Professor Grasemann
Handling Topical Editor, Solid Earth

March 18th 2017

Dear Professor Grasemann

We thank you for reviewing our manuscript and are grateful for your editorial advice that coordinates should be added to our field locations. Coordinates have now been added to Table S2 for all field measuring stations. The localities depicted in Figure 2, 8a, and 8g were not used as field measuring stations, and so their coordinates are given in the figure captions themselves.

In addition, we have made minor revisions to the text to correct typos or where the wording could have been clarified. We thank you for your consideration of our manuscript and we look forward to hearing from you in the near future.

Yours sincerely

Dr Jack Williams

42 **Abstract**

43 Three datasets are used to quantify fracture density, orientation, and fill in the foliated
44 hanging-wall of the Alpine Fault: (1) X-ray computed tomography (CT) images of drill-core
45 collected within 25 m of its principal slip zones (PSZs) during the first phase of the Deep
46 Fault Drilling Project that were reoriented with respect to borehole televiewer images, (2)
47 field measurements from creek sections up to 500 m from the PSZs, and (3) CT images of
48 oriented drill-core collected during the Amethyst Hydro Project at distances of ~0.7-2 km
49 from the PSZs. Results show that within 160 m of the PSZs in foliated cataclasites and

50 ultramylonites, gouge-filled fractures exhibit a wide range of orientations. At these distances,
51 fractures are interpreted to have formed at relatively high confining pressures and/or in rocks
52 that had a weak mechanical anisotropy. Conversely, at distances greater than 160 m from the
53 PSZs, fractures are typically open and subparallel to the mylonitic or schistose foliation,
54 implying that fracturing occurred at low confining pressures and/or in rocks that were
55 mechanically anisotropic. Fracture density is similar across the ~500 m width of the field
56 transects. By combining our datasets with measurements of permeability and seismic velocity
57 around the Alpine Fault, we further develop the hierarchical model for hanging-wall damage
58 structure that was proposed by Townend et al., (2017). The wider zone of foliation-parallel
59 fractures represents an ‘outer damage zone’ that forms in the near-surface. The distinct <160
60 m wide interval of widely oriented gouge-filled fractures constitutes an ‘inner damage zone.’
61 This zone is interpreted to extend towards the base of the seismogenic crust given that its
62 width is comparable to: (1) the Alpine Fault low-velocity zone detected by fault zone guided
63 waves, and (2) damage zones reported from other exhumed large-displacement faults. In
64 summary, a narrow zone of fracturing at the base of the Alpine Fault’s hanging-wall
65 seismogenic crust is anticipated to widen in the near-surface, which is consistent with fault
66 zone flower structure models.

67 **Keywords:** fractures, anisotropy, Alpine Fault, Deep Fault Drilling Project, damage zone

68 **1. Introduction**

69 Conceptual models of fault zone structure in the upper crust often invoke a relatively narrow
70 “fault core” that accommodates most displacement, surrounded by a halo of heavily fractured
71 rock termed the “damage zone” (Caine et al., 1996; Chester et al., 1993; Chester and Logan,
72 1986; Faulkner et al., 2010). These models have been successfully applied in a variety of
73 tectonic settings and for a wide range of fault displacements and exhumation depths (e.g.
74 Choi et al., 2016; Faulkner et al., 2010; Kim et al., 2004; Mitchell and Faulkner, 2009;
75 Savage and Brodsky, 2011). However, the term “damage zone” has been applied by

76 geologists and geophysicists to describe a variety of fault-related features, such as fractures
77 and faults at stepovers and bends (Chester and Chester, 2000; Kim et al., 2004; Mitchell and
78 Faulkner, 2009; Wilson et al., 2003), the volume of inelastic deformation that is induced by
79 dynamic stresses during earthquake rupture propagation (Andrews, 2005; Cowie and Scholz,
80 1992; Rice et al., 2005; Templeton et al., 2008; Vermilye and Scholz, 1998), and the volume
81 of rock in which earthquake swarms or foreshock and aftershock sequences are localised
82 (Kim and Sanderson, 2008; Savage et al., 2017; Sibson, 1989; Yukutake et al., 2011).
83 Furthermore, though damage zones are typically reported to be <1 km wide (Faulkner et al.,
84 2011; Savage and Brodsky, 2011), co-seismic ground shaking can modify fracture
85 permeability many hundreds of kilometres away from the fault source (Cox et al., 2015;
86 Muir-Wood and King, 1993; O'Brien et al., 2016).

87

88 Brittle faults often develop in mylonite sequences or other (e.g. jointed) rocks that contain
89 compositional and mechanical anisotropies (Bistacchi et al., 2012; Chester and Fletcher,
90 1997; Massironi et al., 2011). Evidence from field studies (Bistacchi et al., 2010; Peacock and
91 Sanderson, 1992), experiments (Donath, 1961; Misra et al., 2015; Paterson and Wong, 2005),
92 and numerical modelling (Chester and Fletcher, 1997) demonstrates that such anisotropy can
93 significantly affect the orientation and density of brittle fractures. Despite this, “fault core-
94 damage zone” models are based largely on field observations from relatively isotropic host
95 rocks, and there have been comparatively few field studies (a notable exception being,
96 Bistacchi et al., (2010)) that document the influence of mechanical anisotropy on patterns of
97 brittle fracture damage in large-displacement faults.

98

99 In this contribution, multiple datasets across a range of scales were used to analyse fracture
100 densities, orientations, and mineral fills across the hanging-wall of the Alpine Fault’s central
101 section. Measurements from within 25 m of the Alpine Fault principal slip zones (PSZs) were
102 made from shallow (depths <130 m) drill-cores and wireline logs obtained during the first

103 phase of the Deep Fault Drilling Project (DFDP-1). These are combined with field studies at
104 distances <500 m from the PSZs and analyses of drill-core recovered at 0.7-2 km from the
105 PSZs during the Amethyst Hydro Project (AHP). Results are then compared to measurements
106 of hydraulic conductivity (Cox et al., 2015; Townend et al., 2017) and geophysical studies
107 (Boese et al., 2012; Chamberlain et al., 2017; Eccles et al., 2015) around the Alpine Fault. In
108 doing so, we critically assess the application of “damage zone” models to an active plate-
109 boundary-scale structure. Furthermore, the Alpine Fault rapidly exhumes ductile-to-brittle
110 fault rock sequences from depths of up to 35 km (Little et al., 2005; Norris and Toy, 2014).
111 Fracturing in its hanging-wall therefore overprints a 1-2 km wide mylonite sequence
112 containing a pervasive foliation (Cooper and Norris, 1994; Norris and Cooper, 1997, 2007;
113 Toy, 2008), and so can provide new insights into the relationships between fracturing and
114 mechanical anisotropy.

Deleted: is an active fault that

116 2. Tectonic setting of the Alpine Fault

117 The Alpine Fault is a crustal-scale (along strike extent ~850 km, depth ~35 km) transpressive
118 discontinuity accommodating ~70% of Pacific-Australian plate motion in the South Island of
119 New Zealand (DeMets et al., 1994; Norris and Cooper, 2001, Figure 1a). This study focuses
120 on the central section between the Toharoa and Martyr Rivers (Barth et al., 2013) where it
121 currently accommodates dextral strike-slip at a rate of 27 ± 5 mm/yr and dip-slip at a rate of
122 6-10 mm/yr (Little et al., 2005; Norris and Cooper, 2001).

123

124 In the central section at depths greater than 8-12 km, the Alpine Fault accommodates motion
125 via viscous creep across a >1 km wide ductile shear zone in which the hanging-wall “Alpine
126 Schist” protolith is progressively mylonitised (Norris and Cooper, 2007; Toy et al., 2010).
127 Shear strains increase with proximity to the Alpine Fault and are recorded by protomylonites,

129 mylonites and ultramylonites, which occur in spatial sequence towards the fault (Figure 2;
130 Norris and Cooper, 2003; Reed, 1964; Toy et al., 2008). Foliation in the mylonite sequence is
131 mainly defined by alternating quartzofeldspathic and mica-rich layers (Figure 2). Bottle-green
132 hornblende-rich metabasic mylonites, and purple-dark grey mylonites that are comparatively
133 mica rich are also present. Their presence reflects variations in protolith lithology (Cooper
134 and Norris, 2011; Norris and Cooper, 2007; Sibson et al., 1981; Toy, 2008). As the mylonites
135 in the hanging-wall are exhumed to depths of less than 8-12 km, temperatures drop below
136 those at which quartz plasticity occurs and brittle structures start to overprint the mylonitic
137 shear zone (Norris and Cooper, 2007; Toy et al., 2010, 2015). This brittle overprint is
138 reflected in the formation of a ~20 m thick layer of green, indurated and often foliated
139 cataclasite (Allen et al., 2017; Toy et al., 2015), and a 10-50 cm thick clay-rich PSZ that is
140 preserved adjacent to the currently-active fault trace (Boulton et al., 2017, 2012; Ikari et al.,
141 2014; Mitchell and Toy, 2014).

