ABSTRACT

Geologic carbon storage, as well as other geo-energy applications, such as geothermal energy, seasonal natural gas storage and subsurface energy storage, imply fluid injection/extraction that causes changes in the effective stress field and induces (micro)seismicity. If felt, seismicity has a negative effect on public perception and may jeopardize wellbore stability and damage infrastructure. Thus, induced earthquakes should be minimized to successfully deploy geo-energies. However, the processes that trigger induced seismicity are not fully understood, which translates into a limited forecast ability of current predictive models. We aim at understanding the triggering mechanisms of induced seismicity and to develop methodologies to minimize its occurrence through dimensional and numerical analysis. We find that the properties of the injected fluid, e.g., water or CO₂, have a significant effect on pressure buildup evolution and thus, on fracture/fault stability. In addition to pressure changes, the injected fluid usually reaches the injection formation at a lower temperature than that of the rock, inducing rock contraction, thermal stress reduction and stress redistribution around the cooled region. If low-permeable faults cross the injection formation, local stress changes are induced around them which may reduce their stability and eventually cause fault reactivation. To minimize the risk of inducing felt seismicity, we have developed characterization techniques to reduce the uncertainty on rock properties and subsurface heterogeneity both for the screening of injection sites and for the operation of projects. Overall, we contend that felt induced seismicity can be minimized provided that a proper site characterization, monitoring and pressure management are performed.

Keywords: fluid injection, pressure buildup, coupled processes, caprock integrity, fault reactivation

1. INTRODUCTION

The interest in subsurface energy resources, such as geothermal energy, seasonal natural gas storage, subsurface energy storage and geologic carbon storage, has significantly increased as a means to mitigate climate change (IPCC, 2018). In particular, geologic carbon storage has the potential to store large amounts of carbon dioxide (CO₂) in deep geological formations, reducing CO₂ emissions to the atmosphere (Hitchon et al., 1999; Celia, 2017). Such subsurface energy-related activities imply fluid injection/extraction that change the pore pressure and thus, the effective stresses, causing deformation and potentially fracture and/or fault reactivation that may lead to induced (micro)seismicity (Ellsworth, 2013; Grigoli et al., 2017).

Induced microseismicity, i.e., seismicity of such low magnitude that is not felt on the ground surface (typically moment magnitude, $M < 2$), is positive if confined within the injection formation because shear slip of fractures enhances permeability (Yeo et al., 1998; Vilarrasa et al., 2011; Rutqvist, 2015). This permeability enhancement permits injecting the same amount of fluid at a lower injection pressure, thus reducing compression costs. However, induced microseismicity should be avoided in the caprock because its sealing capacity could be compromised, which could lead to CO₂ leakage. Additionally, if felt, induced earthquakes may damage wells, buildings and infrastructure and may cause fear and nuisance among the local population (Oldenburg, 2012). As a result of these negative effects, several projects have been cancelled before they entered into operation, such as an enhanced geothermal system at Basel, Switzerland (Häring et al., 2008; Deichmann et al., 2014), a geothermal project at Sankt Gallen, Switzerland (Edwards et al., 2015; Diehl et al., 2017) and the seasonal gas storage project of Castor, Spain (Cesca et al., 2014; Gaité et al., 2016). Thus, felt induced seismic events have to be

minimized, and ideally avoided, in order to achieve a successful deployment of geo-energy projects.

Geologic carbon storage projects, both at large scale and pilot scale, have not induced any felt earthquake to date (White and Foxall, 2016). This lack of felt seismicity may be due to some favorable aspects of CO₂ storage with respect to water injection that will be explained in this paper. Yet, induced microseismicity is common, such as at In Salah, Algeria (Stork et al., 2015; Verdon et al., 2015), Decatur, Illinois (Kaven et al., 2015; Bauer et al., 2016), and Otway, Australia (Myer and Daley, 2011), projects. Despite the previous absence of felt seismicity, proper protocols should be defined and followed to avoid inducing felt earthquakes in future geologic carbon storage projects.

The aim of this paper is to examine the potential causes of induced seismicity in geologic carbon storage and to explain methodologies that can serve to minimize the risk of inducing felt seismic events. First, the potential triggering mechanisms of induced seismicity are explained. Next, the stress state of deep geological formations, the pressure buildup evolution and non-isothermal effects resulting from CO₂ injection are described. Then, how CO₂ injection affects fault stability is analyzed and, finally, subsurface characterization techniques that can be used for minimizing the occurrence of felt induced seismicity are presented.

2. TRIGGERING MECHANISMS

The basic principle of induced seismicity is that the pressure build-up caused by fluid injection reduces the effective stresses, which brings the stress state closer to failure (Figure 1). If failure conditions are reached, the elastic energy stored in the rock mass is released and a (micro)seismic event is induced. Failure in geomaterials can occur either

in tensile or shear mode (Jaeger et al., 2009). While tensile failure induces microseismic events of such low magnitude that cannot be felt on the ground surface, shear failure may lead to felt earthquakes if a sufficiently large area of a pre-existing fracture or fault is reactivated. Nevertheless, in the cases in which tensile failure is sought, i.e., to create

5 hydraulic fractures in low-permeable rock to enhance its permeability, shear failure of pre-existing faults may also occur, which may induce felt earthquakes associated to hydraulic fracturing operations (Rubinstein and Mahani, 2015). For example, a felt earthquake occurred at the Preese Hall 1 exploration well for shale gas near Blackpool, UK, during hydraulic fracturing because a pre-existing nearby fault was reactivated

10 (Clarke et al., 2014).

