19 **Abstract**

20 The 2014 eruption at Piton de la Fournaise (PdF), La Réunion, which occurred after 41
21 months of quiescence, began with surprisingly little precursory activity, and was one of the
22 smallest so far observed at PdF in terms of duration (less than 2 days) and volume (less than
23 $0.4 \times 10^6 \text{ m}^3$). The pyroclastic material was composed of spiny-opaque, spiny-iridescent, and
24 fluidal basaltic scoria along with golden basaltic pumice. Density analyses performed on 200
25 lapilli reveal that the spiny-opaque clasts are the densest (1600 kg/m^3) and richest in crystals
26 (55 vol%), and the golden pumices are the lightest (400 kg/m^3) and poorest in crystals (8
27 vol%). The connectivity data indicate that the fluidal and golden (Hawaiian-like) clasts have
28 more isolated vesicles (up to 40%) than the spiny (Strombolian-like) clasts (0-5%). These
29 textural variations are linked to primary pre-eruptive magma storage conditions. The golden
30 and fluidal fragments track the hotter portion of the melt, in contrast to the spiny fragments
31 and lava that mirror the cooler portion of the shallow reservoir. Exponential decrease of the
32 magma ascent and output rates corresponded to progressive tapping of these distinct portions

33 of the storage system. Increasing syn-eruptive degassing and melt-gas decoupling lead to a
34 decrease in the explosive intensity from early fountaining to Strombolian activity. The
35 geochemical results confirm the absence of new hot input of magma into the 2014 reservoir
36 and confirm the emission of a single, shallow, differentiated magma source, possibly related
37 to residual magma from the November 2009 eruption. Fast volatile exsolution and crystal-
38 melt separation (second boiling) were triggered by deep pre-eruptive magma transfer and
39 stress field change. Our study highlights the possibility that shallow magma pockets can be
40 quickly reactivated by deep processes without mass or energy (heat) transfer and produce
41 hazardous eruptions with only short term elusive precursors.

42 **Key words** : Piton de la Fournaise, Hawaiian activity, Strombolian activity, shallow reservoir,
43 texture, petrology, geochemistry

44 **1. Introduction**

45 A detailed characterization and understanding of eruptive dynamics and of processes
46 driving and modulating volcano unrest is crucial in monitoring active volcanoes and
47 fundamental for forecasting volcanic eruptions (Sparks, 2003). Many studies suggest that
48 eruptive phenomena are strongly dependent on the physico-chemical properties of ascending
49 magma in the conduit (e.g., temperature, viscosity, porosity, and permeability) (e.g. Sparks,
50 1978; Rust and Cashman, 2011; Gonnermann and Manga, 2013; Polacci et al., 2014).
51 Integrating petrographic, chemical and textural data can thus provide critical information to
52 constrain both the pre-eruptive storage conditions, and the processes related to magma ascent,
53 degassing and cooling (e.g., reference in Table 1 in Gurioli et al., 2015). This
54 multidisciplinary approach is of even greater importance in the monitoring of volcanoes
55 which emit relatively uniform magma compositions over time, like basaltic volcanoes (e.g. Di
56 Muro et al., 2014; Gurioli et al., 2015; Coppola et al., 2017). As a result, monitoring of
57 textures, and petrochemical properties of lava fragments and pyroclasts is now routinely
58 carried out on a daily basis at active volcanoes such as Kilauea, Etna, and Stromboli (e.g.,
59 Thornber et al., 2003; Polacci et al., 2006; Swanson et al., 2009; Taddeucci et al., 2002; Colo'
60 et al., 2010; Houghton et al., 2011; 2013; 2016; Carey et al., 2012; 2013; Lautze et al., 2012;
61 Andronico et al., 2013a; b; 2014; Corsaro and Miraglia, 2014; Di Muro et al., 2014;
62 Eychenne et al., 2015; Gurioli et al., 2014; Leduc et al., 2015; Kahl et al., 2015). In the past,
63 time series of petrographic and geochemical data have been measured for Piton de la
64 Fournaise (PdF) basalts and particularly for effusive products. The aim of these datasets was

65 to constrain time and space magma evolution for one of the most active basaltic volcanoes of
66 the world (e.g. Albarède et al., 1997; Vlastélic et al., 2005; 2007, 2009; Vlastélic and
67 Pietruszka, 2016; Schiano et al., 2012; Boivin and Bachèlery, 2009; Peltier et al., 2009; Lénat
68 et al., 2012; Di Muro et al., 2014; 2015). However, this type of approach has seldom been
69 coupled with detailed textural studies at PdF and instead has mostly focused on crystal
70 textures and crystal size distribution (Welsch et al., 2009; 2013; Di Muro et al., 2014; 2015).
71 Moreover, only sporadic data exist on the textures of pyroclasts ejected by the PdF (Villemant
72 et al., 2009; Famin et al., 2009; Michon et al., 2013; Vlastélic et al., 2013; Welsch et al., 2009;
73 2013; Morandi et al., 2016; Di Muro et al., 2015; Ort et al., 2016).

74 Within this paper, we present a multidisciplinary textural, chemical and petrological
75 approach to quantify and understand the short-lived 2014 PdF eruption. This approach
76 combines detailed study of the pyroclastic deposit (grain size and componentry) with bulk
77 texture analysis (density, vesicularity, connectivity, permeability, morphology, vesicle
78 distribution and crystal content) and a petro-chemical study (bulk rock, glass, minerals, melt
79 inclusions) of the same clasts. This integrated approach has now been formalized within the
80 French National Observation Service for Volcanology (SNOV), as routine observational
81 systems (DynVolc, Dynamics of Volcanoes, ([http://wwwobs.univ-
82 bpclermont.fr/SO/televolc/dynvolc/](http://wwwobs.univ-bpclermont.fr/SO/televolc/dynvolc/)) and GazVolc, Observation des gaz volcaniques,
83 (<http://wwwobs.univ-bpclermont.fr/SO/televolc/gazvolc/>) to provide data for the on-going
84 activity at PdF (Harris et al., 2017).

85 In spite of being the first of a series of eruptions, the June 2014 event was preceded by
86 only weak inflation and by a rapid increase in number of shallow (< 2 km below volcano
87 summit) volcano tectonic earthquakes that happened only 11 days before the eruption (Peltier
88 et al., 2016). The eruptive event was dominantly effusive, lasted only 20 hours and emitted a
89 very small volume of magma (ca. $0.4 \times 10^6 \text{ m}^3$, Peltier et al., 2016), which makes this event
90 one of the smallest, in terms of duration and volume, observed at PdF up to now. In addition,
91 the eruption started during the night and very little direct observation exists for the first few
92 hours of the activity, when the lava effusion was associated with very weak fountaining
93 activity and Strombolian explosions.

94 This eruption occurred just outside the southern border of the summit Dolomieu
95 caldera, at the top of the central cone of PdF (Fig. 1). This is a high risk sector because of the
96 high number of tourists. Identification of precursors of this kind of activity represents an
97 important challenge for monitoring systems (Bachèlery et al., 2016).

98 Therefore this eruption represents an ideal context to apply our multidisciplinary

99 approach, with the aim of addressing the following key questions:

100 (i) why was such a small volume of magma erupted instead of remaining
101 intruded?

102 (ii) what caused the rapid trigger and the sudden end to this small volume
103 eruption?

104 (iii) which was the source of the eruption (shallow versus deep, single versus
105 multiple small magma batches)?

106 (iv) what was the ascent and degassing history of the magma?

107 (v) what was the time and space evolution of the eruptive event?

108 Furthermore, this eruption provides an exceptional opportunity to study processes leading to
109 the transition from mild Hawaiian (<20 m high fountains, following the nomenclature
110 proposed by Stovall et al., 2011) to Strombolian activity (<10 m high explosions), whose
111 products are little modified by post-fragmentation processes because of the very low intensity
112 of the activity.

113 **2 The 2014 activity**

114 **2.1 Precursory activity**

115 The 20 June 2014 summit eruption represents the first eruption at PdF after 41 months of
116 quiescence. The last eruption had been on 9 December 2010, with a shallow (above sea level)
117 intrusion on 2 February 2011 (Roult et al., 2012). From 2011, the deformation at PdF was
118 constant with two distinct types of behaviour: (i) a summit contraction of a few centimetres
119 every year (Fig. 1d); (ii) a preferential displacement of the east flank at a rate of 1-3
120 centimetres per year (Brenquier et al., 2012; Staudacher and Peltier, 2015). The background
121 microseismicity was very low (< 5 shallow events/day below volcano summit) and low-
122 temperature summit intracaldera fumaroles emitted very little sulphur (H₂S or SO₂) and
123 carbon (CO₂) (Di Muro et al., 2016). After 41 months of rest, a new intense cycle of activity
124 (June 2014, February 2015, May 2015, July 2015, August-October 2015; May 2016;
125 September 2016; January 2017 and July 2017) began with surprisingly little and ambiguous
126 precursory activity.

127 The 2014 summit eruption started during the night of June 20/21, at 21h35 GMT
128 (0h35 local time) and ended on June 21 at 17h09 GMT (21h09 local time), after less than 20
129 hours of dominantly effusive activity. The volcano reawakening was preceded, in March and
130 April 2014, by deep (15-20 km below sea level) eccentric seismicity and increase in soil CO₂

131 flux below the western volcano flank, 15 km NW of the volcano summit (Liuzzo et al., 2015;
132 Boudoire et al., 2017). Background micro-seismicity and inflation of the central cone
133 increased progressively starting on 9 June 2014. Weak inflation recorded on both distal and
134 summit baselines (Fig. 1d) suggest that deep (below sea level) magma up-rise was
135 pressurizing the shallow (above sea level) magma storage system (Peltier et al., 2016). On
136 June 13, 17 and 20, three shallow (hypocentres located above sea level) intense seismic crises
137 occurred below the summit Dolomieu caldera (Fig. 1), with hundreds of events located in a
138 narrow depth range between 1100 and 2100 metres below the volcano summit. These seismic
139 crises consisted of swarms of low magnitude (M: 1-2) volcano tectonic events which
140 increased in number from the first to the third crisis. On June 20, seismicity increased
141 progressively and a final seismic crisis started at 20h20 GMT, only 75 minutes before the
142 eruption. This last seismic crisis was coupled with acceleration in the deformation of the
143 summit area, which began only 60 minutes before the eruption. Interestingly, only slight
144 inflation of the central cone (< 2 cm of dilatation) was detected 11 days before the 2014
145 eruption with a maximum of 1 cm and 1.6 cm enlargement at the summit and the base of the
146 cone, respectively (Peltier et al., 2016 and Fig. 1d). A moderate increase in CO₂ and H₂S
147 emissions from summit intracaldera fumaroles was detected starting on June 2, but only very
148 minor SO₂ emissions occurred before the eruption (mostly on June 7 and 15, unpublished
149 data). Therefore, the acceleration in both geophysical and geochemical parameters was mostly
150 related to the late phase of dyke propagation towards the surface just before the eruption.
151 Following the end of the June 20-21 eruption, a long-term continuous inflation of the edifice
152 began, at a moderate rate, and mostly at the base of the volcano. More than one year after this
153 first eruption, the long-term deformation trends showed that the 2014 eruption marked a kink
154 between the deflation trend which followed the caldera-forming 2007 eruption (Staudacher et
155 al., 2009) and the currently ongoing continuous inflation trend (Fig. 1d, and Peltier et al.,
156 2016; Coppola et al., 2017).

157 **2.2 Chronology of the events**

158 We reconstructed the chronology of events by combining a distribution map of the fissures,
159 pyroclastic deposits and lava flows (Fig. 1) with a review of available images (visible and IR)
160 and videos extracted from the observatory data base, the local newspapers, and web sites (Fig.
161 2). The 2014 eruption occurred at the summit and on the SE slopes of the Dolomieu Caldera
162 (Figs. 1a, 1b and 1c) and evolved quickly and continuously over 20 hours. The full set of
163 fractures opened during a short period of time (minutes) and emitted short (<1.7 km long)

164 lava flows (Fig. 1 and Figs. 2c and 2d). Feeding vents were scattered along a 0.6 km long
165 fissure set (Fig. 1a) and produced very weak (low) Hawaiian to Strombolian activity (Fig. 2).