142

143 To the first-order (i.e. at scales >10 km), the trace of the Alpine Fault is remarkably linear,
144 with an average strike of 055° (Norris and Cooper, 2007). On the basis of geophysical
145 imaging and measurements of the mylonitic foliation -which is thought to parallel the fault- it
146 is estimated to dip at ~45° in its central section (Sibson et al., 1981; Stern et al., 2007), though
147 this may locally exceed 60° (Little et al., 2005; Toy et al., 2017). At scales of 1-10 km,
148 perturbations in the stress field induced by hanging-wall topography results in segmentation
149 of the Alpine Fault. Segmentation is rooted to depths of 0.5-4 km and comprises km-long,
150 approximately E-W striking and steeply-dipping strike-slip fault strands, which adjoin NE-
151 SW striking, gently-dipping (~30°) thrust segments (Barth et al., 2012; Langridge et al., 2014;
152 Norris and Cooper, 1995, 2007; Simpson et al., 1994; Upton et al., 2017).

154 **3. Methods**

155 3.1 Fracture orientations from DFDP-1 drill-core

156 Hanging-wall fracture orientations immediately adjacent to the Alpine Fault's PSZ were
157 assessed through analysis of datasets arising from the first phase of the Deep Fault Drilling
158 Project (DFDP-1, <http://alpine.icdp-online.org>). DFDP-1 successfully sampled the Alpine
159 Fault in two boreholes (DFDP-1A and DFDP-1B, Figure 3) at depths of less than 150 m at
160 Gaunt Creek (Figure 1b, Sutherland et al., 2012). The geophysical properties of the DFDP-1
161 boreholes were characterised by a full suite of wireline logs (Townend et al., 2013). These
162 were combined with visual descriptions of ~70 m of core recovered across the two boreholes
163 to construct a lithological classification scheme for DFDP-1 drill-core (Figure 3, Toy et al.,
164 2015).

165

166 Abundant fractures were observed in X-ray computed tomography (CT) scans of DFDP-1
167 drill-core (Williams et al., 2016). The true orientations of these fracture were obtained by
168 generating 'unrolled' CT images of individual core sections (Mills and Williams, 2017),
169 which are directly analogous to geographically referenced - but lower resolution - borehole
170 televiewer (BHTV) images. Where fractures could be matched between the two images, a
171 rotation could be derived to transform all fracture orientations in the CT scans from a local
172 core reference frame to their true geographic orientation (Figure 4). Depending on the number
173 of fractures matched, core was rotated with a high, moderate, or low degree of confidence. In
174 DFDP-1A, the quality of BHTV imaging was insufficient to attempt matching fractures,
175 whereas in the Alpine Fault's relatively intact footwall (Townend et al., 2013), too few
176 fractures (<1 fracture/core-section) could be imaged to attempt core reorientation. Therefore,
177 the true orientation of fractures was only determined for the depth interval 94-126 m in the
178 DFDP-1B borehole (Figure 3). Given the orientation of the PSZ-1 (which separates hanging-
179 wall and footwall cataclasite) sampled in DFDP-1 (015/43 E; Townend et al., 2013), this

180 spans an orthogonal distance of ~25 m. A full methodology is provided in Appendix A, the
181 rotations applied to DFDP-1 core sections are listed in Table S1, and a complete CT-BHTV
182 image comparison is given in Williams et al. (2017b).

183

184 3.2 Field observations of fracture orientations and densities

185 At orthogonal distances of up to 150-250 m from the PSZs, fracture orientations and densities
186 were measured in four creeks (Gaunt Creek, Stony Creek, Hare Mare Creek and Havelock
187 Creek, Figure 1b) that cut across the hanging-wall sequence approximately perpendicular to
188 the main fault trace (Figure S1). Along each creek, fracture orientations and densities were
189 measured at 3 or 4 stations. This information was also gathered from approximately 500 m
190 from the Alpine Fault at Bullock Creek (Figure 1b). Each creek transect cuts across a thrust
191 segment of the Alpine Fault, so the orthogonal distance between the measuring stations and
192 the PSZs was calculated assuming a fault dip of 30° (Norris and Cooper, 1995, 1997). The
193 mylonite lithology for each station was classified using the scheme presented by Toy (2008).

194

195 The outcrops encountered along these transects are typically sub-vertical and may be covered
196 by debris except at their bases where they are frequently cleaned by flood events (Figure S2).
197 They are therefore poorly-suited for fracture density analysis using circular scanlines (e.g.
198 Mauldon et al., 2001). Instead, the fracture density was calculated from the number and
199 orientation of fractures that intersected a linear transect along the base of each outcrop (Priest,
200 1993; Schulz and Evans, 2000). This technique has the tendency to under-sample fractures
201 oriented at low angles to the scan-line. Therefore, a weighting (w) factor calculated using a
202 modified version of the Terzaghi correction (Massiot et al., 2015; Terzaghi, 1965) was
203 applied to each fracture, and results are shown as 'corrected' fracture density.

204

205 3.3 Fracture orientations in the Amethyst Hydro Project boreholes

206 The Amethyst Hydro Project (AHP) was developed to divert water from the Amethyst Ravine
207 down a 1040 m-long tunnel to a powerhouse on the floodplain of the Wanganui River. Prior
208 to the main phase of tunnelling, four exploratory boreholes (BH1-4; Figure 1b and S3) were
209 completed between 2005-2006, resulting in the recovery of ~890 m of drill-core at depths of
210 50-200 m. The boreholes are situated 1-2 km southeast of a thrust segment of the Alpine
211 Fault, where it may conceivably dip at a range of 30-60° (Norris and Cooper, 1995; Toy et al.,
212 2017). The drill-cores are therefore at orthogonal distances of ~0.7-2.0 km from the PSZs.

213

214 To provide a dataset analogous to the DFDP-1 CT scans, a total of 31.9 m of drill-core from
215 the AHP boreholes was CT scanned at the Southern Cross Hospital in Wellington, New
216 Zealand. Initial descriptions of the drill-core found that the Rock Quality Designation (RQD,
217 the % of intact core lengths >100 mm/1 m of drill-core) varied considerably due to intense
218 fracturing adjacent to the Tarpot Fault and other minor faults that intersect the AHP boreholes
219 (Geotech Consulting Limited, 2006; Savage, 2013). However, for practical reasons scanning
220 was focussed on intervals of high RQD (Figure S3). The CT scanner was operated at 100 mA
221 and an X-ray tube voltage of 120 kVp. Slice spacing was 1.25 mm, field of view 250 mm, and
222 the image size was 512 x 512 pixels. Therefore, the size of one voxel is 0.488 x 0.488 x 1.25
223 mm in the x, y, z directions respectively. Reconstruction of two-dimensional CT slices into
224 three-dimensional images of the drill-core was performed using OsiriX Imaging Software
225 (<http://www.osirix-viewer.com/>).

226

227 AHP drill-core was not oriented. However, the orientation of the schistosity is noted in the
228 drill-core logs to an accuracy of $\pm 5^\circ$ (Geotech Consulting Limited, 2006), where it is
229 consistent with the schistosity orientation measured in the Amethyst Tunnel itself (Savage,
230 2013). It can thus be used as a reference to reorient drill-core CT scans back into a geographic

231 reference frame. For BH2 and BH3 drill-cores, which are vertical, this required only a single
232 transformation. For the inclined BH1 and BH4 drill-cores, this required first rotating the core
233 with respect to the foliation. These orientations were then corrected for the inclination of the
234 drill core using the Planes from Oriented and Navigated Drillcore (POND) Excel spreadsheet
235 (Stanley and Hooper, 2003).

236 3.4 Statistical analysis of fracture orientations

237 The clustering intensity of fracture orientations was quantified using the resultant vector
238 method of Priest, (1993), where the vector for each fracture was weighted by the Terzaghi
239 correction for misorientation bias (Massiot et al., 2015; Terzaghi, 1965). This analysis was
240 performed only for the DFDP-1 and AHP datasets, which sampled a large population (>100)
241 of fractures. Field measuring stations sampled too few (<30) fractures to reliably perform this
242 analysis, and so their clustering is described in a qualitative sense only.

