2014; Hayman and Lavier, 2014; Fagereng et al., 2014; Angiboust et al., 2015).

72 The feedback between brittle and viscous deformation modes is relevant also for the mechanisms of
73 shear zone nucleation, so that fracturing has been proposed to be even a pre-requisite for the initiation
74 of ductile shear zones in the lithosphere (Handy and Stünitz, 2002; Pennacchioni and Mancktelow,

75 2007; Fousseis and Handy, 2008, among others). Shear zones and style of strain accommodation in terms
76 of **distributed vs. localized deformation** in granitoids have been described by different authors (Ramsay
77 and Graham, 1970; Burg and Laurent 1978; Simpson, 1983; Gapais et al. 1987; Goncalves et al. 2016
78 and references therein). In this context, the role of brittle precursors in nucleating **crystal-plastic** shear
79 zones has received ~~more and more~~ consideration ~~being now recognized as having~~ a fundamental role
80 ~~the localization process~~ (Segall and Simpson, 1986; Mancktelow and Pennacchioni, 2005;
81 Pennacchioni, 2005; Pennacchioni and Mancktelow, 2007; Menegon and Pennacchioni, 2010;
82 Pennacchioni and Zucchi 2012, among others).

83 However these works mostly deal with brittle precursors consisting of inherited structures such as
84 ~~discontinuities already existing at the beginning of deformation~~, as ~~the cases of~~ cooling joints,
85 cataclasites and veins (e.g. Guermani and Pennacchioni, 1998; Pennacchioni and Mancktelow 2007)
86 and most of them consider deformation at shallow to intermediate crustal depths (Fousseis and Handy,
87 2008; Mazzoli et al., 2009; Molli et al., 2011) although case studies framed under conditions of upper
88 amphibolite to granulite facies (White, 1996; Pennacchioni and Cesare, 1997; Kisters et al., 2000;
89 Pittarello et al., 2013; Altenberger et al., 2013) and eclogite facies (Austrheim and Boundy, 1994;
90 Austrheim, 2013 and references therein) were also investigated.

91 The case of deformation of crustal units and granitoids during subduction **has been only recently**
92 analysed in terms of rock records of paleo-seismic cycle and/or slow-slip phenomena (Angiboust et al.,
93 2015). A well-documented study from the Dent Blanche Thrust in the Western Alps is framed in the
94 hangingwall of an ancient subduction interface zone (Angiboust et al., 2014; 2015). ~~On the contrary~~,
95 our contribution analyses a microscale example of brittle precursor of a **crystal plastic** shear zone
96 derived from the footwall of a subduction interface ~~in ambient~~ blueschist-facies conditions thus
97 representing ~~a still not yet or less documented~~ case study (Molli et al., 2005; Molli 2007).

98 By virtue of their deep origin, the analysed structures are ideally suited to contribute to the ongoing
99 discussion on the deformation style and mechanisms associated with the broad spectrum of fault-slip
100 behaviour (from seismic slip to stable aseismic creep, to episodic slow slip events and non-volcanic
101 tremors) recorded by seismic and geodetic observations at active plate boundaries (e.g. Peng and
102 Gombert 2010; Beroza and Ide, 2011, and references therein). Slow slip events (i.e. fault slip events
103 with slip rates in between coseismic slip and aseismic creep, and generating equivalent seismic
104 moments similar to large earthquakes) in subduction zones have been recorded in a depth interval that
105 experiences temperatures between 250 and 650° C and pressures between 0.6 and 1.2 GPa (Beroza and
106 Ide, 2011), typically in areas of high Vp/Vs ratios suggestive of local high fluid pressures. This locates
107 slow slip events at the lower end of the seismogenic zone, at metamorphic conditions where the
108 rheology is expected to be viscous or at the frictional-viscous transition. Accordingly, recent studies of

109 shear zones exhumed from similar conditions along the subduction interface have suggested that
 110 coupled fracture and viscous flow, possibly associated with fluctuations in fluid pressure, can originate
 111 tremors and slow slips (e.g. Jereng et al., 2014; Hayman and Lavier, 2014; Angiboust et al., 2015;
 112 Malatesta et al., 2013). Here we show that the HP brittle-viscous transition preserved in the Popolasca
 113 granitoids can also be explained with transient high fluid pressures triggering brittle deformation in an
 114 otherwise viscous regime, and discuss the related implications for fault-slip behaviours in subduction
 115 zones.

116

117 2. Regional background and Geological Setting of studied sample

118 In Alpine-type orogens the study of meso- and microstructural record of exhumed subduction related
 119 thrust zones and its interpretation in terms of subduction zone rheology and seismicity have received
 120 increasing attention since the end of '90 (Stöckhert et al., 1999; Kuster and Stöckhert, 1999). This
 121 subject has been developed in particular in the Alpine Corsica (Austrheim and Andersen, 2004;
 122 Andersen and Austrheim, 2006; Healy et al., 2009; Andersen et al., 2014; Deseta et al., 2014a,b; Magott
 123 et al., 2016a,b) in oceanic units made up of peridotite, serpentinite, gabbro, basalt, calcareous and
 124 siliceous schist and marble exposed as remnants of the lithosphere of the Jurassic Piemonte- Liguria
 125 oceanic basin and its pelagic sedimentary cover (Mattauer et al., 1981; Bezert and Caby, 1988; Jolivet
 126 et al., 1990; Molli, 2008; Vitale Brovarone et al., 2013).