In principle, fluid pressure buildup may seem the only mechanism that induces seismicity. Thus, intuition suggests that stability should improve in the vicinity of the injection well after injection is stopped because fluid pressure drops rapidly. Far away from the injection well, fluid pressure continues to rise and thus, pressure-diffusion could explain continued

15 post-injection induced seismicity (Hsieh and Bredehoeft, 1981), observed for example after the stimulation of enhanced geothermal systems (EGS) (Parotidis et al., 2004). However, pressure-diffusion cannot explain why the magnitude of post-injection seismicity is often higher than that induced during injection, e.g., at Basel, Switzerland (Deichmann and Giardini, 2009), at Soultz-sous-Forêts, France (Evans et al., 2005), and

20 at Castor, Spain (Gaite et al., 2016). Even though this high magnitude post-injection seismicity has not been observed in geologic carbon storage projects, its causes should be understood in order to avoid its occurrence. The counterintuitive occurrence of post-injection induced seismicity is due to the fact that fluid injection in the subsurface involves coupled processes that are more complex than just the hydraulic effect:

- The stress state changes in response to pore pressure variations (Streit and Hillis, 2004; Rutqvist, 2012). Specifically, the total stress increases in the direction of flow due to the lateral confinement that opposes to the expansion of the rock in this direction (Zareidarmiyān et al., 2018). This poro-mechanical effect modifies
5 the initial stress state and thus, the analysis of fault stability cannot be performed as a simple subtraction of the pressure build-up from the initial effective stress state.
- The injected CO₂ usually reaches the injection depth at a colder temperature than that of the rock because CO₂ does not reach thermal equilibrium with the
10 geothermal gradient along its way down the well (Paterson et al., 2008). As a result, the injection formation cools down around the injection well, inducing a thermal stress reduction that brings the stress state closer to failure conditions (Vilarrasa and Rutqvist, 2017). The magnitude of induced thermal stresses is proportional to the rock stiffness. Thus, induced thermal stresses depend on the
15 rock type in which fluid is injected, becoming larger in reservoir rocks than in clay-rich caprocks because they are usually stiffer (Vilarrasa and Makhnenko, 2017).
- The stress changes that arise in the storage formation and the caprock as a result of pressure build-up and cooling vary depending on the rock properties and the
20 contrast between geological layers (Verdon et al., 2011).
- Each (micro)seismic event provokes a stress redistribution around the portion of the fracture or fault that undergoes shear slip (Okada, 1992). This stress transfer controls the distribution of aftershocks in natural seismicity (King et al., 1994) and may be the reason for observed rotations in the direction of the sheared faults

in sequences of induced seismicity during stimulation of EGS (De Simone et al., 2017).

- Not all the shear slip occurring in fractures or faults induces seismic events. Actually, shear slip may occur aseismically (Cornet et al., 1997). This aseismic slip may induce (micro)seismic events away from the slipped surface (Guglielmi et al., 2015).
- Geochemical reactions may alter the frictional strength of faults, which could lead to failure conditions if a fault is weakened. However, laboratory studies have shown that this effect is in general minor (Rohmer et al., 2016), even on fault gouges that have been exposed to acidic conditions for a long period in natural CO₂ reservoirs (Bakker et al., 2016).
- Heterogeneity in the rock type, strength of faults and the stress field, which may present local variations around faults (Faulkner et al., 2006), affect fault stability. However, the knowledge on the role of heterogeneity in induced seismicity is still limited.

All these potential triggering mechanisms are usually neglected because pressure-diffusion is considered sufficient to explain induced seismicity. Though pore pressure diffusion alone may explain certain sequences of induced events (Shapiro et al., 2002), sequences are usually more complex and imply a combination of several coupled processes. For example, cooling-induced stresses resulting from CO₂ entering the storage formation 45 °C colder than the rock may explain part of the microseismicity detected at In Salah, Algeria (Vilarrasa et al., 2015). Another example is Weyburn, Canada, where the scarce microseismic events (around 200) that were induced in the caprock at the beginning of injection were interpreted to be caused by stress changes resulting from the contrast in stiffness between the reservoir and caprock (Verdon et al., 2011). Thus, when

assessing the potential for induced (micro)seismicity of CO₂ storage projects, all these coupled processes should be considered (Figure 2).

3. STRESS STATE

5 A careful examination of the subsurface stress state reveals that while crystalline rocks are critically stressed, sedimentary rocks are generally not critically stressed (Vilarrasa and Carrera, 2015). Since CO₂ will be stored in sedimentary basins, their absence of criticality of stress implies that a certain pressure buildup and cooling can be applied without reaching failure conditions (Figure 3). However, the stress state at each site
10 should be measured in order to determine the maximum sustainable injection pressure and maximum temperature drop that would lead to a safe CO₂ storage (Rutqvist et al., 2007; Kim and Hosseini, 2014). Thus, stress measurements should be routinely performed during wellbore perforation, determining both the magnitude and orientation of the principal stresses (Cornet and Jianmin, 1995). Once the stress state is known, the
15 range of fault strike and dip that is favorably oriented for reactivation can be determined (Morris et al., 1996). This exercise is crucial to identify faults that may induce large seismic events and to foresee an optimal design of the injection strategy and define mitigation measures (e.g., Birkholzer et al., 2012; Buscheck et al., 2012; Dempsey et al., 2014) if induce seismicity is predicted to possibly occur above a predefined threshold.

20 The dependence of the stress state on the rock type is due to the contrast in the rock stiffness. Since crystalline rocks are much stiffer than sedimentary rock, stresses induced by tectonics mainly accumulate in the crystalline basement. In contrast, the relatively soft sedimentary rocks deform without accumulating large stresses and as a result they do not usually become critically stressed. It goes without saying there may be cases of critically

stressed sedimentary rocks, which may lead to unexpected high seismicity if no stress measurements are performed.

4. PRESSURE BUILDUP EVOLUTION

5 The pressure buildup evolution of CO₂ injection is favorable to achieve a long-term geomechanically stable situation. In contrast to water injection, which yields a linear increase of pressure with the logarithm of time when a continuous flow rate is injected (Theis, 1935), CO₂ leads to a peak at the beginning of injection followed by a relatively constant pressure buildup (Figure 4). Thus, pressure buildup is relatively easy to control
10 in CO₂ injection operations, which should help to minimize induced (micro)seismicity (Vilarrasa and Carrera, 2015). Such pressure evolution has been observed in the field, at Ketzin, Germany (Henniges et al., 2011), numerically (Vilarrasa et al., 2010; Okwen et al., 2011) and analytically (Vilarrasa et al., 2013a).