243 4. Results

244 4.1 Fracture orientations in DFDP-1 drill-core within 25 m of the Alpine Fault

245 In the DFDP-1 CT images, a total of 637 fractures were rotated into their true geographic
246 orientation where they show a weak cluster about the orientation of the foliation and Alpine
247 Fault PSZs at Gaunt Creek (015/43 E, Figures 5a, Appendix B; Townend et al., 2013).
248 Features in DFDP-1B BHTV images are also aligned about this orientation, but with a higher
249 cluster intensity than fractures noted in the CT images (Figure 5b, Table 1). This may reflect:
250 (1) features observed at the resolution of the BHTV are more likely to be aligned subparallel
251 to the fault plane and foliation than those visible in CT, and/or (2) some of the planar features
252 identified from the BHTV images were the mylonitic foliation itself. The clustering of
253 fractures hosted in foliated ultramylonites and cataclasites (Units 1, 2 and 4 of Toy et al.,
254 2015) is the same as fractures hosted in relatively homogenous unfoliated cataclasites (Unit 3

255 of Toy et al., 2015; Figures 5c and d, Table 1). We also observed no clear relationships
256 between fracture fill (Table 1 of Williams et al., 2016) and fracture orientation (Figure 5a).

257

258 4.2 Fracture orientations, densities, and fill in field transects within 500 m of the Alpine Fault

259 The orientations and densities of fractures observed in the four field transects are summarised
260 in Figure 7. In these transects, similar fractures to those observed in the CT scans of DFDP-1
261 core are identified (Figure 8). Total fracture density in the transects varies between 3-30
262 fractures/metre, and there is no clear decrease in fracture density with increasing distance
263 from the Alpine Fault in any of the transects (Figure 7a). Gouge-filled fractures (Figure 8a-c)
264 are observed at all distances from the Alpine Fault but are relatively abundant (>1
265 fracture/metre, Figure 7a, Table S2) within 100-160 m of the PSZs (Figure 7a). The thicker
266 gouge-filled fractures (>1 cm) commonly juxtapose different lithologies or offset markers
267 (Figure 8d-f). Thinner gouge-filled fractures (<1 cm) are localised to within 160 m of the
268 Alpine Fault. Open fractures (Figure 8g-i) are present at all stations, though are most
269 prevalent at those furthest from the fault (Figure 7b).

270

271 The composition of the mylonites can also affect fracture density. When they are juxtaposed
272 together, micaceous mylonites and ultramylonites are observed to contain relatively high
273 densities of gouge-filled fractures compared to quartzofeldspathic mylonites and
274 ultramylonites (Figures 9). Localities that showed the widest range in fracture orientations
275 tend to be less than 160 m from the PSZs within the ultramylonites (Figure 7b). Within
276 mylonite units, fracture orientations tend to be more aligned to the foliation (Figure 7b),
277 although gouge-filled fractures can sometimes cut across it (e.g. Bullock Creek).

278

279 4.3 Fractures in AHP drill-core, 0.7-2.0 km from the Alpine Fault

280 The AHP sampled grey, well-foliated Alpine Schist (Figure 10), a subgroup of the Haast
281 Schist (textural zone III-IV, Turnbull et al., (2001); Cox and Barrell., (2007)). Fracture
282 orientations are clustered about the orientation of the host rock schistosity in agreement with
283 the findings during initial drill-core descriptions and observations within the Amethyst
284 Tunnel itself (Figure 11; Geotech Consulting Limited, 2006; Savage, 2013). The clustering of
285 these fracture orientations is stronger than in the DFDP-1 datasets (Table 1). Fractures that
286 cut across the schistosity are most frequent in BH4 (Figure 10d and 11).

287

288 Though fractures are predominantly open, it is conceivable that the original fill may have
289 been lost during the subsequent core handling processes. This means that standard schemes to
290 differentiate between natural and induced fractures (Kulander et al., 1990; Williams et al.,
291 2016) cannot be applied to this dataset. Nevertheless, some open fractures must be natural as
292 they show alteration haloes (Figure 10a) implying that they were once conduits for fluid-flow.
293 Furthermore, packer tests conducted in these boreholes indicate hydraulic conductivities of
294 $\sim 10^{-6}$ - 10^{-5} ms^{-1} , which is equivalent to permeabilities of 10^{-13} - 10^{-12} m^2 (Cox et al., 2015;
295 Geotech Consulting Limited, 2006). No permeability measurements have been made in the
296 schist protolith at greater distances from Alpine Fault, however, these measurements are
297 orders of magnitude higher than has been reported in other metamorphic rock terranes ($\sim 10^{-20}$ -
298 10^{-17} m^2 ; Manning and Ingebritsen, 1999) and for typical continental crust ($\sim 10^{-17}$ m^2 ;
299 Townend and Zoback, 2000).

300 **5 Discussion**

301 5.1 Fracture orientations in anisotropic wall rocks in the Alpine Fault hanging-wall

302 Two styles of fracturing are evident in the foliated Alpine Fault cataclasite, mylonite and
303 schist sequence (Figure 12). Within DFDP-1 drill-core, fractures are predominantly gouge-

304 filled and exhibit a range of orientations (Figure 5 and 6) with only a small proportion (11%)
305 of fractures in foliated cataclasites and ultramylonites clearly foliation-parallel (Williams et
306 al., 2016). However, in schists sampled by the AHP drill-core, the fractures are more
307 clustered about the foliation than in DFDP-1 drill-core (Figure 11, Table 1). The difference in
308 fracture clustering between the DFDP-1 and AHP drill-cores is qualitatively replicated by the
309 field transects, where fractures show variable orientations immediately adjacent to the Alpine
310 Fault but are typically foliation-parallel at the sites furthest from the fault (Figure 7).
311 Furthermore, field transects show that the variably oriented fractures have a gouge-fill, whilst
312 foliation-parallel fractures further from the fault tend to be open (Figures 7 and 8).

313

314 Experimental studies on foliated rocks demonstrate that mechanical anisotropy will exert the
315 greatest control on rock failure when: (1) the angle between the maximum principal stress
316 (σ_1) and the anisotropy (α) is $\sim 30^\circ$, (2) confining pressure is low (< 35 MPa), and (3) the
317 mechanical ‘strength’ of the anisotropy is high (Donath, 1961; Misra et al., 2015; Nasser et
318 al., 2003; Paterson and Wong, 2005). The first factor can be approximated for the Alpine
319 Fault given the mylonite’s average orientation of 055/45SE (Norris and Cooper, 2007) and
320 the stress tensor orientation within the surrounding crust, determined from focal mechanisms
321 of microseismicity in the fault’s hanging-wall (Boese et al., 2012). This yields a value of α of
322 approximately 44° , when measured in the plane containing the maximum and minimum
323 principal stresses. This can be considered an intermediate value of α , since in deformation
324 experiments fractures may form parallel or non-parallel to the foliation depending on the
325 combination of confining pressure and lithology (Donath, 1961; Nasser et al., 2003; Paterson
326 and Wong, 2005).

327

328 Foliation-parallel fractures are least common in the ultramylonites and foliated cataclasites.
329 Indeed, in the DFDP-1 datasets, there is no difference in fracture clustering between foliated
330 and unfoliated units (Table 1). Lithology may control mechanical anisotropy depending on

331 mineralogy, porosity, grain size, and the nature of the foliation surfaces (Donath, 1961;
332 Nasser et al., 2003). It is notable that phase mixing and grain size reduction in the
333 ultramylonites reduces the intensity of the foliation, compared to the relatively coarse-grained
334 schists, protomylonites, and mylonites (Figure 2; Norris and Cooper, 2007; Toy et al., 2010,
335 2008). These data suggest that this lithological change could have a marked effect on the
336 orientation of fractures. Compositional variations between relatively quartzofeldspathic and
337 relatively micaceous mylonites can also influence the density of fractures (Figure 9). These
338 observations highlight that fracturing in the upper crust may be influenced by lithological
339 variations developed within an underlying linked, and synkinematic, shear zone. However, at
340 other localities (e.g. Stony Creek, Figure 7), variations in dominant fracture characteristics are
341 confined within units of similar composition and texture. This suggests that variations in
342 confining pressure may also be important in controlling the relationship between fractures and
343 foliation, as discussed in the next section.

344

345 5.2 Fracture damage around the Alpine Fault

346 Field transects across the Alpine Fault's hanging-wall show that fracture density remains
347 roughly constant (>3.5 fractures/m, corrected for orientation bias) for at least 500 m from the
348 fault (Figure 7a). Furthermore, the AHP (Cox et al., 2015) and DFDP-2B boreholes
349 (Sutherland et al., 2017; Townend et al., 2017) demonstrate an interval of enhanced
350 permeability (10^{-16} - 10^{-13} m²) that extends for at least 2 km into the Alpine Fault's hanging-
351 wall. Permeability in this rock mass is controlled by open fractures (Cox et al., 2015;
352 Sutherland et al., 2017; Townend et al., 2017) that are generally foliation-parallel (Massiot,
353 2017), and so directly analogous to the fractures sampled in the field (Figure 8g-i) and in
354 AHP drill-core (Figure 10). Conventional definitions of fault structure, that use fracture
355 density and permeability as criteria for damage zone width (e.g. Berg and Skar, 2005; Caine
356 et al., 1996; Faulkner et al., 2010; Savage and Brodsky, 2011; Schulz and Evans, 2000),

357 would therefore suggest that the Alpine Fault's damage zone extends for at least 500 m, and
358 possibly 2 km, into its hanging-wall.