127 These widespread occurrences and preservations of relicts of seismogenic exhumed structures are
 128 mainly related to the peculiar geologic history of Alpine Corsica, connected with the development of
 129 the Alps/Apennine orogenic system (Molli and Malavieille, 2011; Guyedan et al., 2017; Beaudoin et al.,
 130 in press) with the lacks of the continent-continent "hard collision"- related structures and thermal
 131 reworking observable in the Alps (e.g. Polino et al., 1995; Schmid et al., 1997; Berger and Busquet,
 132 2008; Butler, 2013; Rosenberg and Kissling, 2013; Carminati and Doglioni, 2014) and a better
 133 preservation of the early stages of subduction-related structures and fabrics.

134 Corsica, therefore, represents a suitable natural laboratory for the investigation of the subduction-related
 135 processes in oceanic and continental crust as firstly suggested by Mattauer et al. (1981) and Gibson and
 136 Horak (1984).

137 In Corsica, continental-derived units, i.e. units derived from the footwall of ancient subduction interface
 138 zone, can be observed in three different structural positions (Fig.1), each of them corresponding to a
 139 different peak metamorphism (Tribuzio and Giacomini, 2004; Molli, 2008; Vitale Brovarone et al.,
 140 2013):

141 the innermost slices (Serra di Pigno/Farinole units) interleaved with oceanic units show eclogite peak
 142 conditions at 1,5/1,5 GPa; 500 ± 50 °C;

143 - the intermediate ones (e.g. the Tenda and Centuri units) are instead characterized by Upper Blueschist
144 facies peak conditions at 0,9/1,1 GPa; 450± 50 °C;

145 - the most external (e.g. Corte/Popolasca units) show high pressure greenschist and/or blueschist facies
146 peak assemblages developed at T =325/370°C, P = 0.75/0.85 GPa (Malasoma et al., 2006; Di Rosa et
147 al., 2016).

148 These occurrences document the progressive underthrusting at different depths and their in-sequence
149 contractional exhumation within an young e-age east-dipping subduction system (Mattauer et al., 1981;
150 Bezert and Caby, 1988; Jolivet et al., 1990; Garfagnoli et al., 2009; Molli and Malavieille, 2011; Maggi
151 et al., 2012; Di Rosa et al., 2016; Guyedan et al., 2017).

152 The studied samples come from the external continental units (Molli, 2008; Molli and Malavieille,
153 2011; Vitale Brovarone et al., 2013) of Alpine Corsica and in more detail from the Popolasca Unit
154 (Bezert and Caby, 1988; Malasoma et al., 2006; Di Rosa et al., 2016). This unit is characterized by a
155 pre-Mesozoic basement mainly formed by granitoids, a Permo-Mesozoic metasedimentary sequence
156 and an Early-Eocene flysch (Fig. 1).

157 Blueschist assemblages in the unit have been described by regional studies (Bezert and Caby, 1988;
158 Malasoma et al., 2006; Molli, 2008; Di Rosa et al., 2016) and can be observed in all suitable rock-types:
159 in metapelites from cover rocks, in metabasic dykes and some of the granitoid suites from the basement.

160 Peak metamorphism has been constrained at 250/350°C, 0.4/0.55 GPa (Bezert and Caby, 1988) or more
161 recently better defined at 325/370 °C and 0.75/0.85 GPa (Malasoma et al., 2006; Di Rosa et al., 2016).

162 The prograde to peak pressure assemblage has been recently dated in the range of 45-36 Ma by Di
163 Vincenzo et al., (2016).

164 The contributions of Malasoma et al., (2006), Di Rosa et al., (2016) analysed the cartographic to
165 mesoscopic-scale structural geometries of deformation in the area of the studied sample.

166 Superimposed foliations and fold structures are typical of the metasedimentary cover, with blueschist
167 assemblages as relict fabrics. On the contrary, in basement rocks a main phase continuous foliation can

168 be observed wrapping around undeformed granitoids. The main foliation is either associated with
169 blueschist or greenschist facies assemblages (Malasoma et al., 2005; Di Rosa et al., 2016; Di Vincenzo
170 et al., 2016). Anastomosed network of fault zones associated with subgreenschist facies assemblages

171 overprints all previous structures and may be related to the activity of a major N/S trending transcurrent
172 fault zone (Central Corsica Fault Zone) reworked by normal kinematics active during Oligocene-

173 Miocene in the frame of rototranslation of Corsica-Sardinia microblock and upper-plate extension
174 associated with Apenninic subduction (Faccenna et al., 2004; Molli, 2008; Molli and Malavieille, 2011;

175 Carminati and Doglioni, 2014; Guyedan et al., 2017).

176

177

178 3. Geometry of deformation and microstructures

179 The analysed sample (Fig.2) is a deformed ~~granitoid of calcalkaline suite~~ (K-feldspar, plagioclase,
180 quartz, biotite) ~~well known in the~~ Hercynian Corsica (Rossi et al., 2001). It shows a continuous
181 foliation (Fig.2,3a,b) mainly defined by the shape preferred orientation of quartz, feldspars and biotite
182 grains.

183 Shape anisotropy of quartz in the host protomylonite shows an aspect ratio around 0,37 (mean X/Z of
184 2,7) which indicates a shear strain γ of c.1 assuming deformation in simple shear.