The initial sharp increase in pressure buildup is due to a local reduction in permeability
15 caused by the desaturation around the injection well (Figure 4b), which decreases the relative permeability of both CO₂ and water. However, once CO₂ fills the pores around the injection well (Figure 4c), the CO₂ relative permeability rises. Additionally, since CO₂ viscosity is one order of magnitude lower than that of brine, CO₂ can flow easily inside the storage formation, which leads to a constant or even a slight drop in pressure buildup
20 (Figure 4a). This fluid pressure evolution induces the largest effective stress changes in the caprock at the beginning of injection, coinciding with the peak in pressure buildup. Thus, progressively increasing the flow rate at the beginning of injection may avoid the initial peak in pressure buildup, minimizing the effect on the caprock integrity.

Maintaining the caprock integrity in the long-term is also favored by two effects that tend to decrease pressure buildup inside the storage formation: (1) CO₂ dissolution into the resident brine, and (2) brine flow across the low-permeability formations that confine the storage formation, i.e., caprock and base rock (Vilarrasa and Carrera, 2015). On the one
5 hand, when CO₂ dissolves into brine, fluid pressure decreases because the total fluid volume is reduced (Mathias et al., 2011a). As observed in natural analogues, the percentage of CO₂ that may become trapped by dissolution can be as high as 90% in carbonate storage formations (Gilfillan et al., 2009). In the short-term, CO₂ dissolution can also be high in storage formations with high vertical permeability ($k > 10^{-13}$ m²)
10 because of the formation of gravity fingers of CO₂-rich brine (Riaz et al., 2006; Hidalgo and Carrera, 2009; Pau et al., 2010). On the other hand, caprock permeability at the field scale is two to three orders of magnitude larger than that at the core scale as a result of the presence of fractures and faults (Neuzil, 1994). Thus, resident brine of the storage formation can flow across the caprock and base rock, lowering the pressure buildup inside
15 the storage formation. Though brine can flow through the caprock, CO₂ cannot because of the high entry pressure of clay-rich formations (Benson and Cole, 2008).

5. NON-ISOTHERMAL EFFECTS

In addition to pressure buildup, thermal effects are also relevant in geologic carbon
20 storage because temperature changes induce thermal stresses that affect fracture stability (Vilarrasa and Rutqvist, 2017). CO₂ reaches the bottom of the injection well at a temperature lower than that of the storage formation because CO₂ flow within the well is isenthalpic (Pruess, 2006) and thus, it heats up at a lower rate than the geothermal gradient (Lu and Connell, 2008). As a result, the rock around injection wells cools down (Figure

5b). The advance of the cooling front with respect to the CO₂ plume is retarded because the rock has to be cooled down (compare Figures 5a and 5b) (Bao et al., 2014; LaForce et al., 2015). Cooling mainly advances by advection in the reservoir, but it also extends into the lower portion of the caprock by conduction (Figure 5b). The extent of the cooling region can become of a few hundreds of meters after some decades of CO₂ injection at industrial scale rates, i.e., megaton injection (Vilarrasa et al., 2014). Thus, unless faults are present in the vicinity of the injection well, they will not be directly affected by cooling. Nevertheless, faults placed far from the cooling region may undergo stability changes as a result of the contraction of the cooled rock, which causes a change in the far-field stresses (Jeanne et al., 2014).

The cooling-induced rock contraction and thermal stress reduction approach the stress state towards shear failure conditions and tensile fractures could be formed if the tensile strength was reached (Luo and Bryant, 2010; Goodarzi et al., 2010; 2012; Gor et al., 2013). The temperature-induced stresses are not isotropic, and thus, the effect on fracture stability depends on the stress regime, i.e., normal faulting, strike-slip or reverse faulting (Vilarrasa, 2016). In general, fracture stability becomes more compromised in the reservoir than in the caprock, which may lead to injectivity enhancement while maintaining the caprock sealing capacity (Goodarzi et al., 2015; Vilarrasa et al., 2017a). This favorable situation specially occurs in normal faulting stress regimes (Vilarrasa et al., 2013b; Kim and Hosseini, 2015).

Figure 6 displays the stress changes that are induced in the reservoir and caprock as a result of cooling and how they affect fracture stability in a normal faulting stress regime. Both the vertical and horizontal stresses decrease inside the reservoir within the cooled region. This stress reduction is proportional to the rock stiffness, the rock thermal expansion coefficient and the temperature change. The vertical stress reduction within the

reservoir causes a disequilibrium in this direction because the overburden on top of the reservoir remains constant (Figure 6a). Thus, to satisfy stress equilibrium and displacement compatibility, the horizontal stresses increase in the lower portion of the caprock, tightening it (Figure 6b). As a result of these stress changes, shear failure conditions are reached within the reservoir, but the caprock remains stable (see the Mohr circles in Figure 6). This contrast in stability between the reservoir and the caprock is highlighted in Figure 5c, which shows that plastic strain, i.e., strain that occurs because failure conditions have been reached, only takes place in the reservoir and not in the caprock (for details on the failure surface, see Vilarrasa and Laloui, 2015). Thus, cold CO₂ injection, i.e., in liquid state (Vilarrasa et al., 2013b), should not be feared because the caprock sealing capacity is not compromised.