166 Fissures opened from west to east, initially sub-parallel to the southern border of
167 Dolomieu caldera and then propagated at lower altitude (Fig. 1). The summit part of the
168 fractures (ca. 2500 m asl, Western Fracture, WF in Fig. 1) emitted only small volumes of lava
169 and pyroclasts. This part of the fracture set was active only during the first few hours of the
170 eruption, at night. The eastern part of the fractures (Upper Fracture, UF in Fig. 1) descended
171 to lower altitude (between 2400 and 2300 m asl, Middle Fracture, Fig. 1) along the SE flank
172 of the summit cone and emitted most of the erupted volume. As often observed in PdF
173 eruptions, the activity progressively focused on a narrow portion of the fractures at low
174 altitude and finally on a single vent located at the lower tip of the fracture system (Main Vent,
175 at 2336 m asl, MV in Figs. 1, 2). The first in situ observations in the morning of June 21 (ca.
176 04h00 GMT) showed that weak Strombolian activity (Figs. 2a and 2b) was focused on a
177 narrow segment of the lower fractures and that a'a lavas had already attained the elevation of
178 1983 m asl (0.2 km before maximum runout, Fig. 2c). A small, weak gas plume was also
179 blowing northwards. A single sample of partially molten lava was collected from the still
180 active lava front and partially water quenched (Reu140621-1, Table S1, Fig. 2d). During most
181 of June 21, the activity consisted of lava effusion in three parallel lava streams (Fig. 2c)
182 merging in a single lava flow (Fig. 2e) and mild-weak "Strombolian" explosions at several
183 closely spaced spots along the lower part of the feeding fracture. At 13.00 (GMT), only weak
184 explosions were observed within a single small spatter cone (Figs. 2f and 2g). Most of the
185 lava field was formed of open channel a'a lavas. The total volume of lava was estimated by
186 MIROVA service (<https://www.sites.google.com/site/mirovaweb/home>), with the use of the
187 MODIS images and the analyses of the flux from the spectral properties, to be within $0.34 \pm$
188 $0.12 \times 10^6 \text{ m}^3$, (Coppola et al., 2017). Satellite derived volume estimates are consistent with
189 independent photogrammetric estimates ($0.4 \pm 0.2 \times 10^6 \text{ m}^3$; Peltier et al., 2016) and rank the
190 2014 eruption at the lower end of the volume range typically emitted by PdF (Roult et al.,
191 2012).

192 **3. Methodology**

193 **3.1 Sampling strategy**

194 Apart from the sample from the front of the still active lava flow (Fig. 2d), all other samples
195 were collected in two phases: 3 days after the eruption (pyroclasts on June 24, Fig. 3a; lavas

196 on July 2) and three months later (pyroclasts from the MV Fig. 1, on November 18) (Table
197 S1). June 24 samples were collected both from the main fractures (WF and UF, Fig. 1a), the
198 MV and the active lava flow (Fig. 1 and Table S1). Twenty five scoriaceous bombs and lapilli
199 (REU140624-9a-1 to REU140624-9a and REU140624-9b-6 to REU140624-9b-25, in Table
200 S3) were collected from the discontinuous deposit (Fig. 3d) emplaced at the WF site (Fig. 1a),
201 active only at the beginning of the eruptive event. Because of the short duration of the activity
202 at the WF, the scoria fragments on the ground were scarce (Fig. 3c). The strategy was to
203 collect a sample that was formed by the largest available number of clasts that was
204 representative of this discrete deposit (REU140624-9 in Table S1). From the Upper Fracture
205 (UF in Fig. 1a) only one big scoria was collected (REU140624-13, Table S1) that broke in
206 five parts, allowing us to measure its vesiculated core and the dense quenched external part
207 (REU140624-13-a to REU140624-13-e, in Table S3). In contrast, the sustained and slightly
208 more energetic activity at the lower tip of the fractures built a small spatter cone (Fig. 2) and
209 accumulated a small volume continuous deposit (Fig. 3a) of inversely graded scoria fallout
210 (Figs. 3b). This deposit is 10 cm thick at 2 m from the vent and covers an area of about ~1000
211 m² (Main Vent, MV, Fig. 1). For this fall deposit we collected two bulk samples, one from the
212 base (within the lower 5 cm, REU141118-6 in Table S1) and the other from the top (within the
213 upper 5 cm, REU140624-3, in Table S1), for the grain size and componentry analyses. The
214 sample at the base was collected in November because on June 24 the loose proximal lapilli
215 blanket was still very hot (405 °C; thermocouple measurement, Fig. 3a) and fumaroles with
216 outlet temperatures in the range 305-60 °C were sampled all along the fractures several weeks
217 after the eruption (Fig. 1b and Table S1). These latter geochemical data are not presented in
218 this paper. We selected 103 fragments from the coarse grained bulk deposit at the top of the
219 MV (REU140624-3-1 to REU140624-3-103, in Table S3) for density, connectivity,
220 permeability, petrological and geochemical analysis. In addition, in November 2014, more
221 than 200 clasts (comprising the REU141118-1 to REU141118-5 samples, Table S1) of similar
222 size (maximum diameter between 16 and 32 mm, see Gurioli et al., 2015) were collected, both
223 close to the MV and in the 'distal' area (30 metres away from the MVt) to complete the
224 particle bulk texture analyses and the chemical analyses.

225 **3.2 Grain size and componentry**

226 We performed grain size analyses on the two bulk samples collected from the MV, following
227 the procedure of Jordan et al. (2015) (Table S2). The samples were dried in the oven at 90°C
228 and sieved at ½ phi intervals in the range of -5 φ to 4 φ (Fig. 3c); the data are also shown in

229 full phi for comparison with the deposits of the 2010 PdF fountaining episode (Hibert et al.,
230 2015; Fig. 3f). Sieving was carried out by hand and for not longer than three minutes to avoid
231 breaking and abrasion of the very vesicular and fragile clasts. For the scattered scoria sampled
232 from the WF (Figs. 1, 3d and 3e), we followed the grain size strategy proposed in Gurioli et
233 al. (2013). Within this procedure we sampled each fragment and we recorded the weight and
234 the three main axes (a being the largest, b, and c). To allow comparison with the sieving grain
235 size analyses (Inman, 1952), we used the intermediate b axis dimension to obtain $\varphi = -\log_2 b$.

236 Following the nomenclature of White and Houghton (2006) the componentry analysis
237 is the subdivision of the sample into three broad components: i) juvenile, ii) non-juvenile
238 particles, and iii) composite clasts. The juvenile components are vesicular or dense fragments,
239 as well as crystals, that represent the primary magma involved in the eruption; non-juvenile
240 material includes accessory and accidental fragments, as well as crystals that predate the
241 eruption from which they are deposited. Finally, the composite clasts are mechanical mixtures
242 of juvenile and non-juvenile (and/or recycled juvenile) clasts. In these mild basaltic
243 explosions, the non-juvenile component is very scarce, so we focused on the juvenile
244 component that is characterized by three groups of scoria: (i) spiny-opaque, (ii) spiny-glassy,
245 and (iii) fluidal, along with golden pumice (Fig. 4). The componentry quantification was
246 performed for each grain size fraction between -5φ to 0.5φ (Figs. 5a and 5b), where a
247 binocular microscope was used for the identification of grains smaller than -1φ (Table S2).

248 In the following, we will use the crystal nomenclature of Welch et al. (2009), with the
249 strictly descriptive terms of macrocrysts (> 3 mm in diameter) mesocrysts (from 0.3 to 3 mm
250 in diameter), and microcrysts (< 0.3 mm in diameter). Regarding the June 2014 products,
251 these ranges of size may however change in comparison to the December 2005 products
252 studied by Welsch et al. (2009).

253 **3.3 Particle bulk texture (density, porosity, connectivity, permeability) and microtexture**

254 For each sample site (WF, UF and MV, Fig. 1a), we selected all the available particles within
255 the 8-32 mm fraction for density/porosity, connectivity and permeability measurements (Table
256 S3). This is the smallest granulometric fraction assumed to be still representative of the larger
257 size class in terms of density (Houghton and Wilson, 1989; Gurioli et al., 2015), and has been
258 used in previous textural studies (e.g., Shea et al., 2010). In addition, this size range is ideal
259 for vesicle connectivity measurements (e.g. Formenti and Druitt, 2003; Giachetti et al., 2010;
260 Shea et al., 2012; Colombier et al., 2017a, b). Density of juvenile particles was measured by
261 the water-immersion technique of Houghton and Wilson (1989), which is based on

262 Archimedes principle. A mean value for the vesicle-free rock density was determined by
263 powdering clasts of varying bulk densities, measuring the volumes of known masses using an
264 Accupyc 1340 Helium Pycnometer, then averaging. The same pycnometer was also used to
265 measure vesicle interconnectivity for each clast using the method of Formenti and Druitt
266 (2003) and Colombier et al. (2017a). Permeability measurements were performed on five
267 clasts: two golden pumices, one fluidal, one spiny glassy and one opaque scoria, all collected
268 from the MV (Table S3). Following Colombier et al. (2017a), the clasts were cut into
269 rectangular prisms to enable precise calculation of the cross-sectional area, which is required
270 to calculate permeability. These prisms were then embedded in a viscous resin, which was left
271 to harden for 24 h. The sample surface had been previously coated with a more viscous resin
272 and then wrapped with parafilm to avoid intrusion of the less viscous resin inside the pores.
273 The coated samples were placed with a sample holder connected to a permeameter built in
274 Clermont-Ferrand following Takeuchi et al. (2008).

275 Vesicle size distribution was performed following the method of Shea et al. (2010) and
276 Leduc et al. (2015), while the total crystallinity, the percentages for both crystal phases
277 (plagioclase and clinopyroxene) and size-populations (meso and microcrysts) were calculated
278 using the raw data from FOAMS program (Shea et al 2010) and the CSDcorrections program
279 of Higgins (2000) and the CSDslice data base (Morgan and Jerram 2006) to have the
280 percentage in 3D. We performed these analyses on eight clasts picked up from each
281 component-density distribution (stars in Figs. 6a and 6b). The choice of the clasts was made
282 mostly on the typologies, rather than on each density distribution, in order to avoid the
283 analysis of clasts with transitional characteristics. For example, two golden pumice fragments
284 were selected from the largest clasts that were the less dense and didn't break, even if the
285 values in vesicularity were similar. A larger number of fluidal fragments were chosen (even if
286 the density distribution was unimodal) because this typology of clasts was the most abundant
287 and was emitted all along the active fracture, so we did our best in order to study products
288 representative of the WF, the UF and the MV activities. Only one spiny glassy and one spiny
289 opaque were selected, because they were emitted only at the MF. A full description of the
290 textural measurements all performed at Laboratoire Magmas et Volcans (LMV), as well as the
291 raw data of these measurements are available at DynVolc Database (2017).