185 Quartz shows ~~typical~~ features of low temperature plasticity (Tullis et al., 2000; Stipp et al., 2002;
186 Vernooij et al., 2006; Trepmann et al., 2007; Derez et al., 2015; Kjøl et al., 2015) (Fig 3), such as
187 **undulatory extinction**, localized extinction bands (LEBs, following the terminology of Derez et al.,
188 2015), typically forming conjugate sets, and up to 100 μm thick intracrystalline bands of recrystallized
189 grains (5-10 μm in size). Bands of recrystallized grains occur parallel to the main foliation as well as in
190 conjugate sets intersecting at ca. 90° and parallel to the conjugate sets of LEBs.

191 Feldspars show local evidence of grain size reduction by microcracking and microfaulting (Fig.3)
192 associated with K-feldspar breakdown to albite (by bulging recrystallization) (Fig.3), stilpnomelane and
193 phengite. Thin needles of Na-amphibole (Fig.4) attest the development of this fabric in HP/LT
194 conditions as described below.

195

196 The main foliation is cross-cut at high angle by a millimetre-thick localized zone of deformation
197 (Fig.2,5). This shows a sharp boundary, truncating flattened quartz and feldspar grains; a feature
198 suggesting its development as unstable fracture (Schmid and Handy, 1991; Passchier and Trouw, 2011).

199 Three compositionally controlled domains can be recognized within the thin localized shear zone
200 (Fig.2,5):

201 Domain 1 is feldspar-dominated and shows microstructural features typical of a cataclasite (Fig.5a,c).
202 Feldspar clasts (and quartz grains) reveal both displacive intragranular fractures and intergranular
203 “stable” cracks (Atkinson, 1982; Schmid and Handy, 1991).

204 Domain 2 is “phyllosilicate”-dominated (stilpnomelane and phengite) and shows microstructural
205 features of a foliated-cataclasite/phylionite (Fig.5a,b). Asymmetric porphyroclasts and shear band
206 systems characterize the phyllosilicate-rich parts of the shear zone.

207 Domain 3 is a quartz-albite rich domain showing microstructural features typical of an ultramylonite.
208 This is characterized by very fine recrystallized albite and quartz grains (5-10 μm in size) (Fig.5a,b;
209 Fig.6) with strong crystallographic preferred orientation (see below). Quartz porphyroclast shows a
210 mean aspect ratio around 0,09 (mean X/Z of 11) which corresponds to a calculated shear strain γ of c. 3

211 At this shear strain the corresponding angle between the foliation and the shear zone boundary in simple
212 shear is around 15° which agrees with the mean orientation of the quartz porphyroclasts shape
213 preferred orientation defining the ultramylonitic foliation (Fig.6a,b,c) Syn to post-kinematic Na-
214 amphibole (Fig.6a) documents shearing in HP/LT metamorphic conditions, as illustrated here below.

215

216 **4. Mineral chemistry and estimate of metamorphic Pressure-Temperature (P-T) conditions**

217 Chemical analyses of coexisting minerals within the metamorphic assemblage (Tab.1) were obtained
218 using a JEOL JXA-8600 electron microprobe, equipped with four wavelength-dispersive spectrometers,
219 at the CNR - Istituto di Geoscienze e Georisorse, Firenze, Italy. Running conditions were 15 kV
220 accelerating voltage and 10 nA beam current on a Faraday cage. Counting time for the determined
221 elements ranged from 10 to 60 s at both peak and background. The Bence and Albee (1968) method
222 was employed for the correction of all data. A number of synthetic and mineral standards were used for
223 instrumental calibration.

224 **Amphibole.** Structural formulae were calculated assuming 23 oxygens, and the classification of Leake
225 et al. (1997) was adopted. Site assignment and ferric iron contents were calculated using the scheme
226 proposed by Schumacher in Leake et al. (1997). Because of the small sizes of the crystals (widths
227 $c.10\mu\text{m}$), it was not possible to make compositional traverses across individual crystals to detect
228 intracrystalline variations in chemical composition, such as core-to-rim zonation. Thus, each analysis
229 reported in Table 1 represents a different crystal. In the studied sample the Na-amphiboles are mostly
230 riebeckite (Tab.1 and Fig. 4b) with low Mg/(Mg+Fe²⁺) ratio (0.13-0.21) and are characterized by Si
231 contents close to the maximum of 8.0 apfu.

232 **Other minerals.** ~~All analysed albites, of which structural formulae~~ were calculated assuming 8
233 oxygens, have composition close to the pure end-member. Stilpnomelane structural formulae were
234 calculated assuming 24 oxygens and all Fe as divalent (Fe²⁺). Stilpnomelanes have Fe amounts ranging
235 from 1.86 to 2.91 apfu and Mg amounts ranging from 0.24 to 0.58 apfu. For K-feldspar and biotite
236 porphyroclasts, structural formulae were calculated assuming respectively 8 and 22 oxygens. The
237 analysed K-feldspars have composition close to the orthoclase pure end-member, with minor amounts
238 of Na.

239

240 The peak metamorphic mineral assemblage is characterised by Na-amphibole + phengite + quartz +
241 albite + stilpnomelane. Na-amphibole is a typical mineral related to the blueschist facies and is
242 indicative of HP/LT gradient metamorphism (e.g. Evans 1990; Schiffman & Day 1999 and references).
243 The minimum temperature (T) and pressure (P) conditions of this mineral assemblage can be estimated
244 using the reaction curves proposed by Schiffman & Day (1999) for the appearance of Na-amphibole

245 (stability field of the blueschist facies); meanwhile the maximum temperature (T) conditions were
246 constrained by the presence of stilpnomelane, as shown by the equilibrium: $\text{Stp} + \text{Phe} = \text{Bt} + \text{Chl} + \text{Qtz} + \text{W}$
247 (Massonne & Szpurka, 1997). Summing up all the available thermobarometric information, the
248 metamorphic conditions can be estimated as temperature (T) around 320 ± 50 °C and pressure (P) ~~> of~~
249 0.70 GPa (Fig.4c); consistent with those described by Malasoma *et al.* (2006) in metagranitic rocks
250 from the area of our studied sample.