359

360 Nevertheless, within the field transects we also note a distinct interval adjacent to the Alpine
361 Fault's PSZs that contains a relatively high density of gouge-filled fractures (>1
362 fracture/metre, Figure 7a). The width of this interval is <147 m (i.e. station 4) from the PSZs
363 at Gaunt Creek, <103 m at Stony Creek (i.e. station 3), <151 m at Hare Mare Creek (at station
364 2, Figure 8c) and <160 m at Havelock Creek (i.e. stations 4). These width estimates are based
365 on assumption that the Alpine Fault dips at 30° below the measuring stations (see the methods
366 section). However, the fault dip may locally vary (for example, the fault dip sampled by
367 DFDP-1 was 43°; Townend et al., (2013)), and there is also uncertainty in the depth extent of
368 its near-surface segmentation (Barth et al., 2012; Norris and Cooper, 1995; Upton et al.,
369 2017). Nevertheless, even if the fault dipped at 45° (Norris and Cooper, 2007) beneath the
370 measuring stations, the zone of higher-density gouge-filled fractures would be <205 m wide
371 (Table S3) and so is still appreciably closer to the Alpine Fault than the intervals sampled by
372 the AHP and DFDP-2 boreholes.

373

374 It is this ~100-160 m wide interval with a high density of gouge-filled fractures that Norris
375 and Cooper (1997, 2007) interpreted as the extent Alpine Fault's central section hanging-wall
376 damage zone. Furthermore, the width of this zone is comparable to damage zones widths
377 estimated elsewhere on the Alpine Fault (e.g. Barth et al., 2013 along the southern section;
378 Wright, 1998 at the northern end of the the central section, Figure 13a) and to other crustal-
379 scale fault zones that have accommodated hundreds of kilometres of displacement (Figure
380 13b; Faulkner et al., 2011; Savage and Brodsky, 2011).

381

382 Interpretations of damage zone width within the Alpine Fault's hanging-wall may therefore
383 differ by an order of magnitude depending on what criteria is used. To reconcile this,
384 Townend et al., (2017) suggested that the ~2 km wide interval of enhanced permeability and
385 foliation-parallel fracturing can be considered as an 'outer damage zone' (Figure 12).
386 Fractures within this zone may have formed by co-seismic shaking and slip on critically-
387 stressed fractures (Cox et al., 2015; Townend et al., 2017), or by the release of confining
388 pressure (Engelder, 1985; Price, 1959; Zangerl et al., 2006) during rapid exhumation (6-9
389 mm/yr) of the hanging-wall (Little et al., 2005; Tippet and Kamp, 1995). Rare gouge-filled
390 fractures (<1 fracture/metre) in this interval (e.g. Figure 8e) may also be the structures
391 accommodating the diffuse, low to moderate magnitude ($M_w < 6$) seismicity that has been
392 recorded in a ~5 km wide zone within the Alpine Fault's hanging-wall (Boese et al., 2012;
393 Chamberlain et al., 2017; Eberhart-Phillips, 1995).

394

395 Conversely, the <160 m wide zone with a relatively high density of gouge-filled fractures
396 defines a narrower 'inner damage zone' (Figure 12; Townend et al. 2017). Microstructural
397 and compositional analysis of these fractures indicates that they formed in response to wear
398 and shearing of the wall rock and were subsequently mineralised due to circulation of
399 hydrothermal fluids (Warr and Cox, 2001; Williams et al., 2017a). Offset markers across
400 gouge-filled fractures (particularly those <1 cm thick) are rarely observed in DFDP-1 core
401 and field transects, but where they are present, reverse offset is most frequently noted (Figure
402 8d; Norris and Cooper, 1997; Toy et al., 2015). "Gouge-filled shears" that accommodated
403 strike-slip (Norris and Cooper, 1997), normal dip-slip (Cooper and Norris, 1994), or a
404 combination of both (Barth et al., 2012) have also been observed.

405

406 Cooper and Norris, (1994) interpreted that dip-slip fractures facilitated imbrication, tectonic
407 thickening and rotation of Alpine Fault thrust sheets as they moved across the irregular
408 topography of the footwall gravels. Dextral shears are interpreted to reflect the partitioning of

409 strike-slip movement away from shallowly dipping PSZs (Barth et al., 2012). The diverse
410 range of fracture orientations and shear senses in gouge-filled fractures therefore indicates
411 complex internal deformation of Alpine Fault thrust sheets in the near-surface (<500 m), as
412 they facilitate transpressional motion under the influence of km scale along-strike variations
413 in stress induced by the topography (Norris and Cooper, 1995; Upton et al., 2017).

414

415 Fractures may have also formed due to dynamic off-fault stresses (Ma, 2009; Rice et al.,
416 2005) during $M_w > 7.5$ Alpine Fault earthquake ruptures (Sutherland et al., 2007). The
417 relatively thin seismogenic crust in the Alpine Fault's hanging-wall (10 ± 2 km, Boese et al.,
418 (2012)) will limit the generation of dynamic co-seismic damage to within ~100-200 m of the
419 fault (Ampuero and Mao, 2017). To the first order, this is comparable to the width of the
420 inner damage zone reported here.

421

422 5.3 Comparison to geophysical data

423 A 60-200 m wide low-velocity zone (LVZ) that extends to depths of ~8 km has been
424 documented around the Alpine Fault from the detection and character of Fault Zone Guided
425 Waves (FZGWs; Eccles et al., 2015). FZGWs are commonly regarded as an *in situ* indicator
426 of fault damage zone width (Ben-Zion and Sammis, 2003; Eberhart-Phillips et al., 1995;
427 Ellsworth and Malin, 2011; Li et al., 2014). Given the comparable widths of the Alpine Fault
428 LVZ (60-200 m) and the inner damage zone described here (100-160 m), we speculate that
429 the inner damage zone may trap FZGWs in the Alpine Fault hanging-wall. If this is true, it
430 implies that the inner damage zone extends to depths of ~8 km, consistent with the relatively
431 high-temperature (<400 °C) mineralising phases (calcite and chlorite) present in the gouge-
432 filled fractures (Williams et al., 2017a).

433

434 Though the boundary between the mylonites and ultramylonites is also ~100 m from the
435 Alpine Fault (Norris and Cooper, 2003; Toy et al., 2008), these two units have roughly
436 similar seismic velocities (Adam et al., 2016; Allen et al., 2017; Christensen and Okaya,
437 2007) and so are unlikely to channel FZGWs. We also note that since FZGWs are an
438 indicator of total fault zone width, our interpretation implies that most of the Alpine Fault's
439 LVZ is located in its hanging-wall. Western Province basement rocks to the west of the
440 Alpine Fault are rarely exposed (Lund Snee et al., 2014; Norris and Cooper, 2007), and so it
441 remains unknown if its footwall damage zone is indeed relatively narrow.

442 .

443 That the FZGWs are not being channelled by the margins of the ~2 km wide outer damage
444 zone leads us to conclude that this is a near-surface feature only (i.e. fractures are not kept
445 open at depth by pressurised fluids). If correct, this model of the Alpine Fault's hanging-wall
446 structure conforms to the expectations of fault zone flower structure models, which predict a
447 narrow inner damage zone that extends through the seismogenic crust, surrounded by a wider
448 zone of fractures in the near-surface at low confining pressures (~<3 km, Figure 12; e.g. Finzi
449 et al., 2009; Sylvester, 1988).

450

451 **6. Conclusions**

452 Fracture orientations and densities in the foliated hanging-wall of the Alpine Fault's central
453 section were quantified in drill-core from the Deep Fault Drilling Project (DFDP-1), field
454 transects in four creek sections, and drill-core recovered from the Amethyst Hydro Project. At
455 distances greater than approximately 160 m from the Alpine Fault principal slip zones (PSZs),
456 open and foliation-parallel fractures dominate. These are interpreted to form at low confining
457 pressures in mechanically anisotropic schist and mylonites. At distances less than ~160 m
458 from the PSZs, gouge-filled fractures with a wide range of orientations predominate. Fracture
459 density and orientation are locally influenced by changes in host rock lithology, but overall

460 fracture density is approximately constant at distances of up to ~500 m from the PSZs (Figure
461 12).