292 **3.4 Bulk geochemistry**

293 For the determination of the bulk chemistry (Table S4 and Fig. 7) of the different pyroclasts
294 we selected the largest pyroclasts of golden pumice and the largest fluidal, spiny glassy and

295 spiny opaque scoriae (Table S4). We also analyzed two fragments of lava, from the beginning
296 and the end of the eruption (Table S4). Samples were crushed into coarse chips using a steel
297 jaw crusher and powdered with an agate mortar. Major and trace element compositions were
298 analyzed using powder (whole rock composition). In addition, for a sub-set of pyroclasts,
299 glass chips (2-5 mm in size) were hand-picked under a binocular microscope and analyzed
300 separately for trace elements. For major element analysis, powdered samples were mixed with
301 LiBO_2 , placed in a graphite crucible and melted in an induction oven at 1050 °C for 4.5
302 minutes, resulting in a homogeneous glass bead. The glass was then dissolved in a solution of
303 deionized water and nitric acid (HNO_3), and finally diluted by a factor of 2000. The final
304 solutions were analyzed by ICP-AES. Trace element concentrations were analysed following
305 a method modified from Vlastélic et al. (2013). About 100 mg of sample (powder and chip)
306 were dissolved in 2 ml of 28M HF and 1 ml of 14M HNO_3 in teflon beaker for 36 hours at
307 70°C. Solutions were evaporated to dryness at 70°C. The fluoride residues were reduced by
308 repeatedly adding and evaporating a few drops of concentrated HNO_3 , before being fully
309 dissolved in ca. 20 ml of 7M HNO_3 . These solutions were diluted by a factor of 15 with
310 0.05M HF (to reach rock dilution factor of ca. 4000) and trace element abundances were
311 determined by quadrupole ICPMS (Agilent 7500). The analyses were performed in plasma
312 robust mode (1550 W). The reaction cell (He mode) was used to reduce interference on
313 masses ranging from 45 (Sc) to 75 (As). The signal was calibrated externally (every 4
314 samples) with a reference basaltic standard (USGS BHVO-2) dissolved as for the samples and
315 using the GeoRem recommended values (<http://georem.mpch-mainz.gwdg.de/>). For elements
316 that are not well characterized in literature (As, Bi, Tl), or which show evident heterogeneity
317 (e.g. Pb) in BHVO-2 powder, the signal was calibrated using the certified concentrations of a
318 synthetic standard, which was also repeatedly measured. The external reproducibility (2σ
319 error) of the method is 6% or less for lithophile elements and 15% or less for chalcophile
320 elements.

321 **3.5 Glass and crystal chemistry**

322 Spot analyses of matrix glass and crystal composition (Table S5) were carried out using a
323 Cameca SX100 electron microprobe (LMV), with a 15 kV acceleration voltage of 4 nA beam
324 current and a beam of 5 μm diameter for glass analyses. However, for the spiny opaque
325 scoria, characterized by abundant crystals with rapid growth textures, a voltage of 8 nA beam
326 current and a beam of 10 μm diameter were used. For this latter sample, 10 analyses per
327 sample were performed due to the heterogeneity within the highly crystallised glass (Fig. 8a),

328 while for the other samples 6 analyses per sample were enough to characterize the clean
329 homogeneous glass. For crystal analysis, a focused beam was used. For the characterization of
330 the meso- and micro-crysts, due to their small size, only two to three measurements were
331 performed, one at the edge, one in the middle and one at the core of the crystals, to check for
332 possible zonation.

333 **3.6 Melt inclusions**

334 Melt inclusions (MIs; Table S6, Figs. 8b and 9) were characterized in the olivine mesocrysts
335 from the three groups of scoriae (fluidal, spiny glassy and spiny opaque), but not in the
336 pumice group, because crystals were too rare and small to be studied for MIs.

337 Olivine crystals were handpicked under a binocular microscope from the 100– 250 and
338 250– 600 μm grain size fractions of crushed tephra. Crystals with MIs were washed with
339 acetone, embedded in epoxy and polished individually to generate adequate exposure of the
340 MIs for *in situ* electron probe microanalysis. The MIs are spherical to oblate in shape and
341 range in size from 10 to 200 μm . Some of the MIs contain shrinkage bubbles but all of those
342 studied are totally deprived of daughter minerals. Major elements were measured on a
343 Cameca SX-100 microprobe at LMV (Table S6). For major elements, the larger MIs were
344 analyzed with a spot diameter of 10-20 μm and sample current of 8 nA, whereas the smaller
345 MIs were analyzed with a beam of 5 μm and a sample current of 4 nA. The results are given
346 in Table S6, and analytical details and uncertainties are listed in Óladóttir et al. (2011) and
347 Moune et al. (2012).

348 **4 Results**

349 **4.1 Deposit texture (grain size, componentry, morphology) and petrological description** 350 **of the samples**

351 The pyroclastic deposits at the WF and UF sites (Fig. 1a) are formed by scattered
352 homogeneous smooth fluidal (Figs. 3d) bombs and lapilli scoria. The average dimension of
353 the fragments is around 4 cm (maximum axis) with bombs up to 10 cm and scoria lapilli up to
354 2 cm in size.

355 At the MV, the reversely graded deposit is made up of lapilli and bombs, with only
356 minor coarse ash (Fig. 3c). The lower 5 cm at the base are very well-sorted and show a perfect
357 Gaussian distribution with a mode at 4 mm. In contrast, the grain size distribution of the upper
358 5 cm is asymmetrical with a main mode coarser than 22 cm and a second mode at 8 mm. This

359 upper deposit is negatively skewed due to the abundance of coarse clasts. The dataset shows a
360 similarity between the grain size distributions of the basal tephra ejected from the 2014 MV
361 and the ones for the lava fountaining of the 2010 summit event (Hibert et al., 2015). On the
362 contrary, the top of the 2014 fall differs from fountain deposits, being coarser and polymodal,
363 and it is ascribed to dominantly Strombolian activity.

364 In terms of componentry of the deposits, four types of clasts were distinguished (Fig.
365 4): (i) golden pumice, (ii) smooth or rough fluidal scoriae, (iii) spiny glassy scoria, (iv) spiny
366 opaque scoria. The pumices are vesicular, light fragments, characterized by a golden to light
367 brown color, sometimes with a shiny outer surface (Fig. 4a). They are usually rounded in
368 shape. Golden clasts studied for textures contain a few microcrysts of plagioclase (up to 0.1
369 mm in diameter), clinopyroxene up to 0.05-0.06 mm in diameter, and small olivine up to 0.03
370 mm in diameter (Fig. 4), together with large areas of clean, light brown glass. The fluidal
371 scoria fragments have dark, smooth or rough shiny surfaces (Fig. 4b). They can be more or
372 less elongated in shape and have spindle as well as flattened shapes. The fluidal fragments are
373 characterized by rare mesocrysts of plagioclase and clinopyroxene and microcrysts of
374 plagioclase, clinopyroxene and olivine (Fig. 4b). The spiny glassy fragments are dark, spiny
375 scoria that range in shape from subrounded to angular (Fig. 4c). These fragments contain
376 abundant glassy areas, while the spiny opaque fragments lack a glassy, iridescent surface.
377 Both groups of spiny clasts are characterized by the presence of dark and light brown glass.
378 The spiny opaque fragments are the densest fragments and have the largest amount of
379 crystals. They contain, as the most abundant phase, relatively large meso- and micro-crysts of
380 plagioclase, up to 3 mm long, together with meso- and micro-crysts of clinopyroxene and
381 olivine (Figs. 4c and 4d). In the dark portions of their matrix, tiny fibrous microcrysts of
382 olivine + clinopyroxene + plagioclase + Fe-Ti oxides occur. The spiny glassy fragments have
383 the same crystal populations as the spiny opaque ones, but their plagioclases are much smaller
384 and attain a maximum length of only 0.3 mm. Clusters of plagioclase and clinopyroxene are
385 present in both the spiny opaque and the spiny glassy fragments, as well as rare macrocrysts
386 of olivine. The olivine macrocrysts exhibit the typical compositional (Fo 84.2) and
387 petrographic features of olivine phenocrysts described in previous studies (Clocchiatti et al.,
388 1979; Albarede and Tamagnan, 1988; Bureau et al., 1998a and b; Famin et al., 2009; Welsch
389 et al., 2013). They are automorphic, fractured with oxides (mostly chromite) and melt
390 inclusions (Fig. 4c). Fluidal and pumice fragments studied for textures contain rare
391 macrocrysts and mesocrysts of olivine, and the crystals are essentially microlites. The pumice
392 and some fluidal fragments have lower contents of microlites than some fluidal and spiny

393 fragments, with the latter having the highest microlite content (Table S4). For comparison two
394 fragments of lava have been analyzed as well (Table S3). The lava fragments are poorly
395 vesiculated and completely crystalline (Fig. 4e). The lava contains the same paragenesis of
396 crystals described in the spiny opaque fragments, with the main difference that its matrix is
397 completely crystallized and constituted mostly by well-formed plagioclase up to 800 microns
398 and clinopyroxene up to 500 microns. Scarce, smaller olivines, are also present Ubiquitous
399 tiny rounded Fe-Ti oxides provide evidence of post emplacement crystallization.

400 The componentry results are reported in Figure 5 for the MV deposits; being the
401 deposits from the WF and UF characterized exclusively by fluidal clasts (Fig. 3). At the base
402 of the MV deposit, the coarse fraction of the deposit is rich in golden and fluidal components
403 that represent more than 60-70 vol% (Figs. 5a and 5b). The proportion of the two groups is
404 similar. In contrast, in the upper, coarse grained fall deposit, the clasts bigger than 8 mm are
405 dominated by the spiny scoria fragments, while the fraction smaller than 8 mm show a
406 dramatic increase in the golden and fluidal fragments, with the fluidal ones always more
407 abundant than the golden ones (Figs. 5a and 5b). Abundant light, golden, coarse lapilli pumice
408 and bombs have been found scattered laterally up to 30 metres from the main axis and were
409 not found in the proximal deposit. On the basis of the high amount of pumice in the lower part
410 of the deposit, we correlate the large, light clasts with the base of the proximal deposit, and
411 consequently we interpret them as material emitted at the beginning of the June 2014 eruptive
412 event.

413 **4.2 Particle density, porosity, connectivity, permeability and micro-texture**

414 Density analyses performed on 200 coarse lapilli reveal a large variation in density values
415 from 390 kg/m^{-3} to 1700 kg/m^{-3} with a median value at 870 kg/m^{-3} (Table S3). The fragments
416 collected from the MV have a bimodal density distribution, with a main population of light
417 fragments having a mode at 800 kg/m^{-3} , and a second and denser population centered at 1400
418 kg/m^{-3} (Fig. 6a). The golden and fluidal fragments form the lower-density population and the
419 spiny fragments are dominant in the denser population (Fig. 6a). For these samples there is a
420 marked correlation between porosity and morphology, so that the spiny-opaque clasts are the
421 densest (up to 1600 kg m^{-3} , with a vesicularity of 45 vol%) and the golden pumice are the
422 lightest (minimum density of 390 kg m^{-3} with a vesicularity of up to 86 vol%; with a Dense
423 Rock Equivalent density of $2.88 \times 10^3 \text{ kg m}^{-3}$). The fluidal fragments collected at the WF (Fig.
424 1b), have a density range from 700 to 1400 kg/m^{-3} and a mode at 1000 kg/m^{-3} (Fig. 6b). The
425 five fragments from the only bomb collected at the UF are characterized by two distinct

426 density values, the low density one ($700\text{-}800\text{ kg/m}^3$) refers to the core of the sample, while
427 the high density one ($1400\text{-}1500\text{ kg/m}^3$) represents the quenched external rim of the bomb.
428 Finally, the two fragments of lava show the highest density values at 1800 and 2150 kg m^{-3} .
429 This last value is one of the highest found in the lava collected from 2014 up to 2017 (see Fig.
430 13 in Harris et al., 2017 and unpublished data)

431 In all these samples, the increase in vesicularity correlates with an increase in the
432 amount of small (0.1 mm), medium ($0.5\text{-}1\text{ mm}$) and large (up to 4 mm) vesicles. In the fluidal
433 clasts, these vesicles have a regular rounded or elliptical shape and are scattered throughout
434 the sample. The lightest pumices are often characterized by the presence of a single, large
435 central vesicle ($10\text{ - }15\text{ mm}$) with the little vesicles and a few medium vesicles distributed all
436 around it (Fig. 4). The spiny glass texture is characterized by a lower amount of large vesicles
437 than in the pumice and by the presence of mostly medium sized vesicles, while the spiny
438 opaque has more irregular shape, very large (up to 10 mm) vesicles with a small and a
439 medium sized bubble population. In the spiny glass samples, the glass is more or less brown,
440 with the dark brown portions being the ones with the lowest vesicle content and the highest
441 microlite content. The opaque samples have a central, very dark glass portion, with low
442 vesicle content, and a more vesicular glassy portion at the outer edges (Fig. 4). The two
443 fragments of lava are poorly vesiculated (Fig. 6a) and characterized by large, irregular
444 vesicles (up to 5 mm in diameter). Clusters of small vesicles (up to 0.1 mm) are scattered
445 between the large ones.