251

252

253

254 5. EBSD data

255 EBSD analysis of quartz was conducted with a Jeol 7001 FEG-SEM equipped with a NordlysMax
256 EBSD detector (Oxford Instruments) at the Plymouth University Electron Microscopy Centre. Working
257 conditions during acquisition of the EBSD patterns were 20 kV, 70° sample tilt and high vacuum. Thin
258 sections were chemically polished with colloidal silica and carbon-coated before the analysis. EBSD
259 patterns were acquired on rectangular grids with step size of 1 μm and 2 μm . EBSD patterns were
260 acquired and indexed with the AZtec software and processed with Channel 5 software (Oxford
261 Instruments). Raw EBSD data were processed to reduce data noise following the procedure tested by
262 Prior *et al.* (2002) and Bestmann and Prior (2003). EBSD results are shown ~~in form of~~ Inverse Pole
263 Figure map, pole figures (~~equal angle, lower hemisphere~~) of crystallographic axes and planes ($\langle 0001 \rangle$
264 c-axis, $\langle 11-20 \rangle$ a-axis, $\{10-10\}$ prism $\{m\}$, $\{10-11\}$ positive rhomb $\{r\}$, $\{01-11\}$ negative rhomb $\{z\}$),
265 misorientation profiles and plots of misorientation axis in sample coordinates.

266

267 5.1 Quartz in the host rock

268 We analysed a monocrystalline quartz ribbon elongated parallel to the host-rock foliation and sharply
269 cut by the thin localized shear zone. The quartz ribbon contains two nearly orthogonal sets of
270 intracrystalline shear bands of recrystallized grains (Fig. 7a); one set is oriented at high angle ($90^\circ \pm 20$,
271 *set 1*) and one at low angle ($\leq 20^\circ$, *set 2*) to the host rock foliation (vertical in Fig. 7a). The average
272 grain size of the recrystallized grains is 5 ± 2 μm . The ribbon ~~contains also fine localized~~ extinction
273 bands (~~up to 20 μm thick~~) (LEBs: Derez *et al.*, 2015) subparallel to the bands of recrystallized grains.
274 Low-angle boundaries are ubiquitous in the ribbon; on EBSD maps they are typically straight, poorly
275 connected, and subparallel to the bands of recrystallized grains (Fig. 7b). Some low-angle boundaries
276 are connected to form subgrains of approximately the same size ~~of~~ the recrystallized grains. Subgrains
277 occur with a higher frequency at the intersection between two sets of recrystallized bands, and in
278 regions sandwiched between closely spaced (≤ 100 μm) subparallel bands of recrystallized grains (Fig.

279 7b).

280 The c-axis of the ribbon is oriented near the pole to the host-rock foliation, ~~i.e.~~ in a position suitably
 281 oriented for the activation of the basal $\langle a \rangle$ slip system of quartz (Fig. 7c). The c-axis orientation of the
 282 recrystallized grains in the intracrystalline bands is mostly spread out along the periphery of the pole
 283 figure, although some scattered grains have their c-axis in intermediate positions between the X and Y
 284 directions of the pole figures (Fig. 7d). Such an orientation suggests that the recrystallized grains have
 285 experienced a rotation around ~~the Y-direction of finite strain (i.e. centre~~ of the pole figure) from the
 286 host-grain orientation (e.g. Van Daalen et al., 1999; Menegon et al., 2011).

287 This is confirmed by the boundary trace analysis (Prior et al., 2002; Menegon et al., 2010) of the two
 288 main sets of straight low-angle boundaries defining localized extinction bands (parallel to bands of
 289 recrystallized grains), one running ENE-WSW (*subset 1*) and one running ca. N-S (*subset 2*) in Fig. 7b.
 290 The dispersion paths of crystallographic directions on the pole figures of subset 1 (Fig. 7e) identifies
 291 $\{m\}$ as the rotation axis, which lies very close to the centre of the pole figure. The pole to the prismatic
 292 plane $\{m\}$ is the rotation axis associated with the basal $\langle a \rangle$ and with the $\{a\} \langle c \rangle$ slip system in quartz
 293 (e.g. Neumann, 2000), and, accordingly, subset 1 can be interpreted as a tilt boundary plane produced
 294 by the activity of the slip system basal $\langle a \rangle$ (Fig. 7e) and containing the boundary trace of subset 1 and
 295 the rotation axis.