462

463 Following Townend et al., (2017), we interpret that the ~2 km wide zone of open foliation-
464 parallel fractures within the hanging-wall represents an “outer damage zone” that forms at
465 low confining pressures and relatively shallow depths. Conversely, the 160 m-wide zone of
466 gouge-filled fractures represents an “inner damage zone.” The width of this zone is similar to
467 estimates for the low-velocity zone (LVZ) around the Alpine Fault made by Fault Zone
468 Guided Waves. We therefore interpret that the inner damage zone is the geological
469 manifestation of the LVZ, which if true, implies that the inner damage zone also extends to
470 depths of ~8 km. Overall, our interpretations are compatible with a flower structure model for
471 damage in the Alpine Fault’s hanging-wall, with a relatively narrow zone of damage
472 extending towards the base of the seismogenic crust, which broadens upwards towards the
473 surface.

474 **Code availability**

475 The code to generate ‘unrolled’ circumferential CT images is available from the GFZ data
476 service ([http://pmd-
477 potsdam.de/panmetaworks/review/7f1b114f11b67f540bb1360ead692dc578a66e3d0935c7fef
478 6ffe210db285300-icdp/](http://pmd.gfz-potsdam.de/panmetaworks/review/7f1b114f11b67f540bb1360ead692dc578a66e3d0935c7fef6ffe210db285300-icdp/)).

479 **Data availability**

480 In the supplementary information, we include detailed field maps and cross sections (Figure
481 S1), photos of outcrops used for quantifying fracture density (Figure S2), a cross section
482 through the Amethyst Tunnel and location of boreholes (Figure S3), and an example of AHP
483 CT scans (Figure S4). The following tables are also provided, a list of rotations applied to
484 DFDP-1B core (Table S1), a summary of field transects [including coordinates of the field](#)

485 [measuring stations](#) (Table S2), and estimates of the distance of field measuring stations from
486 the Alpine Fault for different fault dips (Table S3). Lithological distribution and Alpine Fault
487 location as per University of Otago fault zone mapping program, which is available at:
488 <http://www.otago.ac.nz/geology/research/structural-geology/alpine-fault/af-maps.html>.
489 DFDP-1 and AHP CT scan 'core logs' and CT-BHTV image comparison are available on the
490 GFZ data service ([http://pmd.gfz-](http://pmd.gfz-potsdam.de/panmetaworks/review/52b75045a30f1bd60f7fd5b841e69c468885e2a10dfc3704e50b236df2ef8608-icdp)
491 [potsdam.de/panmetaworks/review/52b75045a30f1bd60f7fd5b841e69c468885e2a10dfc3704e](http://pmd.gfz-potsdam.de/panmetaworks/review/52b75045a30f1bd60f7fd5b841e69c468885e2a10dfc3704e50b236df2ef8608-icdp)

494 **Acknowledgements**

495 DFDP-1 was funded by: GNS Science; Victoria University of Wellington; the University of
496 Otago; the University of Auckland; the University of Canterbury; Deutsche
497 Forschungsgemeinschaft and the University of Bremen; Natural Environment Research
498 Council grants NE/J024449/1, NE/ G524160/1 and NE/H012486/1 and the University of
499 Liverpool; and the Marsden Fund of the Royal Society of New Zealand. The International
500 Continental Scientific Drilling Program, ICDP (www.icdp-online.org) provided extensive
501 support. JW was supported by a University of Otago Doctoral Scholarship. We thank
502 Matthew Parris at the Oncology Department at Dunedin Hospital, and Darren Tod at the
503 Southern Cross Hospital, Wellington, for support in collecting CT scans of DFDP-1 Amethyst
504 Hydro Project drill-core respectively. Katrina Sauer, Ben Melosh and Astrid Vetrhus
505 provided field assistance. Comments by Tim Little and Tom Blenkinsop, and by two
506 anonymous reviewers on an earlier version of this manuscript, improved this paper.

507 **Appendix A: DFDP-1B core rotation methodology**

508 The technique employed to reorient core DFDP-1 here is similar to that described in Jarrard et
509 al., (2001), Paulsen et al., (2002) and Shigematsu et al., (2014), however, instead of

510 comparing DFDP-1 BHTV data to DMT CoreScan system® unrolled core scans, we compare
511 BTHV images to ‘unrolled’ CT core images. The acquisition and interpretation of the DFDP-
512 1 BHTV logs has been previously described by Townend et al., (2013) and McNamara,
513 (2015). DFDP-1 CT scans consist of a stack of core-axial perpendicular image slices with a
514 pixel size of 0.244 mm and a spacing of 1 mm. The CT stack for each core section was loaded
515 into Fiji (<http://fiji.sc/Fiji>) and a circle was manually defined around the irregular boundary of
516 drill-core in a core axial-perpendicular image slice using the code available at Mills and
517 Williams, (2017). This circle was then used to define the path of the image in all other slices.
518 Generation of the unrolled images accounts for the fact that the spacing between individual
519 CT slices (1 mm, i.e. the core-axial parallel pixel size) is greater than the pixel size within the
520 slices (0.244 mm). Unrolled images were then reflected around the borehole axis as an image
521 of the outer surface of the core and a BHTV image are reflections of each other. This
522 technique has benefits over methods using the DMT CoreScan system®, since drill-core does
523 not have to be physically rotated and so can be used without the risk of damaging fragile core
524 sections.

525

526 Unrolled CT images were imported into the composite log viewing software WellCAD®
527 (<http://www.alt.lu/wellcad.htm>) along with the BHTV images, where they are placed side-by-
528 side to allow matching of structures (Figure 4, see also Williams et al., (2017b)). When
529 correlating the two datasets, it was first necessary to account for possible depth shifts between
530 recorded drill-core depths and BHTV imagery due to factors such as stretching of the logging
531 cable and intervals from which no drill-core was recovered (Haggas et al., 2001; Jarrard et al.,
532 2001). In this study, a depth shift of no more than ±30 cm was allowed.

533

534 The orientation of fractures in the DFDP-1 CT images had previously been measured within a
535 local core reference frame (see Figure 4 in Williams et al., 2016). Since the DFDP-1
536 boreholes were vertical, corrections to reorient the drill-core back into a geographic reference

537 frame required only a single rotation about the core axis to correct for the dip direction. When
538 correlating structures, errors may be introduced by: (1) the internal BHTV magnetometer
539 ($\pm 2^\circ$), (2) the manual picking of sinusoidal curves on BHTV and unrolled CT images that can
540 be $\pm 10^\circ$ for shallowly dipping ($< 30^\circ$) structures (Jarrard et al., 2001), and (3) the fact that the
541 DFDP-1B BHTV data imaged the open borehole, which has a larger diameter (127 mm) than
542 the drill-core (85 mm). To mitigate against the cumulative effect of these errors, Jarrard et al.,
543 (2001) stitched unrolled images of many different core sections together that spanned
544 intervals of 5-30 m, prior to the matching with BHTV imagery. This meant that only a single
545 rotation was necessary for all core sections across the entire stitched interval, which could be
546 based on identifying ~ 20 -30 matching structures between the BHTV and unrolled core
547 images.

548

549 In DFDP-1 it was not possible to stitch unrolled CT images of core section together as no
550 prominent reference marker across different sections were identified. Consequently each < 1
551 m long core section had to be reoriented individually, within which we never identified more
552 than 3 matching structures. Therefore, compared to the methodology described by Jarrard et
553 al., (2001), the degree of confidence on the applied reorientation was strongly dependent on
554 the quality of individual matches for each core section and the range of rotations that they
555 indicated. We recorded this qualitatively for each core section using the scheme outlined
556 below.

557

558 • High degree of confidence: images matched with one very prominent structure (e.g.

559 [Figure 4d](#)), or matched with two or more structures whose range of suggested

560 rotations are within 10° of each other ([Figure 4b](#) and [c](#)).

561

Deleted: Figure 4

Deleted: Figure 4

Deleted: Figure 4

564 • Moderate degree of confidence: images matched with one prominent feature or two
565 features that indicate rotations that range 10-19° (e.g. [Figure 4a](#)) or three features
566 whose range of suggested rotations are within 20-30° of each other.

567

568 • Low degree of confidence: images matched with one feature or two features whose
569 range of suggested rotations are within 20-30° of each other.

570

571 In this scheme, a core reorientation is deemed unreliable if the range of rotations suggested by
572 different structures is $\geq 30^\circ$, i.e. equivalent to the cumulative effect of possible errors listed
573 above. For those core sections where more than one matching structure was identified, the
574 rotation that was applied was derived from the average of that required for each match. If one
575 of the matched structures was more prominent, then the applied rotation was biased towards
576 that structure.

577

578 **Appendix B: DFDP-1B core rotation validity**

579 Based on the criteria presented in Appendix A, of the 40 core sections from DFDP-1B in
580 which there was suitable quality of unrolled CT and BHTV images to attempt reorientation
581 (Figure 3), 31 were reoriented (Table S1). Prior to reorientation, fractures in these sections
582 exhibit no clustering (Figure A1a), however, a weak one does develop after reorientation
583 (Figure 5a). Since fractures in nature typically exhibit non-random orientations, this is
584 evidence that the reorientation of the CT scans was successful (Kulander et al., 1990; Paulsen
585 et al., 2002). In addition, fractures within some individual core sections (Figure A1b), and
586 fractures rotated based on a high degree of confidence (Figure A1c) contain a wide range of
587 orientations.