6. FAULT STABILITY

Faults are present at the field and basin scale, as observed in CO₂ storage projects (e.g., Vidal-Gilbert et al., 2010; Rutqvist, 2012; Castelletto et al., 2013a). To name a few, (i) a fault or fractured rock zone opened as a result of pressure buildup at In Salah, Algeria, leading to a double-lobe pattern of uplift on the ground (Vasco et al., 2010; Rinaldi and Rutqvist, 2013); (ii) the storage formation at Snøhvit, Norway, was surrounded by low-permeable faults, which limited its storage capacity (Hansen et al., 2013; Chieramonte et al., 2015); (iii) the Spanish pilot test site at Hontomín contained several minor faults within a few hundreds of meters from the injection well (Alcalde et al., 2013; 2014); and (iv) the pilot test site at Heletz, Israel, is placed in an anticline crossed by two faults, confining the storage formation to a few hundreds of meters (Figueiredo et al., 2015). The nature of these faults, i.e., flow barriers or conduits (Caine et al., 1996), controls the stress

changes occurring around the fault and thus, fault stability (Vilarrasa et al., 2016). Low-permeable faults may lead to the premature closure of storage sites because of pressure limitations on the storage capacity of the formation (Szulczewski et al., 2012). Actually, if multiple low-permeable faults are present and intersecting each other, they will lead to
5 a compartmentalized reservoir (Castelletto et al., 2013b). In such cases, pressure would increase linearly with time (Zhou et al., 2008; Mathias et al., 2011b), eventually leading to fault reactivation, and thus induced seismicity, if injection is maintained at a constant rate (Cappa and Rutqvist, 2011a; Pereira et al., 2014; Rutqvist et al., 2016).

Fault reactivation may enhance fault permeability due to dilatancy by one to two orders
10 of magnitude (Cappa and Rutqvist, 2011b; Guglielmi et al., 2015). This permeability increase raises the question of whether fault reactivation may lead to CO₂ leakage or not. Such assessment should be made site specifically taking into account the hydro-mechanical properties of the rock and faults. Nonetheless, in general, faults crossing sequences of reservoirs and caprocks maintain a low-permeability, at least, in the sections
15 that cross caprocks as a result of the high clay content of the fault (Takahashi, 2003; Egholm et al., 2008). But more importantly, the entry pressure of the fault remains high in the caprock sections (Vilarrasa and Makhnenko, 2017), hindering upwards CO₂ leakage, as observed in numerical simulations that incorporate fault heterogeneity (Rinaldi et al., 2014). Additionally, the stress state of the upper crust, which is
20 characterized by a critically stressed crystalline basement overlaid by non-critically stressed sedimentary rock (recall Section 3), favors nucleation of the largest seismic events in the crystalline basement rather than in the sedimentary rock where CO₂ is stored. This hypocenter distribution has been observed in central US as a result of wastewater injection in the basal aquifer, which implies that permeability enhancement occurs below

the storage formation and thus, fault permeability in the caprock and above it remains unaltered, limiting the risk of CO₂ leakage (Verdon, 2014).

Apart from CO₂ leakage, the magnitude of the potential induced earthquakes is a concern because of the damage and fear that they could generate. The magnitude of earthquakes, M , is proportional to the rock shear modulus, the rupture area and the mean shear slip (Stekettee, 1958). Thus, the magnitude is controlled by the pressurized area of the fault. In this way, the orientation of the injection well affects the magnitude of potential induced seismicity because horizontal wells pressurize a larger area than vertical wells, but take a longer time to exceed the critical pressure at the fault (Rinaldi et al., 2015). The magnitude of induced seismic events is also controlled by the brittleness of the fault. While brittle faults with a slip-weakening behavior can induce large earthquakes ($M > 4$) (Rutqvist et al., 2016), ductile faults give rise to progressive ruptures in which shear slip progressively accumulates, giving rise to aseismic slip or a swarm-like seismic activity (Vilarrasa et al., 2017b).

Another aspect that controls fault stability as a result of fluid injection is fault offset. Figure 7 represents a typical scenario that can be encountered in a normal faulting stress regime setting, i.e., a steep fault in which the hanging wall has slid downwards with respect to the footwall. The fault is considered to have an offset equal to half of the storage formation thickness. The fault is composed by a low-permeable core (10^{-19} m²) and a damage zone on each side of the core. The properties of the damage zone depend on the material it is in contact with, becoming more permeable and less stiff than the intact rock as a result of fracturing. Thus, the damage zone is of high permeability next to the storage formation, but of relatively low-permeability and high entry pressure next to the caprock and base rock (Vilarrasa et al., 2016). The caprock and base rock are more deformable than the storage formation. CO₂ is injected at a constant mass flow rate in the hanging

wall, 1 km away from the fault, which leads to the pressurization of the storage formation. After 1 year of injection, the pressure buildup in the hanging wall of the storage formation is of 10 MPa. The low-permeable fault acts as a flow barrier, causing a rapid reservoir pressurization. This pressure increase expands the storage formation. In particular, the

5 pressurized storage formation pushes the fault towards the right-hand side. This expansion is uniform along the whole thickness of the storage formation, but the deformation of the rock on the other side of the fault depends on the stiffness of the surrounding rock. Since the storage formation is stiffer than the base rock, it contracts less than the base rock, but induces larger stresses. As a result, the induced horizontal

10 stresses in the in-plane direction are high where the storage formation is present on both sides of the fault, but it is low where the base rock is on the other side of the fault.

These stress changes have a direct implication of fault stability. Figure 8 displays the changes in the mobilized friction angle around the fault as a result of CO₂ injection. The most destabilized region is the lower half of the pressurized storage formation. Thus, an

15 induced seismic event would be initiated in that region of the fault, but slip may become arrested below the caprock because fault stability improves within the damage zone of the storage formation on the side that is not pressurized. This difference in fault stability can be easily appreciated by representing Mohr circles in these zones (see inset in Figure

8). While the deviatoric stress is maintained in the lower portion of the pressurized storage

20 formation because the horizontal stress in the in-plane direction does not increase (see red circle in Figure 8), the size of the Mohr circle decreases in the upper portion of the pressurized storage formation because of the increase in the horizontal stress in the in-plane direction where the storage formation is placed on both sides of the fault (see green circle in Figure 8). This fault stability analysis highlights the fact that the accurate

assessment of fault stability changes in geologic carbon storage sites completely depend on proper site characterization.