296 Subset 2 has a similar dispersion path as subset 1, with $\{m\}$ as the identified rotation axis. However, in
 297 this case the boundary trace analysis is not consistent with a tilt boundary produced by the activity of
 298 the slip system basal $\langle a \rangle$, but could indicate the activity of the $\{a\} \langle c \rangle$ slip system (Fig. 7f). However,
 299 activity of c-slip in quartz typically requires temperature in excess of 600° C (Kruhl, 1996; Zibra et al.,
 300 2010) and, therefore, appears unlikely in our samples. Moreover, misorientation profiles across
 301 angle boundaries with a subset 2 orientation show abrupt misorientation jumps of up to 6° (profiles 2
 302 and 3 in Figs. 7b and 7g), as opposed to a gradual accumulation of misorientation towards low-angle
 303 boundaries with a subset 1 orientation (profile 1 in Figs. 7b and 7g). Thus, the low-angle boundaries
 304 with a subset 2 orientation could represent microcracks subparallel to the basal planes (e.g. Kjøl et al.,
 305 2015) that localized rigid body rotation of fragments around the Y-direction (e.g. Trepmann et al., 2007;
 306 Menegon et al., 2013). The rotation around Y of (1) the crystallographic directions of the host grain and
 307 (2) the recrystallized grains (in this case for large misorientation $> 10^\circ$) is confirmed by the plots of the
 308 misorientation axis in sample coordinates (Fig. 2).

309

310 5.2 Quartz in the localized shear zone

311 We analysed polycrystalline ribbons of recrystallized grains from domain 3 of the localized shear zone
 312 (Fig. 8a). The c-axis orientation of the recrystallized grains defines an inclined type-I crossed girdle

313 synthetically oriented with respect to the bulk shear sense of the shear zone (Fig. 8b). The c-axes are
 314 preferentially clustered near the pole to the shear zone boundary, i.e. in an orientation slightly oriented
 315 for the activity of the basal <a> slip system. ~~The average grain size of the recrystallized grains in~~
 316 ~~domain 3 is 6±2 μm.~~

317

318 6. Ultramylonite: Paleopiezometry, flow stress and strain rate

319 The microstructure and the crystallographic preferred orientation of quartz indicate that quartz in the
 320 protomylonite and ultramylonite deformed by **dislocation creep** (concomitant with microcracking in the
 321 protomylonite) and recrystallized to a fine-grained aggregate. Thus, the rheology and the flow stress in
 322 the ultramylonite can be evaluated extrapolating experimentally calibrated flow laws of quartz to the
 323 deformation conditions.

324 The rheology of quartz deforming by dislocation creep is generally described in terms of a power-
 325 law equation:

$$326 \quad \dot{\epsilon} = A f_{H_2O}^m e^{(-Q/RT)} \sigma^n \quad (1)$$

327 Where $\dot{\epsilon}$ is the strain rate, f_{H_2O} is the water fugacity (raised to the power of m), Q is the activation
 328 energy, R is the universal gas constant, T is the temperature, σ is the differential stress, and n is the
 329 stress exponent. We used the ~~theoretical~~ dislocation creep flow law of Hirth et al. (2001), which ~~has~~
 330 ~~derived~~ a linear dependence of strain rate on the water fugacity (m=1) and a stress exponent of 4. A
 331 water fugacity of 172 MPa ~~is calculated from the water fugacity coefficient reported in Töðheide (1972)~~
 332 at T=350°C, P=0.8 GPa.

333 The paleostress (assuming steady-state flow at time of viscous deformation) can be determined by
 334 recrystallized quartz grain size paleopiezometer (e.g. Stipp & Tullis, 2003), which have been calibrated
 335 in the form: $\Delta\sigma = B D^{-X}$, where $\Delta\sigma$ is the steady state differential stress ($\sigma_1 - \sigma_3$), D is the recrystallized
 336 grain size and B and X are empirical constants. Using the recrystallized grain size piezometer of quartz
 337 calibrated by Stipp and Tullis (2003), a recrystallized grain size of 5-10 μm indicates differential stress
 338 in the range of 110-190 MPa. Extrapolation of the flow law of Hirth et al. (2001) yields a strain rate in
 339 the range of $7.6 * 10^{-13} - 6.2 * 10^{-12} \text{ sec}^{-1}$ in the ultramylonite at the estimated deformation temperature
 340 of 350°C.

341

342 7. Discussion and conclusion

343

344 7.1 Viscous-brittle-viscous deformation under HP/LT conditions

345 The analysed example documents a switch in deformation mode and mechanisms within an HP/LT fault
346 zone. ~~On the base of~~ overprinting relationships and microstructural features the following deformation
347 sequence ~~may be suggested~~: stage (1), associated with a distributed deformation and development of a
348 protomylonitic foliation in the granitoid by quartz low temperature plasticity, microfracturing, and
349 albite neo-crystallization from K-feldspar porphyroclasts (Fitzgerald and Stunitz, 1993) has been
350 followed by stage (2), in which localized deformation by brittle fracturing formed a millimeter-thick
351 cataclaste, which acted as a precursor for (3) localization of viscous deformation and ultramylonite
352 development. The synkinematic and postkinematic growth of Na-amphibole in the host rock foliation
353 and in localized ultramylonite indicates that the entire deformation sequence occurred at HP/LT
354 conditions (ca. 350°C at ≥ 0.7 GPa), corresponding to a depth of 23-30 km in the subduction channel.