588

590 The recognition of fractures in unrolled CT images that are not observed in BHTV can be
591 readily explained by the higher resolution of the CT images. However, structures are also
592 observed in the BHTV logs, but not interpreted as fractures in the CT images (Figure 4). This
593 may represent noise in the BHTV images, or in the case of foliation-parallel structures, the
594 ultramylonitic foliation itself since it can be difficult to differentiate these structures. The
595 subordinate north-dipping set of fractures in the BHTV images (Figure 5b) is not recognised
596 in the orientations gathered from CT images (Figure 5a). A similar north dipping fracture set
597 was also recognised in DFDP-2B BHTV images (Massiot 2017), and their causation and
598 relevance is the focus of ongoing work.

944

945 List of Figures

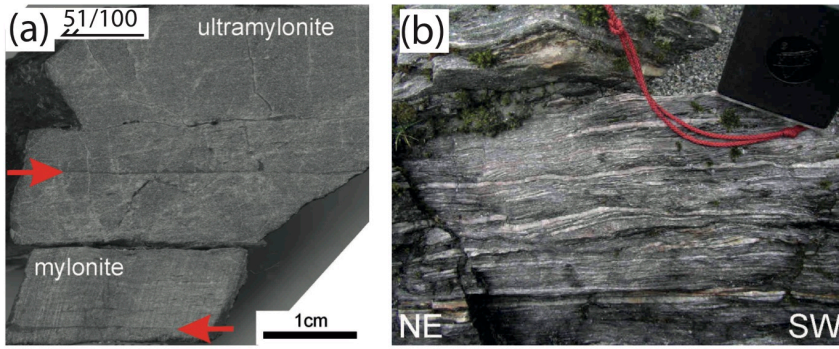

946 Figure 1

947

948 Figure 1: (a) Location map for Alpine Fault (red line) and Marlborough Faults (black line) in the
949 South Island of New Zealand. Box shows extent of (b), a location map for the DFDP-1 and AHP
950 boreholes, and field transects. The generalised underlying geology is derived from the GNS Science
951 1:250000 QMAP project (Rattenbury and Isaac, 2012) and has been draped over a digital elevation
952 model (Columbus et al., 2011).

953

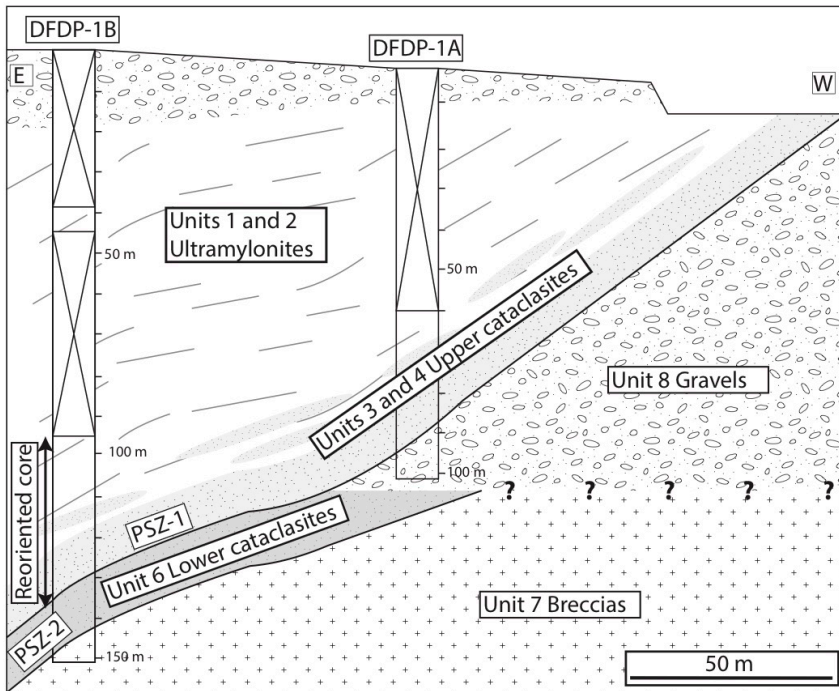

955

956 Figure 2: (a) Quartzofeldspathic Alpine Fault ultramylonite that gradually grades to mylonite at the
957 base of the image [from Gaunt Creek \(43°19'00.62" S, 170°19'32.79" E\)](#). A foliation defined by
958 alternating white quartzofeldspathic bands and dark grey mica bands is hard to distinguish in the
959 ultramylonite but is more apparent in the mylonite. (b) The well foliated Alpine Fault protomylonite-
960 mylonite transition [at Gaunt Creek \(43°19'05.11" S, 170°19'46.16" E\)](#). Compass is 5 cm wide. Both
961 images previously presented in Toy, (2008).

962

Deleted: The sample in (a) was taken from Gaunt Creek, as was the photo in (b).

966

967 Figure 3: Cross section through the DFDP-1 boreholes, showing interval where reoriented drill-core is
 968 located. Boxes with diagonal lines depict intervals in borehole with no core recovery, grey lines
 969 represent mylonitic foliation. Modified from Sutherland et al., (2012), with lithological units
 970 previously defined by Toy et al., (2015).

971

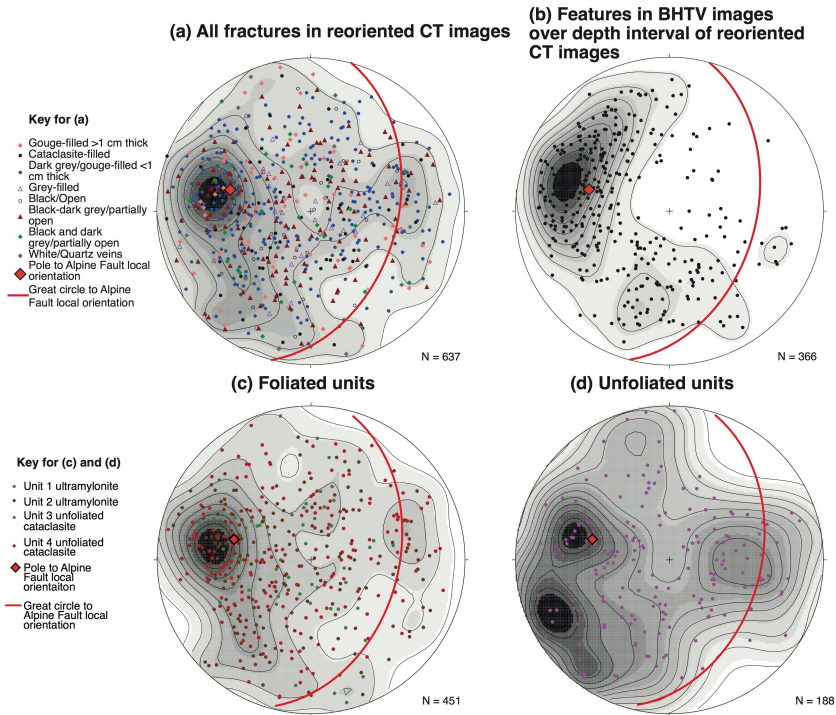

972 **Figure 4**

973

974 Figure 4: Examples of matching structures between BHTV images and unrolled CT images. In each
975 image, the first two columns are the BHTV amplitude image, without and with interpretations
976 respectively, whilst the third and fourth columns depict the unrolled CT image over the same interval,
977 also without and with interpretations. Fractures that have been traced in red indicate those that were
978 matched to reorientate core.

979

981

982 **Figure 5: Lower hemisphere equal area stereoplots depicting orientation of fractures in DFDP-1.**

983 Contouring on stereoplots was applied to poles that are weighted depending on their orientation

984 correction w (see Sect. 3.2), and that are rounded to the nearest whole number. Contours were then

985 generated for the weighted poles using a probability distribution calculated by a Kernel function in the

986 RFOC package for R (Lees, 2014). Great circle represents orientation of Alpine Fault plane and

987 foliation at DFDP-1 site (Townend et al., 2013). (a) Orientation of all fractures that were reoriented by

988 matching structures between unrolled CT images and BHTV images, sorted by fracture type (Williams

989 et al., 2016). (b) Orientation of features recognised in the BHTV images over the interval of reoriented

990 core (94-126 m in DFDP-1B). Fracture orientations extracted from reoriented DFDP-1 CT images in

991 (c) foliated units and (d) unfoliated units, using the DFDP-1 lithological classification scheme (Toy et

992 al., 2015).