7. CHARACTERIZATION TECHNIQUES

5 Site characterization has traditionally been considered as an activity that should be performed before a projects enters into operation. Though necessary, such previous characterization tests are limited in time and thus, they can only characterize a small volume of rock around the injection well (Niemi et al., 2017). However, the size of the region affected by injection grows with the square root of time and since geologic carbon
10 storage projects are planned to last several decades, full characterization can only be achieved by considering operation as a continuous characterization. This continuous characterization approach is necessary to reduce surface uncertainty in predictive models of felt seismicity.

To assess whether CO₂ injection may induce felt seismicity, it is necessary to characterize
15 the geological media in order to build a conceptual model of the site. This conceptual model should include the geological layers (at least the caprock, potential secondary caprocks, the storage formation and subjacent layers down to the crystalline basement) and faults. Apart from the geometry, the hydraulic (permeability and porosity), thermal (thermal conductivity and heat capacity) and geomechanical (stiffness and strength)
20 properties are required. Additionally, the initial conditions should be determined, i.e., the fluid pressure profile (if pressure is hydrostatic or if there are pressure anomalies), the geothermal gradient, Gutenberg-Richter law and the stress state. Determining the magnitude and orientation (and their variability) of the stress tensor is critical, because fault stability depends on the orientation of a given fault with respect to the stress tensor

(Morris et al., 1996). These properties can be measured in the laboratory from core samples or in the field. While laboratory measurements allow a tight control of test conditions, they usually test only the rock matrix and fail to acknowledge scale effects associated to spatial variability of the above properties and the impact of discontinuities
5 (e.g., Ledesma et al., 1996; Zhang et al., 2006; Cai et al., 2007). Thus, interpretation of field measurements is more representative.

To obtain estimates representative at the field scale of the hydraulic and geomechanical properties, Vilarrasa et al. (2013c) proposed a hydro-mechanical characterization test for CO₂ storage sites (Figure 9). The test consists in injecting water at a high flow rate until
10 microseismic events are induced. Ideally, the same brine from the storage formation should be injected to avoid geochemical reactions around the injection well that may alter rock properties. However, injecting brine would imply having a large surface facility to store the brine from the storage formation that would have been pumped previously. The test has to be closely monitored with pressure, temperature, deformation and
15 microseismicity monitoring. The hydraulic properties of the storage formation and caprock can be determined from the interpretation of injection as a hydraulic test (Cooper and Jacob, 1946; Hantush, 1956). If heterogeneities are present in the storage formation, their effect is only detectable for a limited period of time (Wheatcraft and Winterberg, 1985; Butler and Liu, 1993). For this reason, it is extremely important to continuously
20 measure pore pressure changes during injection. As for the geomechanical properties of the storage formation and caprock, they can be derived from the interpretation of the vertical displacement at the top of the storage formation and the caprock. Additionally, measuring the pressure evolution in the caprock, which undergoes a pressure drop in response of the pressure buildup in the storage formation (Hsieh, 1996), also gives
25 information on the geomechanical properties. The magnitude of this reverse-water level

fluctuation is inversely proportional to the storage formation stiffness (Vilarrasa et al., 2013c). Injection should be maintained until microseismic events are induced in the caprock, which gives an initial estimate of the maximum sustainable injection pressure that should not be exceeded during CO₂ injection to avoid compromising the caprock sealing capacity. This test is valuable to characterize storage sites in a pre-operation stage, but it should be complemented by a continuous site characterization during operation to characterize geological features present in the far field and reduce subsurface uncertainty.

A continuous characterization technique that permits detecting and locating low-permeable faults is that proposed by Vilarrasa et al. (2017c). The idea is to use diagnostic plots, i.e., plots that include the fluid pressure evolution together with the derivative of the fluid pressure with respect to the logarithm of time (Bourdet et al., 1983; Renard et al., 2009), to detect faults significantly before (in the order of days) than if only fluid pressure evolution interpretation would be used (Figure 10a). This early identification of faults should permit decision makers to perform pressure management if necessary to mitigate future induced seismicity. This methodology only detects faults that are at least three orders of magnitude less permeable than the storage formation. However, this should not be a problem in terms of induced seismicity because faults that do not act as a flow barrier induce relatively small changes in fault stability (Vilarrasa et al., 2016). Low-permeable faults generate an additional pressure buildup that differs from the expected pressure evolution in an aquifer that would not contain that fault. Thus, by comparing the measured pressure evolution, and its derivative with respect to the logarithm of time, with the predicted one, low-permeable faults can be detected. This additional pressurization also affects the CO₂ dynamics because CO₂ is pushed away from the direction of the fault, leading to an asymmetric CO₂ plume (Figure 10b). Such asymmetry could be detected at monitoring wells, suggesting the presence of a fault, but it could also be due to reservoir

heterogeneity (Chen et al., 2014). Once a fault is detected and located, it should be incorporated into the conceptual model of the site. Additional characterization techniques may be necessary to obtain a precise information on the detected faults. Then, field measurements should be compared with the updated conceptual model, which will permit
5 identifying and locating new faults (Figure 10c) from the determination of the divergence time and the use of type curves (Figure 10d). Such continuous characterization techniques are needed in order to minimize the risk of inducing seismicity in geologic carbon storage projects.