446 The vesicle Size Distribution (VSD in Fig. 4) histograms picture well the decrease in
447 percentage of vesicles from the golden to the lava as well as the increase in coalescence and
448 or expansion in the spiny fragments, marked by the increasing of the large vesicles population
449 (Figs 4c and 4d). This trend is also marked by the decrease in number of vesicle per unit of
450 volume (N_v , Fig. 4) from the golden to the lava. Finally, the trend is also mirrored by the total
451 percentage of crystals (calculated in 3D, Fig. 4 and reported both in 3D and 2D for each
452 sample in Table S3) that increases with the increase of density of the clasts, from a minimum
453 of 8% in vol. for the golden up to 55% in vol. for the spiny opaque scoria, and 100% in vol.
454 for the lava (Fig. 4). Mesocrystals, formed mostly by the same proportion of plagioclase and
455 clinopyroxenes are absent or very scarce in the golden and fluidal fragments, while they reach
456 their maximum values, up to 21% in vol. in the spiny opaque fragment. The population of
457 microcrystals is mostly constituted by plagioclases that range from a minimum of 6% in vol.
458 in the golden, up to $23\text{-}25\%$ in vol. in the spiny fragments and to 64% in vol. in the lava.

459 The connectivity data (Fig. 6c) also indicate that the fluidal and golden clasts have a
460 larger amount of isolated vesicles (up to 40% in volume) with respect to the spiny products.
461 The fluidal clasts from the WF are the most homogeneous with an average percentage of
462 isolated vesicles around 30% in volume. In contrast, both the pumice and the fluidal
463 fragments from the MV, characterized by higher values of porosity (> 75%), have a wide
464 range in percentage of isolated vesicles (between 20 and a few percentage in volume). The
465 fragments of the bomb collected at the UF are consistent with a vesiculated core characterized
466 by scarce isolated vesicles and the quenched rind that has 30 % of isolated vesicles. Finally
467 the spiny fragments have the lowest content of isolated vesicles (0-5% in volume). Despite the
468 presence of these isolated vesicles, all the samples show high values of permeability (Fig. 6d).

469 **4.3 Chemistry of the products**

470 Major and trace element concentrations of whole-rock and hand-picked glass samples are
471 reported in Table S4. Whole rock major element composition is very uniform (e.g.,
472 $6.5 < \text{MgO} < 6.7$ wt%) and well within the range of Steady State Basalts (SSB), the most
473 common type of basalts erupted at PdF (Albarède et al., 1997). However, compatible trace
474 elements, such as Ni and Cr, are at the lower end of the concentration range for SSB
475 (<100ppm) indicating that the June 2014 eruption sampled relatively evolved melts. Ni and Cr
476 generally show higher concentrations in 2014 bulk rocks ($79 < \text{Ni} < 92$ ppm and $71 < \text{Cr} < 87$ ppm)
477 compared to the 2014 glass chips ($66 < \text{Ni} < 73$ ppm and $54 < \text{Cr} < 59$ ppm for all but two chips).
478 In the Cr vs Ni plot (Fig. 7a), whole rocks plot to the right of the main clinopyroxene +/-
479 plagioclase-controlled melt differentiation trend. This shift reflects the addition of Ni-rich
480 olivine (Albarède and Tamagnan, 1988). We estimate that the Ni excess results from the
481 occurrence of a low amount (0.7 to 1.3 wt%) of cumulative olivine in whole rocks, consistent
482 with thin section observations. The composition of olivine macrocrysts (ca. Fo₈₄) is too
483 magnesian to be in equilibrium with the low-MgO evolved composition of the 2014 magma.
484 Using our estimate for the amount of cumulative olivine, we recalculate the olivine-corrected
485 MgO content of the 2014 magma at 6.2 wt%. The June 2014 melt is thus only moderately
486 depleted in compatible elements compared to the previous eruption of December 2010
487 (MgO~6.6 wt%, Ni~80 ppm, Cr~120 ppm). Conversely, the June 2014 melt is significantly
488 depleted in compatible elements compared to the earlier November 2009 eruption, which
489 sampled relatively primitive magmas (average MgO~7.7 wt%, Ni~135 ppm, Cr~350 ppm)
490 (Fig. 7a). The 2014 evolved composition plots at the low-Ni-Cr end of PdF historical
491 differentiation trend (Albarède and Tamagnan, 1988), near the composition of lavas erupted

492 on 9 March 1998 after 5.5 years of quiescence (1992-1998). Note that olivine accumulation at
493 PdF generally occurs in melt having ca.100 ppm Ni (Albarède and Tamagnan, 1988). Olivine
494 accumulation in evolved melts (Ni < 70 ppm) seems to be a distinctive feature of many small
495 post-2007 eruptions (e.g. this event and the three 2008 eruptions, see Di Muro et al., 2015).

496 A closer inspection of Ni-Cr variability in June 2014 whole rock samples (Fig. 7b)
497 reveals that scoria from the Western Fracture (140624-9b-6, Table S4) and early erupted lavas
498 (1406-21-1, Table S4) have the lowest amount of olivine (<0.9%) whereas scoria from the
499 Upper Fracture (140624-13a) and late erupted lavas (140324-12) have a slightly higher
500 amount of olivine (>1.2%). This is consistent with the general trends observed at PdF of
501 olivine increase from the start to end of an eruption (Peltier et al., 2009).

502 The so called “olivine control trend” in Ni-Cr space cannot be explained either by
503 addition of pure olivine (which contains less than 500 ppm Cr (Salaün et al., 2010; Di Muro et
504 al., 2015; Welsch et al., 2009), or by the addition of olivine plus pyroxene (which would
505 require ca. 50% pyroxene with 970 ppm Ni and 4800 ppm Cr, see Fig. 7 caption). Instead,
506 addition of olivine hosting ca. 1% Cr-spinel (with 25 wt.% Cr) accounts for data and
507 observations, and is consistent with crystallization of olivine and Cr-spinel in cotectic
508 proportions (Roeder et al., 2006). The fact that some samples (golden pumice) plot off the
509 main, well-defined array, can be explained either by addition of more or less evolved olivine
510 crystals (within the range of Fo 80-85 measured in June 2014 samples) and/or slight
511 variations ($\pm 0.02\%$) in the proportion of Cr-spinels (Fig. 7b).

512 The glass chemistry of the four clast types allows us to correlate porosity and oxide
513 contents and shows an increase in MgO from the spiny opaque to fluidal and golden
514 fragments (Fig. 8a). Consistent with petrological and textural observations, the spiny opaque
515 is the most heterogeneous type of clast in terms of glass composition (Fig. 8). The glassy
516 portion at the edge of the clast is similar to the spiny glass, while the interior, characterized by
517 dark areas rich in tiny fibrous microcrysts, shows scattered glass compositions with very low
518 MgO content as well as a decrease in CaO (Fig. 8). We attribute the significant variation in
519 glass composition within the different components to variable degrees of micro-crystallisation
520 as the bulk chemistry of all clasts is very similar and globally homogeneous.

521 **4.4 Melt inclusions**

522 MI analyses must be corrected for post-entrapment host crystallisation at the MI - crystal
523 interface. We used a $K_d = (\text{FeO}/\text{MgO})_{\text{ol}} / (\text{FeO}/\text{MgO})_{\text{melt}} = 0.306$ (Fisk et al., 1988; Brugier,

524 2016) and an average $\text{Fe}^{3+}/\Sigma\text{Fe}_{\text{total}}$ ratio of 0.11 (Bureau et al., 1998a; Di Muro et al., 2016 and
525 references therein) defined for PdF magmas. For the June 2014 melt inclusions, the post
526 entrapment crystallization (PEC) ranges from 2.9 to 10.5 wt%. Raw and corrected major and
527 volatile element concentrations of MIs are reported in Table S6.

528 Host olivines span a large compositional range from Fo_{80} to Fo_{86} . Despite the evolved
529 bulk composition of the magma, most olivines are quite magnesian (Fo_{83-85}) and are not in
530 equilibrium with the evolved host magma. On the contrary, Mg-poor olivines (Fo_{80-81}) can be
531 considered as being in equilibrium with the bulk rock composition. The corrected
532 compositions of MIs in phenocrysts from the different samples partly overlap with the
533 evolved bulk rocks (MgO_{wr} : 6.1-7.2 wt%) and extend to higher MgO contents of up to 8.8
534 wt% (Table S6). MIs display a narrow range of transitional basaltic compositions (K_2O = 0.5-
535 0.9 wt%) and show no significant difference between the three types of scoriae. The major
536 element composition of melt inclusions correlates with that of the host olivines. Melt
537 inclusions in the high Fo-olivines have the highest MgO, CaO and TiO_2 and lowest K_2O
538 concentrations (Table S6). It is interesting to note that the June 2014 products contain two
539 populations of magnesian ($\text{Fo}_{>83}$) olivines hosting melt inclusions with two distinct Ca
540 contents. Most of the magnesian olivines contain MIs with unusually high CaO contents (11.6
541 – 12.9 wt%) and high $\text{CaO}/\text{Al}_2\text{O}_3$ ratios (0.8-0.9), higher than that of the bulk rocks (0.8) (Fig
542 8). The occurrence of olivines with “high Ca” melt inclusions has been observed in all three
543 different types of scoriae. A few magnesian olivines and all Mg-poor olivines ($\text{Fo}_{80.5-83.6}$) host
544 MIs with lower CaO contents (11.4 wt%). This latter composition overlaps with that of the
545 bulk rock (Fig 8). The “high Ca” population of inclusions is also enriched in TiO_2 and Al_2O_3
546 and depleted in MgO, FeO_T and Na_2O for a given olivine Fo content with respect to the “low
547 Ca” population. Both low- and high-Ca populations of melt inclusions have similar K_2O
548 contents and total alkali content increases from 3 wt% at 12.6 wt% CaO, to 3.5 wt% at 10.8
549 wt% CaO. However, we remark that high Ca melt inclusions from the June 2014 activity
550 record a significant scattering in K_2O contents, which range from 0.55 to 0.9 wt%. These
551 anomalous compositions potentially track processes of crystal dissolution (e.g. pyroxene
552 dissolution).

553 MIs in olivines from June 2014 can best be compared with those of other recent small-
554 volume and short-lived eruptions which emitted basalts with low phenocryst contents, like
555 those in March 2007 ($0.6 \times 10^6 \text{ m}^3$) and November 2009 ($0.1 \times 10^6 \text{ m}^3$) (Roult et al., 2012).
556 March 2007 aphyric basalt has a bulk homogeneous composition with intermediate MgO

557 content (MgO_{wr}: 7.33 wt%; K₂O: 0.67 wt%). Their olivines (Fo 81) are in equilibrium with
558 the bulk rock and their composition is unimodal (Di Muro et al., 2014). November 2009
559 products are the most magnesian lavas emitted in the 2008-2014 period, slightly zoned
560 (MgO_{wr}: 7.6-8.3 wt%; K₂O: 0.75 – 0.62 wt%) and contain a few percent of normally zoned
561 olivine macrocrysts with bimodal composition (Fo₈₁ and Fo_{83.5}, see Di Muro et al., 2016).
562 June 2014 bulk rocks (MgO_{wr}: 6.7 wt%; K₂O: 0.75 wt%) and melt inclusions in Fo₈₀₋₈₁
563 olivines are quite evolved. Their composition is close to that of products emitted by summit
564 intracaldera eruptions in 2008, ca. 1.5 years after the large 2007 caldera forming eruption (Di
565 Muro et al., 2015) (Fig. 8). As already reported for 2008 products, many olivine macrocrysts
566 of 2014 are clearly too magnesian to be in equilibrium with the relatively evolved host melts.
567 Overall, MgO content in 2007-2014 melt inclusions tends to decrease with decreasing Fo
568 content of the host olivines. MIs in olivines also exhibit a trend of linear decrease in MgO and
569 increase in FeO from April 2007 to 2009-2014 products (Fig. 9). Melt inclusions in March
570 2007, November 2009 and June 2014 follow the same trend of FeO enrichment (Fig. 9). In the
571 large-volume and olivine-rich April 2007 products, MIs in magnesian olivines with Fo_{>82} have
572 distinctly higher MgO, FeO and lower SiO₂ and Al₂O₃ than MIs in 2009-2014 products. The
573 distinctive FeO enrichment of many of the MIs from the April 2007 oceanite has been
574 interpreted by Di Muro et al. (2014) as a result of post-entrapment modification related to new
575 magma inputs into long lasting magma storage.