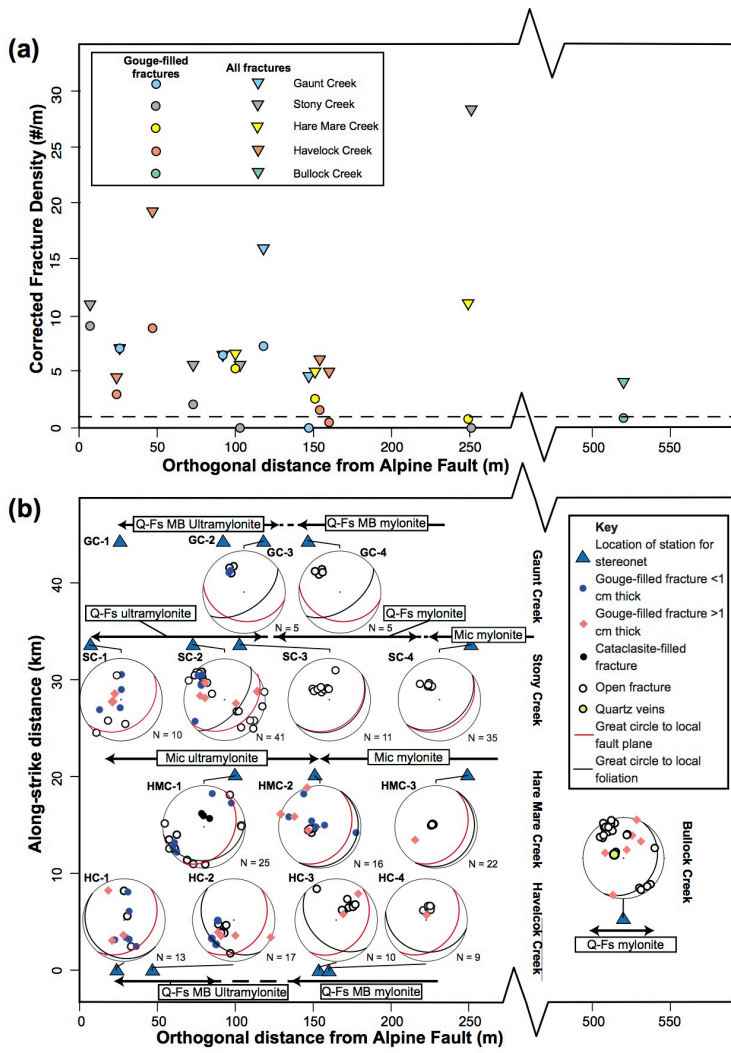

993 **Figure 6**

994

995 Figure 6: The relationship between foliation and fracture orientations in Alpine Fault ultramylonite, as
996 observed in 2D CT image slices of DFDP-1 drill-core. Intervals are (borehole, core section and run,
997 depth interval): (a) DFDP-1A 55-1 75.45-75.62 m, (b) DFDP-1B 35-1 102.49-102.64 m, and (c)
998 DFDP-1B 25-2, 44.80-45.20 m. In (a) and (b) fractures tend to cross-cut the ultramylonitic foliation
999 (orientation represented by white line in top left corner of each image). (c) Fractures show a greater
1000 preference to be aligned parallel to the foliation. Note that (c) was previously shown in Williams et al.,
1001 (2016), and is not included in the reorientation analysis in [Figure 5](#), as there was no BHTV imagery
1002 for this interval.

Deleted: Figure 5

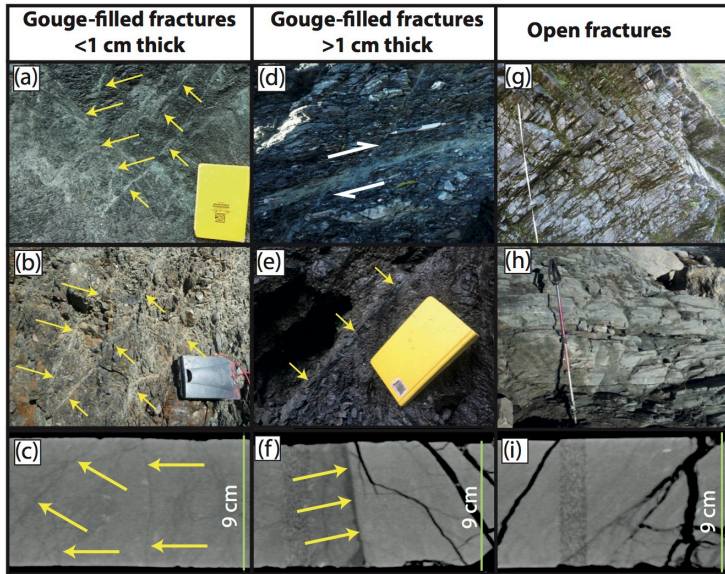

1005

1006 Figure 7: (a) Corrected fracture density at all stations for gouge-filled fractures and all fractures.
 1007 Dashed line indicates a corrected fracture density of 1 fracture/metre. No orientation data was
 1008 collected at Gaunt Creek stations 1 and 2, so fracture density is calculated from the two perpendicular
 1009 transects. (b) Compilation of stereoplots for fracture orientations at each field station. Stations have

1010 been plotted as a function of distance from the fault and distance along-strike (with respect to
1011 Havelock Creek) along within fault rock lithologies (Toy, 2008). Dashed lines indicate gradational or
1012 obscured lithological boundaries. Qfs, Quartzofeldspath; MB, metabasic; Mic, Micaceous. For field
1013 cross sections and location of stations, see Figure S1 and Table S2.

Deleted: and
Deleted: . Results are also summarised in Table S2

1017

1018 Figure 8: Examples of the three main types of fractures observed in the field around the Alpine Fault,
 1019 and correlative fractures in DFDP-1 CT scans. (a-c) Thin gouge-filled fractures (yellow arrows) have a
 1020 range of orientations and found exclusively within 160 m from the fault. They are equivalent to type
 1021 iii of fractures from Williams et al., (2016). (d-f) Thicker gouge and cataclasite filled fractures are
 1022 equivalent to type i and ii fractures of Williams et al. (2016) and may be observed at all distances from
 1023 the Alpine Fault. Offset markers can be observed across these fractures (e.g. the vein indicated by the
 1024 pen and white arrows in (d)). (g-i) Open fractures are mainly foliation-parallel. Equivalent to type v
 1025 fractures of Williams et al., (2016). Location of field photos: (a) Waikukupa thrust ([43°26'34.7" S,](#)
 1026 [170°04'10.9" E](#)), (b) Stony Creek 2, (d) Havelock Creek 2, (e) Bullock Creek, (g) Stony Creek
 1027 ([43°22'23.92" S, 170°12'53.63" E](#)), (h), Havelock Creek 4. Compass clinometer 8 cm and yellow
 1028 notebook 20 cm in length. Measuring tape in (e) 1.1 m long, walking pole in (g) 1 m in length. DFDP-
 1029 1 CT scan intervals: (c) DFDP-1B 56-2 125.35-125.49 m, (f) DFDP-1B 35-1 102.00-102.15 m, (i)
 1030 DFDP-1B 33-2 99.45-99.60 m

Deleted: , (b) and (g) Stony Creek, (d) and (h) Havelock Creek, (e) Bullock Creek

1034

1035 Figure 9: Field observations of changes in fracture density at lithological contacts. (a&b) Intervals of
 1036 micaceous and metabasite mylonite containing a relatively high proportion of gouge filled fractures
 1037 (denoted by yellow arrows) compared to interlayered quartzofeldspathic mylonite. (c) Transition from
 1038 micaceous mylonite to quartzofeldspathic mylonite coincides with furthest extent of intensive gouge-
 1039 filled fractures, as shown by yellow arrows in (d). Taken at (a) Gaunt Creek [1](#), (b) Havelock Creek [2](#),
 1040 (c&d) Hare Mare Creek [3](#). Compass clinometer 8 cm and yellow notebook 20 cm in length.