355 The estimated P, T conditions are consistent with low-T plasticity regime in quartz (Stipp et al., 2002;
356 Derez et al., 2015 and refs therein). Accordingly, the deformation microstructures of quartz produced
357 during stage (1) in the host rock appear to be the product of the competition between dislocation activity
358 and fracturing. Localized extinction bands at high angle to the host rock foliation (subset 1 in Fig. 7b)
359 are consistent with the activity of the basal $\langle a \rangle$ slip system, whereas localized extinction bands
360 subparallel to the host-rock foliation (subset 2 in Fig. 7b) are interpreted as fractures subparallel to the
361 basal plane, as previously observed by Kjöll et al. (2015). Some localized extinction bands (especially
362 those with a subset 2 orientation, see Fig. 7b) contain isolated small new grains that are considerably
363 smaller than the average grain size in the recrystallized bands, and that are only slightly misoriented
364 with respect to the host grain. Moreover, the high-angle boundaries in such localized extinction bands
365 are not always fully connected to define entire new grains. Together with the abrupt misorientation
366 jumps (Fig. 7g), these observations further suggest that localized extinction bands with a subset 2
367 orientation represent fractured domains in which the fragments have rotated passively and sealed
368 together as proposed by e.g. Derez et al. (2015).

369 Despite the local fracturing of the host grain, deformation of the recrystallized grains in the conjugate
370 intracrystalline bands involved dislocation activity, as indicated by the cluster of misorientation axis
371 around the prism $\{m\}$ for low misorientations (compare Fig. 7h with 7d). This is consistent with the
372 local activity of the basal $\langle a \rangle$ slip system in the recrystallized bands, as also indicated by the CPO of
373 the recrystallized grains in the bands at high angle to the host rock foliation (Fig. 7d).

374 The type-I crossed girdle c-axis CPO of quartz in the ultramylonite suggests the concomitant activity of
375 basal $\langle a \rangle$, rhomb $\langle a \rangle$ and prims $\langle a \rangle$ slip systems in the recrystallized ribbons (Fig. 8). The grain size
376 of recrystallized quartz in the ultramylonites is in the same range (5-10 μm) as in the intracrystalline
377 bands in the host rock. This suggests that 5-10 μm represents the equilibrium grain size with the flow
378 stress (estimated in the range of 110-190 MPa with recrystallized grain size piezometry) during viscous

379 deformation before and after the transient brittle event of stage (2).

380 During stage (2) the development of cataclasite and related dilatancy resulted in an increase of
 381 permeability and thus facilitated fluid access and fluid mobility in the shear zone. This enhanced
 382 mineral transformations as testified by modal enrichment of stilpnomelane (by biotite breakdown) and
 383 Na-amphibole in the ultramylonite.

384 Therefore, the observed structures witness a change in deformation style (from distributed to localized
 385 strain in brittle precursor), and a switch in the dominant deformation mechanism (from low T plasticity
 386 in the host rock to cataclasis and back to crystal plasticity in the ultramylonite), which occurred at the
 387 footwall of subduction interface at temperature conditions typical of the brittle/viscous transition in
 388 quartz/feldspathic rocks.

389 Finally, the transition from stage (2) and stage (3) is consistent with the general observation that
 390 nucleation of localized ductile shear zones requires the presence of a planar compositional or structural
 391 precursor (e.g. Pennacchioni and Zucchi, 2012, and references therein). The example from the
 392 Popolasca granite demonstrates that (i) nucleation on brittle precursors also occurs under HP/LT
 393 conditions in the subduction channel, and (ii) the brittle precursors are not necessarily inherited from an
 394 earlier deformation event, but can be the manifestation of switches in deformation mode in the footwall
 395 of the subduction interface.

396

397 **7.2 Significance of the switch in deformation mode and implications for fault-slip behaviours in** 398 **subduction zones**

399 We interpreted the inferred deformation sequence and structures as the result of transient instabilities
 400 (Sibson, 1980; White, 1996; Handy and Brun, 2004) possibly representative of mixed fault-slip
 401 behaviours at seismogenic depth in the subduction channel. We have estimated the conditions resulting
 402 in the transient brittle event during stage (2) under the following assumptions and approximations:

- 403 1. The coefficient of internal friction, μ_i , is generally between 0.5 and 1.0 in intact rocks (Sibson,
 404 1985). We considered $\mu_i = 0.6$ in the failure envelope for the intact Popolasca granitoid.
- 405 2. We used a cohesive strength of 35 MPa as representative for granitoids (Amitrano and
 406 Schmittbuhl, 2002), with a resulting tensile strength of 17.5 MPa.
- 407 3. We assumed an Andersonian stress field and a thrust regime. The effective vertical stress σ'_v
 408 corresponds to the effective minimum principal stress $\sigma'_3 = \sigma_3 - P_f$, where P_f is the pore fluid
 409 pressure. We considered a hydrostatic pore pressure ($\lambda = 0.4$, $P_f = 320$ MPa for $\sigma_3 = 800$ MPa)
 410 during the formation of the gneissic foliation in the host rock.
- 411 4. We assumed a differential stress of 110-190 MPa during viscous flow of the granitoid prior to

412 brittle failure at $\sigma_v = 480$ MPa, as derived from the recrystallized grain size piezometry in the
413 protomylonite.

414 The results of our analysis are shown in Fig. 9a. For brittle failure, it is necessary to invoke high
415 differential stresses (of the order of 1.1 GPa assuming a hydrostatic pore fluid pressure), or higher fluid
416 pressure (Fig. 9a). Differential stresses in excess of 1 GPa have been associated with intermediate depth
417 (50-300 km) earthquakes in the subduction channel (e.g. John et al., 2009), and are expected to result in
418 extensive development of pseudotachylytes in granitoid rocks (e.g. Austrheim 2013 and references
419 therein), which, on the contrary, have not been observed in the sample studied here.