10 **8. MINIMIZING THE RISK OF INDUCING FELT SEISMICITY**

To effectively minimize the risk of inducing large earthquakes that are felt on the ground surface and may damage structures, the following steps should be followed:

- 1) performing a detailed initial site characterization, including the determination of:
 - the geomechanical properties (Young's modulus, Poisson ratio, cohesion and
15 friction angle) of the geological formations relevant to the site (at least of the storage formation, the caprock and base rock);
 - the hydraulic properties (permeability and porosity) of the geological formations relevant to the site (at least of the storage formation, the caprock and base rock);
 - the thermal properties (thermal conductivity and heat capacity) of the geological
20 formations relevant to the site (at least of the storage formation, the caprock and base rock);
 - the seismic velocities v_p and v_s from the surface to the crystalline basement. An accurate determination of these velocities is important to locate the hypocenters of the induced seismicity with precision;

- the baseline of natural seismicity to establish the initial a and b values of the Gutenberg-Richter law in order to discriminate induced from natural seismicity;
 - the initial pressure, temperature and stresses profiles with depth from the surface to the crystalline basement. The determination of the stress state is particularly
5 important to perform a fault stability analysis of the identified faults and determining the strike and dip of critically oriented faults;
 - characteristics of geological formations and faults and their location and orientation through 3D seismic data;
- 2) putting in place proper monitoring for performing continuous characterization,
10 including:
- an array of geophones at depth to measure and locate induced microseismicity;
 - a network of geophones on surface or in shallow wells with adequate spatial distribution, covering the whole footprint of the storage site to accurately locate
15 induce seismicity. Induced events should be located in quasi-real time, together with their focal mechanisms to detect potentially unidentified faults that may induce large earthquakes. Inversion of the stress tensor is also important to detect possible rotations (Martinez-Garzon et al., 2013, 2014), which could be induced by pressure buildup, cooling and/or shear slip stress transfer (De Simone et al.,
2017). This seismic continuous characterization is particularly important when
20 CO₂ is injected in the basal aquifer (Verdon, 2014; Will et al., 2016);
 - monitoring wells measuring pressure, temperature and CO₂ saturation in the storage formation, caprock and secondary aquifer above the storage formation. Monitoring in secondary aquifers is useful for detecting brine and CO₂ leakage (e.g., Chabora and Benson, 2009; Zeidouni et al., 2014). Pressure measurements

can be used for a continuous characterization technique as the one described in Section 7;

3) carrying out pressure management:

- based on the thermo-hydro-mechanical-seismic (THMS) monitoring and characterization, predictive models of induced seismicity that consider coupled THMS processes should be applied to identify the injection scenario that minimizes future induced seismicity. The continuous characterization will permit updating the fault stability analysis by incorporating newly detected faults. The range (taking into account the uncertainty on faults properties) of pressure buildup that makes faults become critically oriented for shear failure can be determined from the initial stress state, the strike and dip of faults, and the stress changes induced by CO₂ injection. Pressure management should be applied to avoid exceeded hazardous levels of pressure buildup around faults. To limit pressure, the injection rate may need to be lowered or pressure may need to be released in the vicinity of critically oriented faults (Birkholzer et al., 2012);
- storage alternatives to the conventional concept of storing CO₂ in deep saline aquifers may be used to have a better control on pressure buildup. For example, injection of CO₂ dissolved into brine is achieved by creating dipoles of wells in which brine is extracted from the storage formation and reinjected together with CO₂ in the same formation (Burton and Bryant, 2009; Jain and Bryant, 2011; Pool et al., 2013). The dipoles of wells limit pressure buildup and allow to have a better control on it. Similarly, geothermal energy production using CO₂ as a working fluid permits lowering pressure buildup and additionally extract geothermal energy (Randolph and Saar, 2011). Despite the promising potential of this technology, the only pilot site that has tried CO₂ as a working fluid yielded

a low performance because the thermosyphon that should permit circulating CO₂ with a negligible energy consumption was not formed properly (Freifeld et al., 2016). Nevertheless, future research should enable a successful deployment of this technology.

5

9. CONCLUSIONS

Geologic carbon storage can successfully store gigatone scale of CO₂ at a low level of induced seismicity provided that proper site characterization, monitoring and pressure management are performed. There are several factors that favor the low induce seismicity risk. First, sedimentary formations where CO₂ is planned to be stored are, in general, not critically stressed, which permits generating a certain pressure buildup without reaching shear failure conditions. Special care should be taken if CO₂ is injected in the basal aquifer, because the crystalline basement is critically stressed and may contain unidentified faults that are critically oriented for shear slip. Additionally, CO₂ pressure evolution is relatively easy to control because pressure stabilizes after an initial sharp pressure buildup, becoming practically constant. Despite this favorable pressure evolution, if low-permeable faults are present, an additional pressure buildup may cause large stress changes in the fault, leading to its reactivation. To prevent this situation, a detailed site characterization, both before the start of operation of projects and continuously during the whole operational stage, monitoring and pressure management should permit minimizing the risk of inducing large (felt) earthquakes.

FIGURES

Figure 1: (a) Initial stress state of a fracture or fault of arbitrary orientation with respect to the far field effective stress and (b) Mohr circles showing how the reduction in effective stresses as a result of pressure buildup, ΔP , may induce shear failure in pre-existing fractures or faults. σ'_1 and σ'_3 are the maximum and minimum principal effective stresses, respectively, τ is tangential stress, σ'_n is normal effective stress to the fracture or fault, and μ is the friction coefficient.

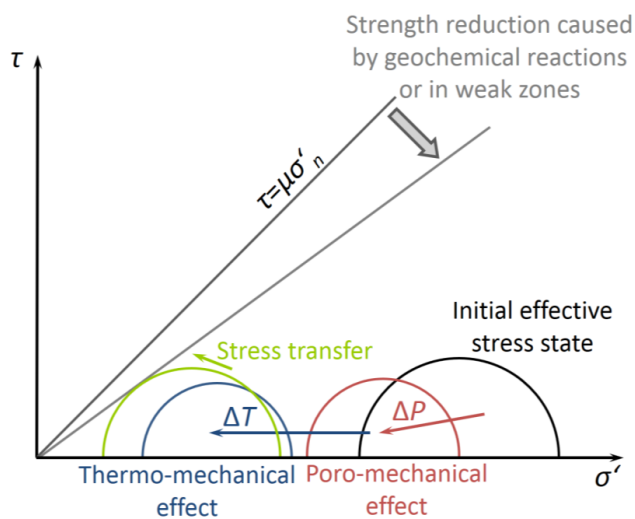

Figure 2: Schematic representation of several coupled effects on fracture/fault stability.