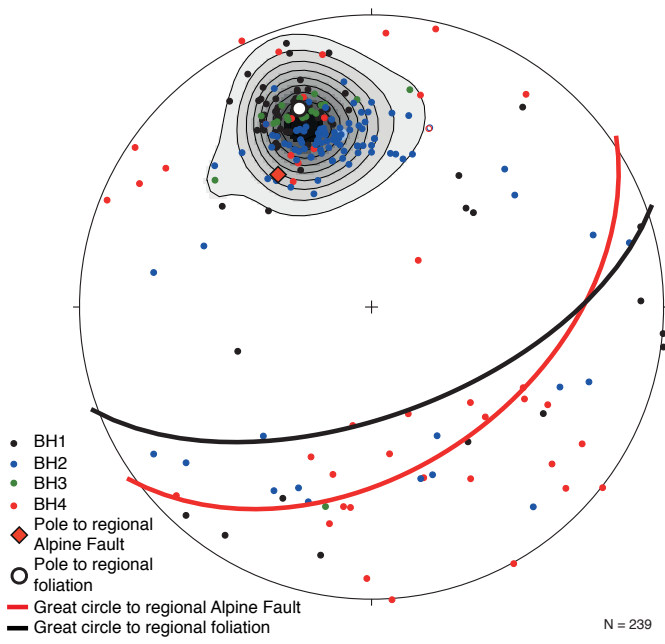

1042

1043 Figure 10: Fractures in the Amethyst Hydro Project (AHP) drill-core. Unrolled images of AHP drill-
 1044 core (BH1 45-2 124.3-124.9 m) taken by (a) DMT core scanner and (b) generated from a CT image.
 1045 (1) Identifies fracture cutting across foliation, (2) foliation-parallel fracture with alteration halo, (3)
 1046 foliation defined by quartzofeldspathic bands that have low CT numbers. (c&d) Core-axial parallel CT
 1047 image slices of AHP drill-core. In (c) white arrows point to a 'crush zone' sub parallel to foliation
 1048 (BH2 75-2 155.92-156.04 m). (d) more variable fracture orientations identified in BH4 (Section 70-4
 1049 196.62-196.80 m).

1050

1051 **Figure 11**

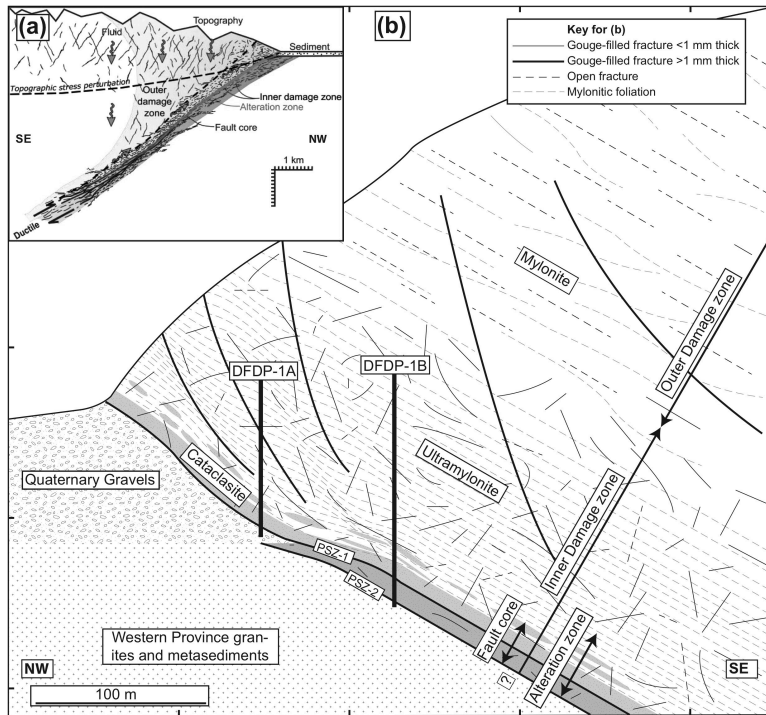

1052

1053 Figure 11: Equal area, lower hemisphere projection of fracture orientations recognised in CT scans of

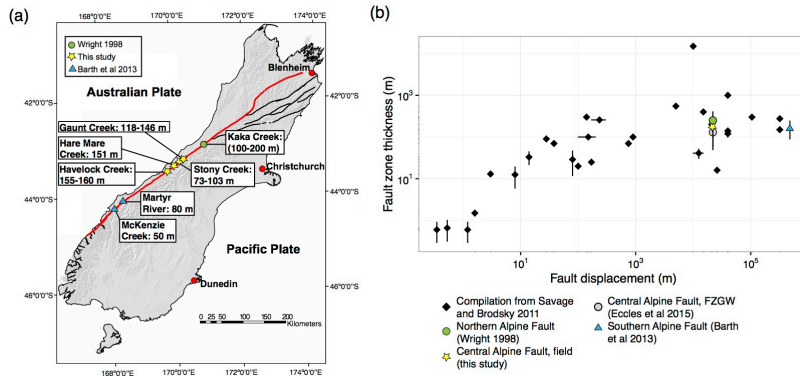

1054 AHP drill-core separated by borehole. Contours plotted with weighted poles (see Figure 5).

1055

1057

1058 Figure 12: Schematic cross sections through the Alpine Fault illustrating its hanging-wall
 1059 structure. (a) Crustal-scale cross section illustrating the flower shaped geometry of the outer
 1060 damage zone (after Townend et al., (2017)). (b) A thrust section within the central section of
 1061 the Alpine Fault, depicting fracture network, its relationship to foliation, and the distribution
 1062 of subsidiary faults. Respective position of DFDP-1 boreholes also shown. Constructed from
 1063 cross sections previously presented in Norris and Cooper, (2007) and Sutherland et al.,
 1064 (2012).

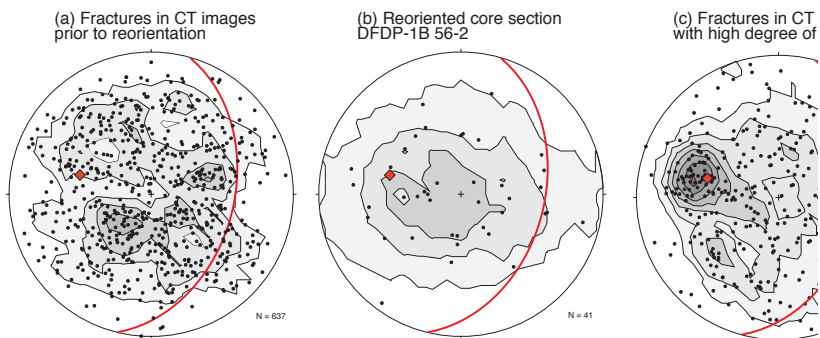

1066

1067 Figure 13: (a) Compilation of estimates of the ‘inner damage zone’ width on the Pacific Plate
 1068 side of the Alpine Fault (red line) from four creek sections in this study (Gaunt Creek, Stony
 1069 Creek, Hare Mare Creek and Havelock Creek). This is combined with other along-strike
 1070 estimates of damage zone thickness for the Pacific Plate side of the Alpine Fault: McKenzie
 1071 Creek and Martyr River (Barth et al., 2013) and Kaka Creek (Wright, 1998). (b) Log-log plot
 1072 of fault zone thickness as a function of fault displacement previously presented in Savage and
 1073 Brodsky, (2011), combined with estimates made for the Alpine Fault assuming footwall
 1074 damage is no more extensive than in the hanging-wall. Displacement for the Alpine Fault is
 1075 480 km (Norris and Cooper, 2007; Wellman, 1953). However, convergence along the Alpine
 1076 Fault’s central section requires that it erodes its own fault rocks so these points are plotted to
 1077 reflect only the brittle displacement the rocks themselves have accommodated as they are
 1078 exhumed through the seismogenic zone (22 km, Barth et al., (2012)). Error bars reflect
 1079 uncertainty in constraining fault zone width (as for example, footwall damage is largely
 1080 unknown), not necessarily variability in fault zone thickness.

1081

1082 **Figure A1**

1083

1084 Figure A1: Stereoplots to tests the confidence in reorientations applied to rotate DFDP-1 CT
1085 scan fracture orientations into geographic coordinates. Red great circle and diamond in each
1086 plot represents plane and pole to the Alpine Fault orientation measured in DFDP-1B. Plotted
1087 with Kamb contours with intervals of two standard deviations. (a) Orientation of fractures
1088 shown in Figure 5a before rotation, (b) orientation of reoriented fractures within a single core
1089 section (DFDP-1B 56-2), and (c) orientation of fractures in CT images from core sections that
1090 were oriented with a high degree of confidence with BHTV images.

1091

1092 **List of Tables**

1093 **Table 1**

	Number of fractures	Resultant Plane dip direction	Resultant Plane dip	Resultant vector length (Cluster intensity, 2 s.f.)
All reoriented DFDP-1 CT fractures	637	80	58	0.58
Reoriented DFDP-1 CT fractures, foliated units	451	87	58	0.58
Reoriented DFDP-1 CT fractures, unfoliated units	188	71	61	0.58
DFDP-1B BHTV features (depth interval 94-126 m)	365	103	47	0.72
AHP Fractures	239	164	58	0.76

1094 Table 1: Clustering analysis of the different fracture datasets documented in this study, using
1095 the resultant vector methodology outlined by Priest, (1993). DFDP-1 foliated units comprise
1096 ultramylonites and foliated cataclasites (Units 1, 2 and 4 of Toy et al., (2015)). DFDP-1

1097 unfoliated units comprise unfoliated cataclasites (Unit 3 of Toy et al., (2015)). The resultant
1098 vector orientation for each dataset, which has been converted to spherical coordinates, is also
1099 reported. See text for full details.