420 For the differential stress range and the vertical stress considered here, brittle failure requires
421 (sub)lithostathic fluid pressure ($0.96 < \lambda < 1$, Fig. 9). The strength envelope plotted for pore fluid
422 pressure between 0.98 and 0.94 and for a strain rate of 10^{-12} s⁻¹ (Fig. 9b) suggests that viscous
423 deformation at the estimated depth range (23-30 km) is only possible for pore fluid pressure ≤ 0.94 ,
424 otherwise brittle deformation is expected to occur. Thus, under the assumptions listed above, ~~our~~
425 ~~analysis indicates that~~ local fluctuations in pore fluid pressure can explain the cyclic viscous-brittle-
426 viscous deformation switch. However, despite the synkinematic growth of hydrous minerals in the
427 cataclastite and the high pore fluid pressure required at failure, there is no evidence of macroscopic
428 veining or hybrid fractures in the samples. Our analysis is consistent with this observation, in that
429 failure occurs entirely in the shear fractures field and not in the (hybrid) shear extension fractures field
430 (Fig. 9a).

431 Drawing from the results shown in Figs. 9a,b and using concept and inferences coming from modern
432 studies of convergent subduction system (e.g. Ozowa et al., 2002; Fu and Freymuller, 2013; Bedford et
433 al., 2013) ~~we may suggest~~ the following deformation path (Fig.10) ~~for the structural features of our~~
434 ~~analysed sample~~. A first stage of distributed deformation (stage 1) may be associated with large scale
435 anastomosed shear zone development and aseismic creep, then, following Angiboust et al. (2015), two
436 possible deformation scenario and slip patterns may be envisaged: (a) propagation at seismic rate of
437 microrupture followed by afterslip or (b) slow slip phenomena in an aseismically creeping crust. In the
438 first case transient strain rate increase associated with brittle fracturing would represent the deep
439 response of the transition zone to a specific stage of the seismic cycle taking place higher up along the
440 seismogenic portion of the subduction interface (Fig.10c, scenario 1) or in less deformed domains
441 acting as local stress raisers nearby (Fig.10c, scenario 2). Cataclastic deformation would then correlate
442 with coseismic to postseismic deformation higher up along the interface. In that case, the mylonitization
443 of the brittle precursor would be the record of subsequent interseismic deformation at lower strain rates,
444 taking place in the time frame between two earthquakes.

445 In the second case (Fig.10d), the transient highs in strain rates related to brittle fracturing and cataclasis

446 could be the ~~field evidence of deformation associated with~~ slow slip events (SSEs) or other transient
447 slips, generally localized along the subduction interface at this depth range itself (e.g., Shelly et al.,
448 2006; Fagereng et al., 2014). We are aware that the mechanism(s) of SSEs initiation are still poorly
449 understood, and that stress/strain rate perturbations triggered by an earthquake nearby followed by
450 postseismic slip and interseismic creep is an equally feasible mechanism to explain the deformation
451 sequence recorded in our sample. However, our preferred interpretation is that the transient brittle
452 deformation recorded in our studied sample is the manifestation of a slow slip event, for the following
453 reasons: (1) subduction interface SSEs typically occur at the downdip transition from stick-slip
454 behaviour to aseismic creep (e.g. Wallace and Beavan, 2010), and, in granitoid rocks, this transition is
455 expected to occur at the T range of deformation of our case-study, as witnessed by the deformation
456 microstructures of quartz and feldspar in the host protomylonite; (2) SSEs are often related to high pore
457 fluid pressure (e.g. Liu and Rice, 2007).

458 Whatever the actual process triggering brittle deformation was, we want to emphasize that detailed
459 microstructural studies of exhumed shear zones are a valuable complement to the geodetic,
460 seismological and experimental studies that aim to unravel the complex fault-slip behaviours at the
461 subduction interface. In this context, our studied sample represents a new and still not yet documented
462 case study of brittle-viscous transition zone and processes in subducted continental crust. Moreover, our
463 study reinforces the concept that the external zones of Alpine Corsica represent a unique target to
464 document and understand footwall deformation structures and processes related with HP/LT continental
465 subduction.

892 **Figures list and caption**

893

894 Fig.1 a) Alpine Corsica within the Alps/Apennine framework. b) Tectonic map of north Corsica
895 showing the main tectonic units and the area of studied sample. 1,2) Corsican continental crust, mainly
896 Carboniferous-Permian granitoids, their host pre-Carboniferous basement and a Mesozoic to Eocene
897 cover: (1a) “autochthonous” Hercynian Corsica and (1b) greenschist/lower-blueschist external
898 continental units (Corte; Popolasca); 2) inner continental units: (2a) upper-blueschist units (Tenda
899 Massif; Centuri) and (2b) eclogite slices (Serra di Pigno-Farinole); 3) Schistes Lustres nappe
900 (undifferentiated); 4) Nappe Superiore i.e. upper non-metamorphic units (Balagne, Nebbio and
901 Macinaggio units); 6) Miocene sediments; c) Regional cross-section with indication of study sample
902 from Popolasca area.

903

904 Fig.2. Mesoscopic view of the analyzed sample: protomylonitic metagranite host with millimetre-scale
905 ultramylonite localized after brittle precursor. All observable deformation structures were developed
906 under HP/LT metamorphic conditions.