Pressure buildup, ΔP , decreases the effective stresses and causes poro-mechanical stresses that change the size of the Mohr circle; temperature variations, ΔT , induce thermal stresses; seismic and aseismic shear slip and interactions between geological layers with different rock properties produce total stress changes; and geochemical reactions may alter the strength of fractures and/or faults.

Figure 3: Stress state of crystalline and sedimentary rocks, showing that sedimentary rocks, which are the rocks where CO₂ will be stored, are usually not critically stressed.

5

10

Figure 4: (a) CO₂ injection pressure evolution, (b) showing the CO₂ plume shape at the beginning of injection, coinciding with the peak in injection pressure (see number 1 in (a)), and (c) the CO₂ plume once gravity override dominates and the capillary fringe has

5 been developed, leading to a slight pressure drop (see number 2 in (a)).

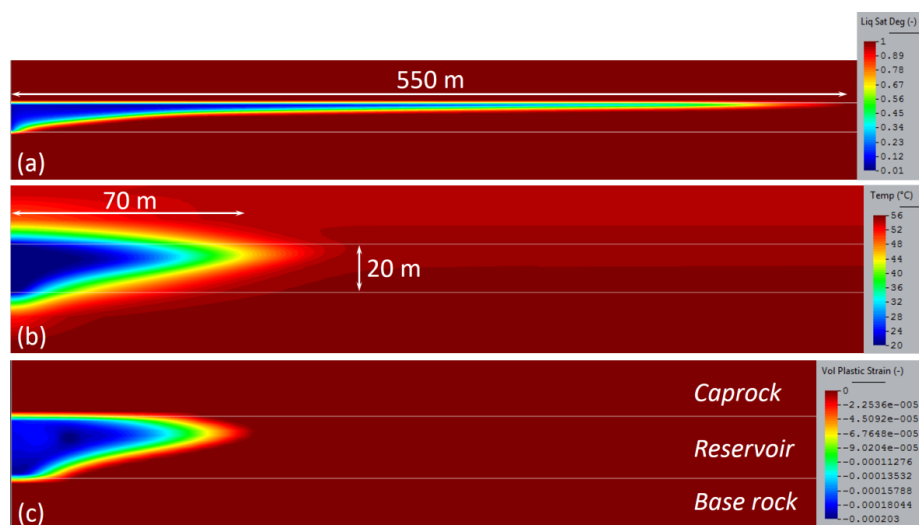

Figure 5: (a) Liquid saturation degree, (b) temperature distribution and (c) volumetric plastic strain after 2 years of injecting 1 Mt/yr of CO₂ through a vertical well. While (b) and (c) are plotted at the same scale, (a) is plotted at a smaller scale.

5

10

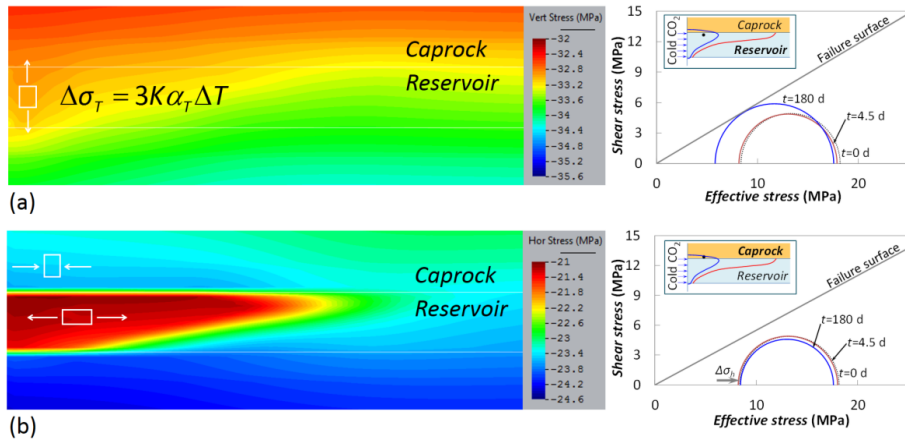

Figure 6: Total stresses in the (a) vertical and (b) horizontal direction after half a year of injecting 1 Mt/yr of CO₂ through a vertical well, indicating the sign of the induced stresses. Thermal stresses, $\Delta\sigma_T$, are proportional to the bulk modulus, K , the thermal expansion coefficient, α_T , and the temperature difference, ΔT . The change in the Mohr circles in (a) the reservoir and (b) the caprock is also represented.

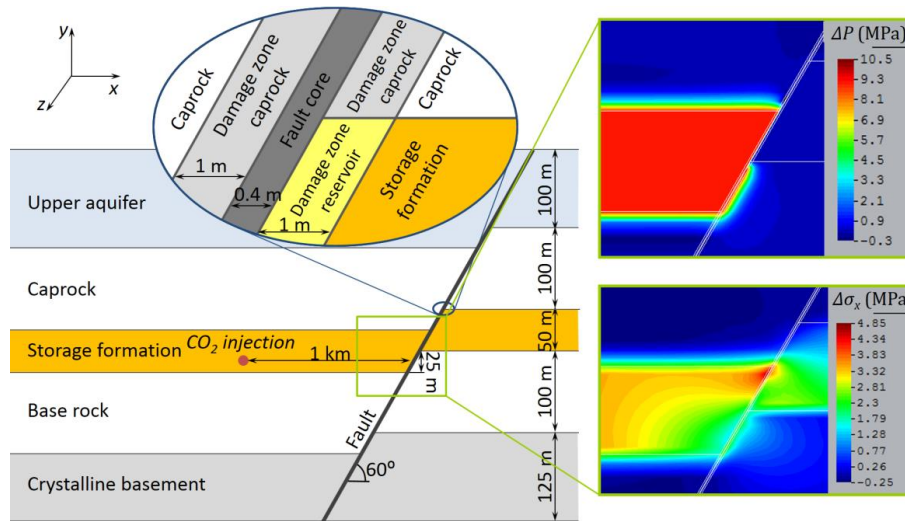

Figure 7: Geological setting in a normal faulting stress regime, including a low-permeable fault that leads to reservoir pressurization, ΔP , and horizontal stress changes in the in-plane direction, $\Delta\sigma_x$, when CO_2 is injected in the hanging wall for 1 year.