576 Two populations of low- and high-Ca melt inclusions are also found in the November
577 2009 olivines. Low-Ca melt inclusions from the November 2009 and June 2014 eruptions
578 indicate a single trend of chemical evolution (Fig. 8), consistent with bulk rock compositions.
579 June 2014 products have lower MgO and CaO contents than those from November 2009.
580 Significant scattering in K₂O content (0.6-0.9 wt%) is found in low-Ca inclusions from 2009,
581 as observed in high-Ca inclusions from the 2014 eruption, but they share similar K₂O
582 contents. In 2009 and 2014 products, K₂O content of melt inclusions is partly anti-correlated
583 with the olivine Fo content. This observation has been attributed to moderate heterogeneity of
584 primary melts feeding the plumbing system of PdF. Rapid temporal changes of K₂O content in
585 PdF basalts have been reported (Boivin and Bachelery, 2009).

586 **4.5 Mineral composition and glass – plagioclase equilibrium**

587 All 2014 scoriae (spiny, fluidal, golden) contain the same paragenesis of olivine,
588 clinopyroxene and plagioclase. The composition of minerals found in golden, fluidal and
589 spiny scoriae is indistinguishable.

590 In olivines, average MgO content decreases from macrocrysts (Fo_{84.1}) to mesocrysts
591 (Fo_{79.6}) to microlites. Olivine microlites (Table S5) are normally zoned. Their composition
592 ranges from Fo_{78.0-75.3} in the cores to Fo_{74.3-70.5} in the rims. Overall, olivines in 2014 products
593 span the full range of typical Fo contents of recent PdF magmas (Boivin and Bachèlery, 2009;
594 Di Muro et al., 2014; 2015). Clinopyroxene composition (augites) ranges from En₅₃Fs₁₅Wo₃₂
595 to En₄₁Fs₁₄Wo₄₅. Their average composition (En₄₅Fs₁₄Wo₄₁) is consistent with that found in
596 other recent evolved melts like those emitted by the 2008 eruptions (Di Muro et al., 2015) and
597 more generally in recent PdF products (Boivin and Bachèlery, 2009). Clinopyroxenes are
598 unzoned, the composition of cores and rims is very similar and close to that found in
599 microcrysts and mesocrysts. Plagioclase composition ranges from An_{79.5}Ab_{19.9}Or_{0.6} to
600 An_{63.1}Ab_{35.7}Or_{1.2} with a bimodal distribution (An_{76.5-79.5} and An_{63.1-72.9}, Fig. 10a). Similar
601 bimodal distributions were observed in many other products, at PdF (Di Muro et al., 2015).
602 Mesocrysts (An_{75.5}Ab_{23.8}Or_{0.7} on average) are more calcic with respect to microcrysts
603 (An_{65.7}Ab_{33.1}Or_{1.2} on average). Normal zoning is found from plagioclase cores to rims (Fig.
604 10a). The composition and zonation of 2014 plagioclases clearly contrast with the complex
605 and often reverse zoning patterns and intermediate composition of the 2008 PdF products that
606 were attributed to pre-eruptive magma heating (Di Muro et al., 2015).

607 Plagioclase-melt equilibrium and melt composition in pyroclastic rocks and water-
608 quenched lavas were used to estimate both temperature and water content dissolved within the
609 melt (Fig. 10b and Table S5). Temperature estimates are based on the (dry) equation of Helz
610 and Thornber (1987) recalibrated by Putirka (2008). Dissolved water content was calculated
611 from the plagioclase hygrometer of Lange et al. (2009) at 50 MPa. This pressure corresponds
612 to the average CO₂-H₂O saturation pressure (recalculated with Papale et al., 2006) typically
613 recorded in melt inclusions from central products at PdF (e.g. 1931 eruption in Di Muro et al.,
614 (2016) and references therein). This pressure roughly corresponds to the sea level depth,
615 which is inferred to be the location of the potential main shallow magmatic reservoir (Peltier
616 et al., 2009; Lengliné et al., 2016; Coppola et al., 2017). The application of the plagioclase
617 hygrometer of Lange et al. (2009) makes it possible to estimate the dissolved water content in
618 the melt with a nominal uncertainty of 0.15 wt% and is only slightly dependent on pressure.
619 Plagioclase compositions not in equilibrium with the melt (glass or bulk rock) are those of
620 mesocryst cores with the highest (An_{>76.5}) anorthite content (Fig. 10a and Table S5). Such
621 compositions are more in equilibrium with CaO-richer magnesian melts than those measured
622 in matrix glasses and bulk rocks of 2014 eruption and likely formed during early stages of
623 shallow magma differentiation (Fig. 10a).

624 In order to determine pre-eruptive conditions, calculations were performed only on
625 paired plagioclase rims and matrix glasses in equilibrium, using the plagioclase-melt
626 equilibrium constant of Putirka (2008) calibrated for melts whose temperature exceeds
627 1050°C ($K_{\text{An-Ab}} = 0.27 \pm 0.05$). Our review of published and unpublished data shows that melt
628 temperature progressively decreases from April 2007 (1188 \pm 16 °C) to January-October
629 2010 (1147 \pm 9°C) and positively correlates with K₂O content in melts which increases from
630 0.70 to 0.96 wt% (Fig. 10b). The melts from the June 2014 eruption record the lowest
631 temperatures in post-2007 eruptions (1131 \pm 15 °C) together with the highest K₂O-enrichment
632 (K₂O: 0.90 \pm 0.12 wt%). The lowest temperatures are recorded by spiny scoriae, while the
633 temperature of golden scoriae overlaps with that of 2010 products emitted before the 2010-
634 2014 phase of quiescence. In spite of the large variability in melt composition and
635 temperature, average pre-eruptive water content dissolved in the melts (0.5 \pm 0.2 wt%) is
636 quite homogeneous for the whole 2008-2014 period. In 2014, the lowest estimated dissolved
637 water content (down to 0.38 wt%) is for the golden and some fluidal scoriae, while the
638 maximum amount (0.68 wt%) is for the spiny opaque scoriae. However, water content
639 estimated from core-bulk rock equilibrium (0.3 \pm 0.1 wt%) is slightly lower than that estimated
640 from rim and microlite-matrix glass equilibrium (0.5 \pm 0.2 wt%), but the difference broadly
641 overlaps the nominal uncertainty related to calculations. Dissolved water contents in melts of
642 the pyroclasts are thus intermediate between those measured in 2007 melt inclusions (H₂O:
643 0.8 \pm 0.15 wt% and up to 1.1 wt%) and those typically found in degassed matrices of lava
644 and Pele's hairs of 2007 (Fig. 10; 0.2 wt%; see Di Muro et al., 2015; 2016).

645 **5 Discussions**

646 **5.1 Eruptive dynamics**

647 The activity fed by the uppermost WF and UF (Fig. 1) was very short-lived, as shown by the
648 presence of only scattered bombs and coarse lapilli (Figs 3d and 3e). The homogeneity of
649 these clasts, their coarse grained nature and the fluidal smooth texture are in agreement with
650 very short-lived fire-fountaining/magma jets. Glassy outer surfaces of clasts have been
651 interpreted as a late-stage product of fusion by hot gases streaming past the ejecta within the
652 jet/fountain (Thordarson et al., 1996; Stovall et al., 2011). However, the occurrence of this
653 process is not supported by the homogeneous glass composition in our fluidal clasts.
654 Therefore, we interpret these features here just as rapid quenching and not re-melting.
655 Vlastélic et al. (2011) have documented the mobility of alkalis and other elements on PdF

656 clasts that experienced long exposures to acid gases. In the 2014 eruption pyroclasts, the
657 mobility of elements is prevented by the short duration of the events.

658 At lower altitude and close to the MV (Fig. 1), the 5 cm layer at the base of the fall
659 deposit is fine-grained (Figs. 3b and 3c), rich in fluidal and golden fragments (Fig. 5), with a
660 perfect Gaussian grain size curve (Fig. 5), and similar to that reported from the weak 2010
661 fountaining event (Fig. 3f and Hibert et al., 2015). Therefore, we interpret this deposit as
662 being due to weak Hawaiian like fountaining (sustained, but short-lived) activity. We want to
663 remark here that this activity happened during the night and was not observed. The top of the
664 same deposit is coarse grained (Figs 3b and 3c), bimodal, has a lower content in coarse ash
665 (Table S2) and is rich in spiny opaque and spiny glass fragments (Fig. 5). The reverse grain
666 size likely records the transition from early continuous fountaining to late discrete
667 Strombolian activity (observed and recorded on the 21 of June 2014, Fig. 2). This transition in
668 activity is typical of many eruptions at PdF (Hibert et al., 2015). The reverse grading of the
669 whole deposit (Figs. 3b and 3c) is thus not correlated with an increase in energy of the event,
670 but with two different eruptive dynamics and fragmentation processes. The decrease in coarse
671 ash, which correlates with the decrease in energy of the event, highlights the most efficient
672 fragmentation process within the Hawaiian fountaining with respect to the slow gas ascent
673 and explosion of the Strombolian activity. These conclusions are consistent with (i) the
674 continuous and progressive decrease in intensity of Real time Seismic Amplitude
675 Measurement recorded by the OVPF seismic network (unpublished data), and (ii) satellite
676 derived TADR which suggest continuous decay of magma output rate after an initial short-
677 lived intense phase (Coppola et al., 2017).

678 **5.2 Interpretation of the different textural signatures and the meaning of the 4 typologies** 679 **of clasts.**

680 1) Background on the texture of clasts from Hawaiian and Strombolian activities

681 The first microtextural analysis of Hawaiian ejecta was performed by Cashman and Mangan
682 (1994) and Mangan and Cashman (1996) on pyroclasts from 1984 to 1986 Pu'u Ō'ō
683 fountainings. The authors defined two clast types: 1) 'scoria' consisting of closed-cell foam of
684 $\leq 85\%$ vesicularity, with round, undeformed, broadly-sized vesicles, and 2) 'reticulite', an
685 open-cell polyhedral foam with $\sim 1 \mu\text{m}$ thick vesicle walls with $>95\%$ vesicularity. They stated
686 that the scoria to reticulite transition is a consequence of Ostwald ripening, where larger
687 bubbles grow at the expense of smaller bubbles due to post-fragmentation expansion of clasts

688 within the fountain. According to this model, scoria preserves textures closer to conditions at
689 fragmentation, whereas continued vesiculation and clast expansion in the thermally-insulated
690 core of the fountain results in reticulate. This model was confirmed at lava fountains at Etna
691 (Polacci et al., 2006), Villarrica (Gurioli et al., 2008), Kīlauea Iki, (Stovall et al., 2011 and
692 2012), Mauna Ulu (Parcheta et al., 2013) and Al Madinah (Kawabata et al., 2015). These last
693 authors also measured the connected and isolated porosity in the AD1256 Al-Madinah
694 Hawaiian fountaining eruptions. They found that the reticulite-like textures from the central
695 part of these very high fountains showed isolated vesicles in agreement with low shear rates
696 and low viscosity melts, where bubbles may grow spherically and remain isolated. In contrast,
697 at margins of the fountains, high shear may lead to stretching and mechanical coalescence of
698 bubbles, forming the common, fluidal types of particles seen also in the deposits. They also
699 stated that lower vesicularity and greater isolated porosity were found in some tephra
700 interpreted as resulting from violent Strombolian eruptive phases.