907

908 Fig.3. Microscopic views of host-rock showing Quartz microstructures typical of low temperature
909 plasticity: a) intracrystalline deformation (undulatory extinction, deformation lamellae, deformation
910 bands, localized extinction bands, LEBs) associated with recrystallization along intragranular conjugate
911 shear bands sets; b) brittle fracturing in domino-style of K-feldspar associated with K-feldspar
912 breakdown to albite, stilpnomelane and phengite; c) quartz deformation lamellae and intergranular
913 recrystallization by bulging; d) K-feldspar intergranular recrystallization and albite-neocrystallization,
914 recrystallization also observable along later cracks and microfractures (horizontal to sub-horizontal).

915

916 Fig.4 a) BSE image of the metamorphic mineral assemblage in the host granitoids of the studied
917 sample; Ab, albite; Amp, Na-amphibole; Kfs, K-feldspar; Phe, phengite; Qtz, quartz; b) composition of
918 sodic amphiboles, using the classification of Leake et al. (1997); c) estimated peak-metamorphic
919 pressure/temperature conditions for the studied sample (cross-hatched area) constrained by the
920 reactions indicated.

921

922 Fig.5 a) Microscopic view of millimetre-scale shear zone nucleated after brittle precursor, with
923 indication of the structural-compositional domains within the shear zone. Domain 1 relict domain of
924 cataclasite; Domain 2 phyllonite; Domain 3 ultramylonite; b) detail of the sharp shear-zone boundary
925 heritage of former host-fracture contact and ultramylonite to phyllonite transition within the microscale

926 shear zone are well observable; c) detail of domain 1, relict domain of cataclasite, mainly K-feldspar
927 dominated. Angular fragments of variable size are indicative of brittle comminution.

928

929 Fig. 6 Microscopic view of ultramylonite; a) synkinematic Na-amphibole, boudinaged within the
930 quartz and albite ultramylonite matrix; b) Quartz and albite recrystallized matrix, in the lower part the
931 boundary of microscale shear zone with an host quartz porphyroclast; c) Quartz-ribbon with a strong
932 elongation (1:15, X/Z ratio) defining a shape preferred orientation oblique (15°) to the shear zone
933 boundary; d) detail of quartz recrystallization in the ribbon porphyroclast and matrix.

934

935 Fig. 7. EBSD analysis of quartz in the host protomylonite. (a) Microstructure of the analysed site. The
936 white arrows indicate localized extinction bands that have been analysed with the boundary trace
937 analysis and misorientation profiles as shown in Figs. 7b-g. (b) Inverse Pole Figure Map with the
938 respect to the protomylonitic foliation in the host rock (vertical in the figure). Location of subset 1 and 2
939 and trace of misorientation profiles 1-3 are shown. (c) Pole figure of the host grain, colour coded per the
940 quartz inverse pole figure shown in (b). (d) Pole figure of recrystallized quartz in the intracrystalline
941 bands. The blue and red line indicates the average orientation of the trace of the intracrystalline bands
942 with a subset 1 and 2 orientation, respectively. (e) Boundary trace analysis of the localized extinction
943 band of subset 1. (f) Boundary trace analysis of the localized extinction band of subset 2. (g) Point-to-
944 point misorientation profiles. See (b) for location of the traces of the profiles. (h) Misorientation axis of
945 the host grain and of the recrystallized grains in sample coordinates.

946

947 Fig. 8. EBSD analysis of quartz in the ultramylonite. (a) Microstructure of the recrystallized quartz from
948 domain 3 in the ultramylonite. (b) Pole figure of recrystallized quartz grains from (a). Only grains from
949 recrystallized ribbons in the ultramylonite were analysed.

950

951 Fig.9. a) Brittle failure analysis for our studied sample, see text for assumptions and approximations.
952 For the differential stress range and the vertical stress considered, brittle failure requires
953 (sub)lithostathic fluid pressure ($0.96 < \lambda < 1$) whereas viscous deformation at the estimated depth range
954 (23-30 km) is only possible for pore fluid pressure ≤ 0.94 ; b) Rheological profile calculated for a fixed
955 strain rate of 10^{-12} s^{-2} (see text for calculation details) using the quartz flow law of Hirth et al. (2001).
956 Cycle of switching in deformation style and mechanisms is suggested for the analyzed sample in its
957 ambient depth-range. Frictional Byerlee envelope is calculated using an average friction coefficient of
958 0.7 for various pore fluid pressure ratio values (Fig.9a and text). Stress estimates based on recrystallized
959 quartz piezometry (grey shaded area) have been calculated following Stipp and Tullis, (2003).

960

961

962 Fig.10. a) Simplified view of the ancient subduction of the corsican continental crust, with indication
963 where the mechanical coupling is the highest (seismogenic zone) and lowest (stable slip). The white
964 rectangle corresponds to the inferred zone of the studied sample. The pink to red shading figured the
965 lower to higher blueschist- to eclogite-facies peak metamorphism in continental-derived crustal units;
966 b,c,d Multi-stage scenario for development of the association of granitic protomylonites and
967 ultramylonites from brittle precursors in the Popolasca area: a) General sketch showing the east-dipping
968 ancient alpine subduction of the corsican continental crust. b): Formation of crustal scale anastomosed
969 network of shear zones within the host granitic crust, active distributed deformation with aseismic
970 creep; c: Formation of brittle instabilities (stage 2) in the shear zone by seismic ruptures nucleated along
971 the subduction interface (1) or the core of granites (2) and having propagated across and beyond the
972 granitic mylonites, followed by post-seismic creep, with localization of shear zone after brittle precursor
973 (stage 3); d) Formation of brittle instabilities by seismic tremors and slow-slip events followed by post-
974 seismic (post-tremors) creep.