5

10

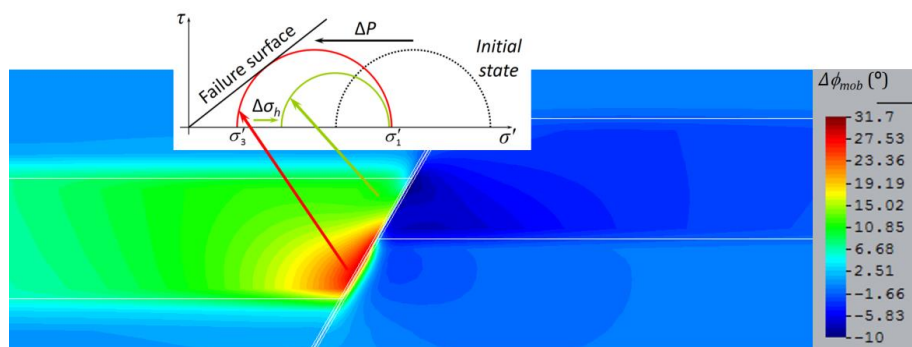

Figure 8: Distribution of stability changes induced by the pressure and stress changes shown in Figure 7, measured in terms of the mobilized friction angle, $\Delta\phi_{mob}$. The insert shows the Mohr circles before and after reservoir pressurization.

5

10

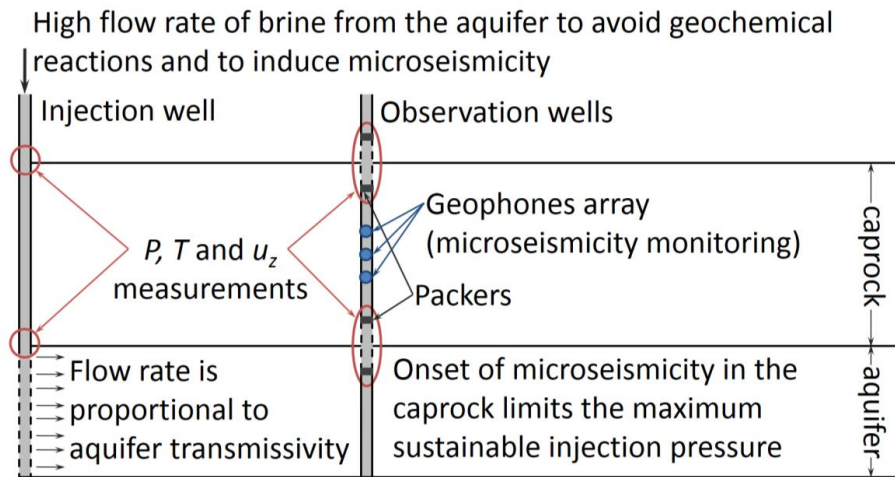

Figure 9: Hydro-mechanical characterization test proposed by Vilarrasa et al. (2013c) to quantify the rock properties at the field scale and obtain an initial estimate of the maximum sustainable injection pressure. P refers to pressure, T to temperature and u_z to

5 vertical displacement.

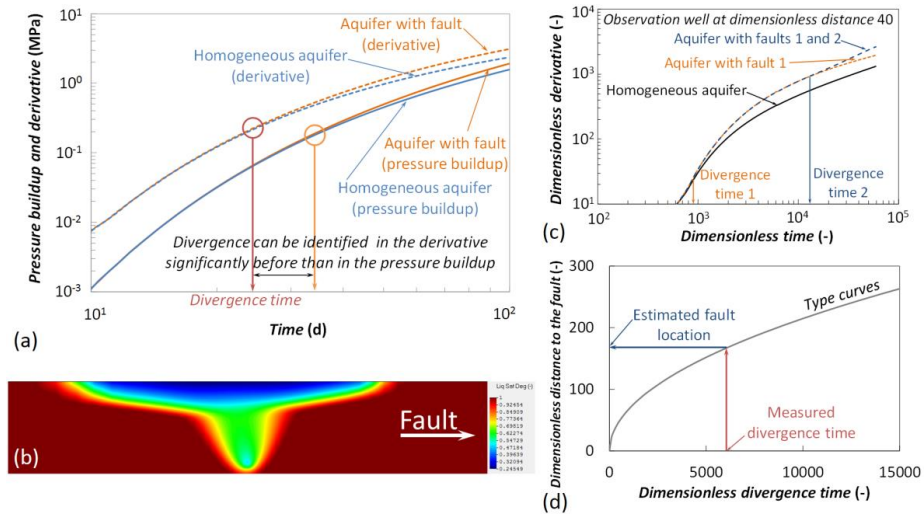

Figure 10: (a) Concept of the continuous characterization technique proposed by Vilarrasa et al. (2017c) to detect and locate low-permeable faults using diagnostic plots; (b) asymmetric CO₂ plume as a result of the additional pressurization caused by a low-permeability fault, which displaces CO₂ towards the opposite direction of the fault; (c) detection of multiple faults by updating the conceptual model of the site and comparing field measurements with predictive simulations; and (d) estimation of the fault location from the measured divergence time in the derivative of the pressure evolution using type curves.