701 The data that we found in our study of the typical activity of PdF agree only partially
702 with all these interpretations. The reason is that we sampled and measured products of very
703 weak Hawaiian to Strombolian activities. If we plot the approximate durations and masses of
704 these events on the Houghton et al. (2016) diagram, the 2014 activity of PdF falls into the two
705 fields for transient and fountaining activity, but at the base of the diagram. We here show for
706 the first time that short lived and weak fountaining can preserve pyroclast textures that record
707 magma ascent and fragmentation conditions before the explosions and also provide some
708 information about the pre-eruptive storage conditions. The occurrence of time-variable ascent
709 conditions is also reflected in the time evolution of eruptive dynamics, with the golden and
710 fluidal scoriae emitted from the low Hawaiian fountaining episodes and the spiny fragments
711 from the Strombolian-like explosions

712 2) The four typologies of clasts and their distribution in space and in time in the 2014
713 eruption at PdF

714 So, as described in 5.1, longitudinal variation in eruptive style along the fracture system
715 produces a spatial variability in the proportions of the four typologies of clasts. The
716 uppermost fractures (Western and Upper Fractures, Fig. 1a) are characterized solely by fluidal
717 fragments (Fig. 4b); they lack both the spiny and the golden components. In addition, these
718 fluidal clasts are the ones showing the smoothest surfaces (indicative of rapid quenching in a
719 very hot environment), low porosity values (between 50 to 77%, Fig. 6b), the highest content
720 in isolated vesicles (~ 30% in vol. Fig. 4c), and low vesicle numbers (3 to 5 x 10⁶, Fig. 4b),

721 comparable to the spiny fragments. They have scarce mesocrysts (1-2 % in vol. Table S3) and
722 very low amount of microcrysts of plagioclase and clinopyroxene (3 to 11 % in vol., Table
723 S3). These fluidal scoria fragments were emitted by short lived jets of magma, therefore they
724 underwent rapid quenching in a very hot environment that prevented any expansion or further
725 vesiculation and preserved a very high number of isolated vesicles (Fig. 6d). Syn-eruptive
726 crystallization was hindered by high ascent velocities in the dyke, due to the sudden release of
727 over-pressure in the shallow magma reservoir.

728 The four typology of clasts, golden pumice, fluidal scoria and the spiny fragments
729 (Fig. 4), were found associated only at the MV. The proportion of these fragments correlate
730 with the eruptive dynamics, being the golden lapilli and fluidal clasts dominant in the
731 Hawaiian, more energetic activity at the beginning of the eruption (during the night between
732 the 20 and the 21 of June 2014) and the spiny fragments dominant during the Strombolian
733 activity, coinciding with the decreasing in Mass Discharge Rate (MDR, early in the morning
734 of the 21, Fig. 2 and Coppola et al., 2017). The golden and fluidal fragments from the MV
735 show the highest porosity (86 %, Fig. 6a), variable proportions of isolated vesicles (Fig. 6c)
736 and high, but variable, N_V numbers (Figs. 4a). They are also characterized by a uniform
737 vesicle size population with clear evidence of incipient expansion, especially in the fluidal
738 fragments (Figs. 4a and 4b). From the connectivity graph, there is a clear decrease in isolated
739 vesicles with the increase in vesicularity (Fig. 6c). The content in crystal, mostly formed by
740 microcrysts of sodic plagioclase (Fig. 10a) due to magma degassing during its ascent and
741 decompression in the conduit (Di Muro et al., 2015), is very low, especially in the golden
742 pumice (up to 15% in vol.), and slightly higher for the fluidal clasts (up to 23 % in vol.). We
743 interpret the golden fragments, at the MV, to be the fastest (low amount of microcrysts) and
744 less degassed magma (high vesicularity coupled with high N_V), which experienced only a
745 very short residence time in the magma transport system (dyke+vent), followed by the fluidal
746 fragments. In contrast the spiny fragments, characterized by higher percentage of microcrysts
747 and mesocrysts, by the lack of isolated vesicles, by the presence of coalescence signature and
748 low N_V values (Figs. 4c and 4d), are indicative of an extensively degassed and cooled magma.
749 The presence of the mesocrysts (that formed in the shallow reservoir) in the spiny fragments,
750 and their slightly cooler temperature (Fig. 10b), strongly support this interpretation. The spiny
751 fragments likely record the slowest ascent velocity and the longest residence time in the
752 reservoir+dyke+vent system compared to the golden/fluidal counterpart. Therefore these
753 fragments are associated with Strombolian events, and decreasing MDR, in agreement with
754 their slower ascent that allows extensive syneruptive crystallization.

755 Among spiny fragments, the opaque ones are the densest, they lack a uniform glassy
756 surface, and they are characterized by i) very high microlite content, ii) strong coalescence
757 signature (Fig. 4d), iii) heterogeneous glass chemistry, and iv) mingling with hotter magma at
758 the clast edges (Fig. 8a). All these features reveal the composite nature of these clasts. We
759 interpret the spiny opaque as spiny glass fragments recycled inside the eruptive vent during
760 the explosions, being the densest portion of the magma prone to fall back in the vent/fracture
761 (Fig. 2b).

762

763 3) Degassing-driven versus cooling-driven crystallization

764

765 Syn-eruptive degassing is favoured by bubble connectivity/permeability in the ascending
766 magma, enhanced by syn-eruptive crystallisation in the conduit (especially microcrysts of
767 plagioclase, Fig. 10a), even for magmas at low vesicularity. However, our dataset also support
768 the occurrence of magma stratification in the reservoir. Textural and petrological data
769 demonstrate that the initial activity emitted a small volume of melt (represented by golden and
770 large part of the fluidal fragments) with very scarce crystals. This crystal-poor melt was
771 followed in time by the main volume of magma that contains a larger amount of mesocrysts
772 (spiny clasts and lava). Lava flows represent the main volume emitted in the 2014 eruption.
773 Mesocrysts are absent in the golden, scarce in the fluidal and more abundant in the spiny (Figs
774 4b, 4c and 4d) and lava (Fig. 4e) and consist in an equal percentage of plagioclase and
775 clinopyroxene and minor olivine. Their composition indicate that they formed in the reservoir,
776 as shown by their different composition in respect to the microcrysts counterparts (Fig. 10a)
777 that formed during melt degassing in the conduit. Most important, a large amount of
778 microcrysts in lava formed in the reservoir as well during magma cooling (Figure 10a). So,
779 we have a range of crystallization conditions. The fact that the lighter plagioclase are not
780 concentrated in the upper and early erupted portion of the reservoir can be due either to the
781 fact that often they are locked in clusters with the clinopyroxene or that this melt was expelled
782 from the crystal-rich portion of the reservoir (see Figure 10b). Water exsolution from the melt
783 can result from its extensive crystallization, which induces an increase in dissolved volatile
784 content, up to saturation (second boiling) and can drive melt-crystal separation.

785 In conclusion, the crystals in the 2014 fragments do reflect the shallow reservoir
786 conditions and the ascent degassing processes.

787

788 4) Textural syn-eruptive versus post fragmentation modifications

789

790 To prove that the 2014 vesiculation of the clasts have been not modified by post
791 fragmentation expansion process, following Stovall et al. (2011), we use a plot of vesicle-to-
792 melt ratio (V_G/V_L , after Gardner et al., 1996) and vesicle number density (N_V , Fig. 11). As
793 demonstrated by Stovall et al. (2011), addition of small bubbles leads to an increase in N_V and
794 only a slight increase in V_G/V_L . Bubble growth by some combination of diffusion and
795 decompression leads to an increase in V_G/V_L at constant N_V . N_V decreases while V_G/V_L
796 increases during bubble coalescence, whereas loss of bubbles via collapse or buoyant rise
797 leads to a reduction in both parameters. Intermediate trends on the diagram reflect
798 combinations of more than one of these processes. The pumice and the scoria from the MV of
799 PdF show the highest V_G/V_L , but also the highest N_V , suggesting preservation of small
800 vesicles and growth by some combination of diffusion and decompression. The presence of
801 the small vesicles and the lack of a strong coalescence/expansion signature confirm that the
802 weak PdF activity leads to only limited post-fragmentation expansion inside the hot portions
803 of the short-lived fountains. These data contrast with the data from the more energetic
804 fountaining events observed at Kilauea or elsewhere, where pre-eruptive information is
805 basically erased because pumice textures are dominated by expansion effects due to their
806 longer residence within the long-lived energetic fountaining. In contrast, the densest, spiny
807 scoriae and the scoria from the Fractures activity show the lowest values of N_V and V_G/V_L ,
808 due to incipient coalescence and/or loose/lack of small bubbles.

809 According to previous works (listed above), the golden pumice of PdF should be
810 derived from the central part of the fountains, but they do not show the strong post expansion
811 signatures reported in the literature (Fig. 11). It is interesting to note that the fluidal fragments
812 at the MV are less smooth (Fig. 4), more vesiculated, and have a lower content of isolated
813 vesicles than the fluidal scoria from the uppermost Fractures (Fig. 6). Therefore fluidal
814 fragments at the 2014 MV could indeed represent clasts that have been partly modified during
815 their residence in the external part of the fountains, while the golden samples could come
816 from the central part (Stovall et al., 2011 and 2012). However, the slight differences in
817 crystallinity and glass chemistry between the fluidal and golden fragments support the idea
818 that each of these fragments has an imprint from the pre-fragmentation setting. In contrast, the
819 spiny fragments from the MV and the fluidal fragments from the Fractures show low N_V and
820 low V_G/V_L in agreement with loss of vesicles and coalescence. However, the presence of large
821 numbers of isolated vesicles within the fluidal scoria from the Fractures agrees with their
822 provenance from a fast hot ejection of relatively degassed magma (low N_V). In contrast the

823 spiny fragments, especially because of the presence of abundant mesocrysts and increase in
824 syneruptive microcrysts, are indicative of the slowest ascent velocity and extensively
825 degassing and cooled magma. The spiny fragments are the most degassed, densest and the
826 most crystal rich magma that was emitted during low-energy activity by Strombolian
827 explosion, where recycling phenomena were also very frequent (Fig. 2f).

828 Our vesicle connectivity results are in full agreement with the recent review of
829 Colombier et al. (2017b). According to these authors, connectivity values can be used as a
830 useful tool to discriminate between the basaltic scoria from Hawaiian (fire fountaining) and
831 Strombolian activity. The broad range in connectivity for pumice and scoria from fire
832 fountaining is interpreted simply as being due to variations in the time available before
833 quenching due to differences in location and residence time inside the fountain. The fluidal
834 fragments from the WF are the richest in isolated vesicles because they are transported by
835 very short lived hot lava jets. In contrast, the higher connectivity observed in scoria from
836 Strombolian activity is probably related to their higher average crystallinity, and more
837 extensive degassing prior to the eruption, (Colombier et al., 2017b). The spiny surface of
838 these Strombolian fragments is due to the fact that these weak explosions emit only a small
839 solid mass fraction and the partially quenched dense clasts land quickly after a short cooling
840 path through the surrounding atmosphere (e.g. Bombrun et al., 2015).

841 All the clast, from golden to spiny, are very permeable, independent on their
842 vesicularity, crystal content and/or of the presence of isolated vesicles. This is in agreement
843 with our interpretation that magma degasses during its ascent in the conduit and that promotes
844 microlite nucleation (see the sodic plagioclase, Fig. 10a) before magma fragmentation (see
845 also Di Muro et al. 2015 with the Pele's hairs ad tears samples for the three 2008 eruptions).
846 Moreover, we always find that some of the spiny clasts (especially the opaque ones) are
847 slightly less permeable than the golden and fluidal ones, but not as impermeable as we would
848 expect by their low vesicularity.

849 In conclusion, we can state that i) the crystals lower the percolation threshold and
850 stabilize permeable pathways and ii) this is true for the syn-eruptive sodic plagioclase that
851 favor an efficient degassing in the relatively crystal-rich magma, because of their low wet
852 angles that favor degassing against nucleation (Shea, 2017) and their aspect ratio (e.g. Spina
853 et al. 2016) iii) therefore permeability develops during vesiculation through bubble
854 coalescence, which allows efficient volatile transport through connected pathways and
855 relieves overpressure (Lindoo et al., 2017). Pervasive crystal networks also deform bubbles
856 and therefore enhance outgassing (Oppenheimer et al., 2015). Based on Saar et al. (2001)

857 crystals should start to affect the behavior of the exsolved volatile phase when they approach
858 20 vol% (Lindoo et al., 2017). In our dataset, apart from the golden and part of fluidal, all the
859 other clasts do have microlites >20%. Our data completely support that slow decompression
860 rate allows more time for degassing-induced crystallization, which lowers the vesicularity
861 threshold at which bubbles start to connect.

862 Rapid re-annealing of pore throats between connected bubbles can happen due to short
863 melt relaxation times (Lindoo et al; 2016). This phenomenology could explain the high
864 amount of isolated vesicles in the fountaining samples. However, vesicle distributions of the
865 golden and fluidal fragments are almost perfect Gaussian curves, so it seems that if the
866 relaxation process happens it just merged perfectly with the expected vesicle distribution. In
867 contrast, coalescence and/or expansion (as we observe in the spiny fragments) do not fit the
868 curves (Fig. 4). In addition, we should expect that in crystal-poor fragments, due to melt
869 relaxing and pathways closure, the clasts became impermeable after quenching, as revealed
870 by some petrological experiments performed on crystal-poor basaltic magma (Lindoo et al.,
871 2016). In contrast, in high crystalline magmas, the presence of micro-crystals increases
872 viscosity thus preserving the coalesced textures (see Moitra et al., 2013). The isolated vesicle-
873 rich fragments of the 2014 PdF eruption are highly permeable, and are characterized by
874 variable ranges of porosity and numbers of vesicles (Fig.4 and Fig. 6d) that seem more related
875 to the pre-eruptive conditions than to the post relaxation of low-viscosity melts. In the 2014
876 crystal-poor samples, the permeability increases rapidly once the percolation threshold has
877 been reached, and efficient degassing prevents bubble volumes from expanding past the
878 percolation threshold (Rust and Cashman 2011).

879 **5.4 Integration between the physical and textural characteristics of the products and** 880 **their geochemical signature: insight into the feeding system**

881 According to Peltier et al. (2016), the June 2014 eruption emitted magma from a shallow
882 pressurized source located only 1.4-1.7 km below the volcano summit. Coppola et al. (2017)
883 suggest that the 2014 event was fed by a single shallow and small volume magma pocket
884 stored in the uppermost part of the PdF central plumbing system. All 2014 clasts show
885 homogeneous and evolved bulk compositions, irrespective of their textural features. June
886 2014 products are among the most evolved products erupted since at least 1998 and are
887 moderately evolved with respect to those emitted in 2010, just before the 2010-2014
888 quiescence. Bulk rock and melt inclusion data suggest that the 2014 evolved magma can be
889 produced by crystal fractionation during the long lasting (4.6 years) storage and cooling of the

890 magma injected and partly erupted in November 2009. The different types of scoria and
891 pumice emitted in 2014 show significant variations in glass composition (Fig. 8b) due to
892 variable degrees of micro-crystallization. In theory, microcrysts can reflect late stage (during
893 magma ascent and post-fragmentation) crystallization. In this case, their variable amount
894 within, for instance, the glassy and opaque parts of the spiny scoria might reflect slower
895 ascent velocity or longer residence time in the system (e.g. Hammer et al., 1999, Stovall et al.,
896 2012; Gurioli et al., 2014) in agreement also with the vesicle signature. However, the four
897 typologies of clasts differ also in terms of mesocryst content (from rare to 5 vol% for the
898 golden and fluidal and 14-23 vol% for the glassy spiny and spiny opaque, respectively).
899 Equilibrium plagioclase-melt pairs record an almost constant and moderate dissolved water
900 content, intermediate between that expected for melts sitting in the main shallow reservoir
901 (located close to sea level) and the degassed matrix of lavas. Dissolved water contents are
902 thus consistent with pre-eruptive magma water degassing during its storage at shallow level,
903 as suggested by geophysical data, and suggest that the plagioclase mesocrysts and some of the
904 microlites in the spiny scoria and in the lava grew during magma storage. Melt composition
905 records a potential pre-eruptive thermal gradient of ~ 30 °C between the hotter (pumice and
906 fluidal) and the cooler (spiny) magma.

907 Tait et al. (1989) suggest that magma evolution can lead to oversaturation of volatile
908 species within a shallow reservoir and trigger a volcanic eruption. At PdF, the golden and the
909 fluidal clasts might represent the portion of magma located at the top of the shallow reservoir
910 and enriched in bubbles of water rich fluids, released by the cooler, more crystallized and
911 more degassed “spiny-lava” magma (Fig. 10b). The small volume of magma, its constant bulk
912 composition and the very small inflation recorded prior to the eruption (Fig. 1d) could be
913 consistent with an internal source of over-pressure related to volatile exsolution. Larger
914 inflation rates over a broader area are expected when shallow reservoir pressurization is
915 related to a new magma input from a deeper source. Slight baseline extensions both on distal
916 and proximal sites suggest that magma transfer towards shallower crustal levels started short
917 before (11 days) the final magma eruption. Geochemical data do not support the occurrence of
918 a new magma input in the degassed and cooled 2014 reservoir. We can thus speculate that
919 stress field change related to progressive deep magma transfer has promoted volatile
920 exsolution, melt-crystal separation and melt expansion in the shallow reservoir. Textural
921 heterogeneity of the 2014 products partly reflects a pre-eruptive physical gradient recorded by
922 the variability in crystal and bubble contents in the shallow reservoir feeding this eruption.
923 The golden and fluidal fragments are the bubble richer and hotter portion of the melt. The

924 spiny fragments are the degassed and cooler portion of the reservoir, whose progressive
925 tapping led to a decrease in explosive intensity (from fountaining to Strombolian activity).
926 Our results are also consistent with processes of mechanical reservoirs/dyke stratification, as
927 observed by Menand and Phillips (2007). As explained earlier, magma ascent promoted
928 syneruptive degassing induced crystallization. The spiny opaque clasts can be considered as
929 being recycled material that fell back into the system. Accumulation of olivine crystals out of
930 equilibrium with the host magma produces minor variations in mesocryst contents as
931 observed within the same type of clasts sampled at different times/locations during the
932 eruption, with the scoria from the WF and early erupted lava being the ones with the lowest
933 amount of olivine (Table S4 and Fig. 7b). Again, this temporal variation supports an increase
934 in large heavy crystals within the most degassed magma emitted toward the end of activity,
935 further suggesting that it corresponds to the lower part of the reservoir.

936 Our dataset permits us to propose that the 2014 eruption was fed by a physically zoned
937 magma reservoir. The lighter crystal-poor, bubble-rich magma located at reservoir top
938 ascended first, rapidly and fed the early more energetic phase, the Hawaiian fountaining. This
939 lighter magma is not more evolved than the spiny one (same bulk compositions) and it is not
940 necessarily richer in dissolved volatile amounts; it is just poorer in crystal and richer in
941 bubbles. Second boiling, possibly triggered a few days before the eruption by stress field
942 change, is responsible of the extraction of bubble rich melt from a crystal-rich network. This
943 last one is represented by the main volume of the erupted lava. Fast ascent of the foam hinders
944 its crystallization and preserves high number of vesicles, high vesicularity and it is only little
945 modified by post-fragmentation expansion. Decrease in initial overpressure translates in a
946 progressive decrease in magma ascent rate and output rate (e.g. Coppola et al., 2017 and
947 references therein). Nucleation of microcrysts is enhanced in melt ascending with lower speed
948 and is mostly related to syneruptive degassing (for the spiny).

949 The larger volume (dense lava) corresponds to crystallized and less vesiculated magma
950 which experiences a slow ascent in the dyke and even further micro-crystallisation during its
951 subaerial emplacement.

952 Melt inclusion results allow us to confirm the involvement of a single and only slightly
953 heterogeneous magma source in 2014, related to cooling and fractional crystallisation of an
954 older magma batch (November 2009). Interestingly, this latter short lived summit eruption
955 was also characterized by the same large range of pyroclastic products found in 2014 in spite
956 of its more mafic composition.

957 This suggests that bubble accumulation and source pressurisation is highly dependent
958 on the shallow storage depth, which facilitates rapid water exsolution (Di Muro et al., 2016),
959 and it is not necessarily the outcome of slow magma cooling and differentiation (Tait et al.,
960 1989).

961

962 **6. Proposed model for the 2014 eruption and conclusions**

963

964 In this paper we show that textural and petro-chemical study of the eruptive products can be
965 used to characterize the on-going activity at PdF and to constrain both the trigger and the
966 evolution of short-lived and small-volume eruptions. This approach is extremely valuable in i)
967 understanding processes that lead to an eruption which was preceded by short-lived and
968 elusive precursors, and ii) in reconstructing the time evolution of eruptive dynamics in an
969 eruption with poor direct observations.

970 Following the sketch in Figure 12, we infer that residual magma from the 2009
971 eruption ponding at shallow levels experienced long-lasting cooling and crystallization (Fig.
972 12a). Between 2010 and 2014 the volcano progressively deflated (Fig. 12b) possibly because
973 of magma degassing and cooling, facilitated by the shallow depth of the reservoir. During this
974 phase mesocrysts and some microlites formed (Figs. 4e and 10a).

975 The occurrence of deep (>10 km bsl) lateral magma transfer since March-April 2014
976 has been inferred by Boudoire et al., (2017) on the basis of deep (mantle level) seismic
977 swarms and increase in soil CO₂ emissions on the distal western volcano flank. The incipit of
978 magma transfer towards shallower crustal levels is potentially recorded by subtle volcano
979 inflation about 11 days before the June 2014 eruptions (Figs. 1d and 12c). We suspect that
980 these deep processes can have progressively modified the shallow crustal stress field and
981 favoured magma vesiculation and melt-crystal separation. Second boiling could thus have
982 over-pressured the shallow seated reservoir and triggered magma ascent (Fig. 12c).

983 Without this deep magma transfers we believe that the small reservoir activated in
984 2014 would have cooled down completely to form an intrusion (as suggested by the pervasive
985 crystallization of the lava, one of the densest emitted from 2014 to 2017). The 2014 event
986 represented instead the first of a long series of eruptions, whose magmas became
987 progressively less evolved in time (Coppola et al., 2017). In this scenario the trigger
988 mechanisms of 2014 activity are both internal and external in the sense that the small shallow
989 reservoir hosting cooled magma permitted to create the conditions favourable to a second
990 boiling (Fig. 12c, and Tait et al., 1989). The second boiling was likely trigger by an almost

991 undetectable stress field change, and was favoured by the shallow storage pressure of the
992 magma (Fig. 12c) that promotes fast water exsolution and rapid magma response to external
993 triggers. The second boiling possibly contributed to the inflation registered 11 days before the
994 eruption at 1.4-1.7 km (Fig. 12c) caused both by magma expansion and transfer of hot fluids
995 to the hydrothermal system (Lénat et al., 2011).

996 Our data permit to exclude (i) new magma input and/or fluid inputs (CO₂-rich fluids)
997 from deep magmatic levels to trigger the June 2014 eruption. We also exclude (ii) heating and
998 enhanced convection of the shallow magma reservoir (due to heat diffusion without fluid or
999 mass transfer), because this process is very slow. Furthermore, the 2014 minerals do not
1000 record evidences of magma heating. We can exclude equally (iii) deformation of the volcanic
1001 edifice and decompression of the magma reservoir and/or hydrothermal system due to flank
1002 sliding because geodetic data show no evidence of flank sliding able to produce stress change
1003 in the hydrothermal and magmatic system. Geophysical and geochemical data have permitted
1004 to track vertical magma and fluid transfer below the volcano summit in April 2015, that is
1005 about one year after the early deep lateral magma transfer (Peltier et al., 2016). Deep
1006 processes are difficult to detect for any monitoring network.

1007 We conclude that the overpressure, caused by the second boiling, triggered the
1008 eruption. The occurrence of a hydrous almost pure melt at shallow depth permitted its fast
1009 vesiculation upon ascent towards the surface. In turn, fast ascent of the foam (Fig. 12d)
1010 hindered its crystallization and preserved high number of vesicles. Decrease in initial
1011 overpressure translated in a progressive decrease in magma ascent rate and output rate (e.g.
1012 Coppola et al., 2017 and references therein) and a temporal transition from Hawaiian activity
1013 to Strombolian activity (Fig. 12 d). Nucleation of microcrysts was enhanced in melt ascending
1014 with lower speed and in turn this syn-eruptive crystallization favoured bubble
1015 connectivity/permeability in the ascending magma, even for magma at low vesicularity. The
1016 largest volume (dense lava) corresponds to highly-crystallized and degassed magma already
1017 in the reservoir, that experienced a slower ascent in the dyke and even further micro-
1018 crystallisation during its subaerial emplacement.

1019 The texture of the products allowed us to follow the dynamic evolution of the system
1020 in space, from smooth fluidal scoria emitted from rapid jet of lava at the fractures, to a more
1021 stable activity at the MV, and in time. At the MV, in fact, we observed the transition from the
1022 golden and fluidal fragments emitted from Hawaiian fountaining, at the peak of the intensity
1023 of the eruption, to the spiny fragments, emitted from a declining Strombolian activity at the
1024 end of the eruption.

1025 Therefore we here show for the first time that short lived and weak Hawaiian
1026 fountaining and Strombolian events can preserve pyroclast textures that can be considered a
1027 valid approximation to magma ascent and fragmentation conditions before the explosions and
1028 correlate to the eruptive dynamics as well.

1029 To conclude, these results highlight the importance of petrological monitoring, which
1030 can provide complementary information regarding the ongoing volcanic activity to other
1031 geophysical and geochemical monitoring tools commonly used on volcanoes.

1440 **Figure 4** Textural features of June 2014 pyroclasts and lava. Clast = photo of the different types of juvenile pyroclasts and lava channel. The
1441 photo of the lava channel is from Laurent Perrier. WF = Western Fracture (smooth fluidal scoria), MV = Main Vent (fluidal scoria, less smooth
1442 than the ones at the WF). Thin section = thin section imaged with a desktop scanner. Microscope = picture taken with an optical microscope
1443 using natural light; SEM (25X) = image captured using a scanning electron microscopy (SEM), in BSE mode at 25x magnification: black are
1444 vesicles, white is glass, grey are crystals. VSD = vesicle volume distribution histograms, where the diameter, in mm, is plotted versus the volume
1445 percentage, n = number of measured clasts; Crystal vol. % : Tot = total percentage of crystals corrected for the vesicularity; Mplg = percentage
1446 of mesocrysts of plagioclase; μ plg = percentage of microcrysts of plagioclase; Mcpx = percentage of mesocrysts of pyroxene; μ cpx = percentage
1447 of microcrysts of pyroxene; Nv = number density corrected for the vesicularity.

1448

1449

1450

1451

1452 **Figure 5** Proportion of each type of clast measured from the base to the top of the 10 cm thick
1453 deposit emplaced during the eruption, at the MV site. The deposit is dominated by Hawaiian-
1454 like lapilli fragments at the base (golden pumice and fluidal scoria) and Strombolian-like
1455 bombs and lapilli at the top (spiny scoria): (a) componentry within the different grain size
1456 classes; b) normalized componentry composition from the base to the top of the deposit.

1466

1467 **Figure 6** Density, connectivity and permeability data of June 2014 pyroclast and lava
 1468 fragments: a) density distribution histogram for all the pyroclast fragments measured at the
 1469 MV + two lava fragments collected from the Eastern front of the lava flow (see Fig. 1 for
 1470 location). n = number of measured clasts; b) density distribution histogram for the pyroclasts
 1471 sampled at the WF and the bomb sampled at the UF. The bomb broke in five fragments (2
 1472 fragments from the core, the least dense, and three fragments from the quenched edges, the
 1473 densest); and c) In both the density histograms the stars represent the density intervals from
 1474 which we picked the clasts for the textural measurements; c) graph of the connected
 1475 vesicularity versus total vesicularity. The diagonal line represents equality between the
 1476 connectivity and vesicularity, beneath this line the samples have isolated vesicles and the
 1477 straight lines represent lines of equal fraction of isolated vesicles. To note that the bomb from
 1478 the UF has the high vesicular core with less than 5% of isolated vesicles, while the three low
 1479 vesicular fragments from the core have more than 25% of isolated vesicles (see pink spots); d)
 1480 Darcian permeability (k_1) versus the vesicularity fraction. Data from June 2014 eruption and
 1481 February 2015 eruption are reported.

1482

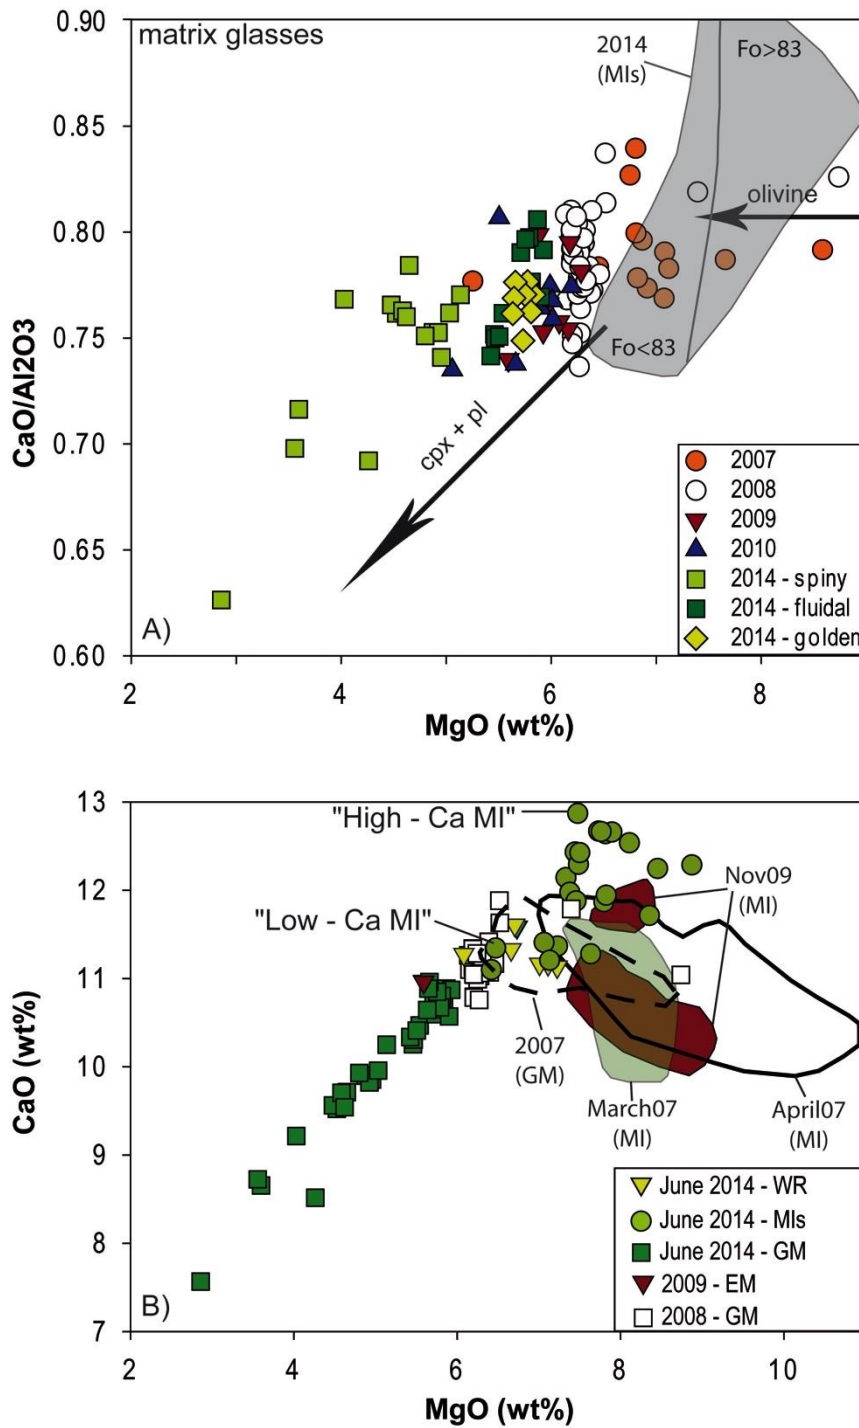

1483

1484 **Figure 7** Ni-Cr concentration plot. (a) Ni-Cr signature of the June 2014 lavas compared to
 1485 that of recent eruptions (Di Muro et al. (2015) and unpublished data). Whole-rock (circles)

1486 and glass (triangles) compositions are shown for the June 2014 eruption. Olivine controlled
1487 lines are indicated for olivine hosting 1.2 and 0.6 wt.% Cr-spinel. Compositions used for
1488 olivine (Ni=1900 ppm, Cr=300ppm), clinopyroxene (Ni=970 ppm, Cr=4800 ppm), and Cr
1489 spinel (Ni=1500 ppm, Cr=25%) are inferred from Salaün et al. (2010), Di Muro et al. (2015)
1490 and Welsch et al. (2009). (b) Zoom of the Ni-Cr relationship between glass (triangles) and
1491 whole-rock (circles) samples from the June 2014 eruption. Fracture I = Western Fracture,
1492 Fracture II = Upper Fracture. Careful sample selection has permitted to obtain a set of
1493 virtually olivine-cpx free crystals. Any addition of mafic crystals translates into enrichment in
1494 Ni-Cr; those samples that contain a few % of crystals (consistent with textural and
1495 petrological observation) are slightly enriched in compatible elements.

1496

1497

1498

1499 **Fig. 8** (a) Evolution of CaO/Al₂O₃ ratio in the matrix glasses of recent eruptions at Piton de la
 1500 Fournaise as a function of MgO content (directly proportional to melt temperature). MI =
 1501 Melt inclusions (grey area for the 2014 samples). (b) CaO versus MgO content for Piton de la
 1502 Fournaise products. WR = whole rock, GM = ground mass; MI = melt inclusion, EM =
 1503 embayment glass

1519

1520 **Figure 10** a) Anorthite versus Albite compositions for the plagioclase crystals measured for
 1521 June 2014 eruption of PdF; b) Temperature, composition (K₂O) and dissolved water content
 1522 (H₂O) for the evolution of 2007-2014 melts from glasses. The data have been obtained by

1523 studying the glass-plagioclase equilibrium or on the basis of matrix glass analyses.
1524 Temperature estimation based on the MgO-thermometer of Helz and Thornber (1987)
1525 modified by Putirka (2008). Water content from the plagioclase hygrometer of Lange et al.
1526 (2009). Only plagioclases in equilibrium with melts are considered, following the procedure
1527 described by Putirka (2008) for $>1050^{\circ}\text{C}$ melts ($K_d = 0.27 \pm 0.05$). Error bars reported in
1528 Figure 10b correspond to the standard deviation of the plagioclase dataset, whose range is
1529 larger than error of the method. We stress that reported temperatures are obtained using Helz
1530 dry model; further uncertainty arises from the dependence of the method on dissolved water
1531 content as shown recently by Putirka (2008); in order to minimize the number of assumptions
1532 and perform a comparison between distinct eruptions, we preferred to adopt the dry model.
