13 **Abstract**

14 We investigate the pore space of rock samples with respect to different petrophysical parameters using
15 various methods, which provide data upon pore size distributions, including micro computed tomography
16 (μ -CT), mercury intrusion porosimetry (MIP), nuclear magnetic resonance (NMR), and spectral induced
17 polarization (SIP). The resulting cumulative distributions of pore volume as a function of pore size are
18 compared. Considering that the methods differ with regard to their limits of resolution, a multiple length
19 scale characterization of the pore space is proposed, that is based on a combination of the results from all of
20 these methods. The approach is demonstrated using samples of Bentheimer and Röttbacher sandstone.
21 Additionally, we compare the potential of SIP to provide a pore size distribution with other commonly used
22 methods (MIP, NMR). The limits of resolution of SIP depend on the usable frequency range (between
23 0.002 Hz and 100 Hz). The methods with similar resolution show a similar behavior of the cumulative pore
24 volume distribution in the overlapping pore size range. We assume that μ -CT and NMR provide the pore
25 body size while MIP and SIP characterize the pore throat size. Our study shows that a good agreement
26 between the pore radii distributions can only be achieved if the curves are adjusted considering the
27 resolution and pore volume in the relevant range of pore radii. The MIP curve with the widest range in
28 resolution should be used as reference.

29

30 Keywords: Pore Space Analysis, Joint Interpretation, Fractal Dimension, Spectral Induced Polarization

31 **1 Introduction**

32 Transport and storage properties of reservoir rocks are determined by the size and arrangement of the pores.
33 In this paper we use the term geometry to refer to the relevant pore sizes, such as the pore throat radius,
34 pore body radius, body to throat ratio, shape of the pore, and pore volume corresponding to certain pore
35 radius. Different methods have been developed to determine the pore size distribution of rocks. These
36 methods are based on different physical principles. Therefore, it can be expected that the methods
37 recognize different geometries and sizes. Additionally, the ranges of pore sizes that are resolved by the
38 methods are different (Meyer et al., 1997). Rouquerol et al. (1994) stated in the conclusions of their
39 recommendations for the characterization of porous solids that no experimental method provides the
40 absolute value of parameters such as porosity, pore size, surface area, and surface roughness. It should be
41 noted that these parameters indicate a fractal nature. That means that the value of the parameter depends on
42 the spatial resolution of the method.

43 An enhanced pore space analysis using different methods should be able to provide a better description of
44 the pore space over a wide range of pore sizes. Our study of pore space analysis is based on the following
45 methods: micro computed tomography (μ -CT), mercury intrusion porosimetry (MIP), nuclear magnetic

46 resonance (NMR), and spectral induced polarization (SIP). The first three methods can be regarded as
47 standard methods to derive a pore size distribution. Since these methods can reveal the inner structure of
48 the rocks, they are widely applied in geosciences (e.g. Halisch et al., 2016b, Mees et al., 2003,
49 Behroozmand et al., 2015, Weller et al., 2015). The main aim of our paper is to integrate an electrical
50 method in this study. Electrical conductivity and polarizability (or real and imaginary part of electrical
51 conductivity) are fundamental physical properties of porous materials. The SIP method measures the low-
52 frequency electric behavior of rocks and soil material that can be efficiently represented by a complex
53 electric conductivity (e.g. Slater and Lesmes, 2002). The electric properties of a porous material depend to
54 a large extent on key parameters including the porosity, the grain and pore size distribution, the specific
55 internal surface, the tortuosity, the saturation and the chemical composition of the pore-filling fluids. SIP is
56 a non-destructive method that can be applied to characterize the geometry of the pore system. Müller-
57 Huber et al. (2018) proposed the integration of SIP in a combined interpretation with NMR and MIP
58 measurements for carbonate rocks in order to use the partly complementary information of each method.
59 The SIP method is used to explore correlations between parameters derived from complex conductivity
60 spectra and specific pore space properties. We go a step ahead and compare directly the pore size
61 distributions derived from the different methods. Procedures to derive pore size distributions from induced
62 polarization (IP) data have been proposed only recently (Florsch et al., 2014; Revil et al., 2014; Niu and
63 Zhang 2017; Zhang et al., 2017).

64 We are aware that further methods can be applied for the characterization of pore size distribution, e.g.
65 synchrotron-radiation-based computed tomography (Peth et al., 2008), focused ion beam tomography
66 (Keller et al., 2011), transmission electron microscopy (Gaboreau et al., 2012), scanning electron
67 microscopy (SEM), ¹⁴C labeled methylmethacrylate method (Kelokaski et al., 2005), and gas adsorption
68 and desorption method (BET) (Avnir and Jaroniec, 1989).

69 Our study presents an approach to describe and quantify the pore space of porous material by combining
70 the results of methods with different resolution. Samples of Bentheimer and Röttbacher sandstone are
71 investigated by μ -CT, MIP, NMR, and SIP. Each method provides the pore size distribution in a limited
72 range of resolution. It is not our intention to combine the data of the different methods in a joint inversion
73 to get a more reliable pore size distribution as proposed by Niu and Zhang (2017). We prefer to compare
74 the resulting pore size distributions to each other to get two different pore radii distributions, one for the
75 pore body radius and one for the pore throat radius. The comparison of the two curves enables the
76 determination of the ratio between pore body and pore throat radius. A joint inversion that ignores the
77 difference between pore body and pore throat provides a simplified model that ignores the complexity of
78 pore space geometry.

79 Considering the fractal nature of pore space geometry an attempt is made to determine the fractal
80 dimension of the pore volume distribution for the two investigated samples. The fractal dimension is a

81 useful parameter for up-and downscaling of geometrical quantities. Zhang and Weller (2014) investigated
82 the fractal behavior of the pore volume distribution by capillary pressure curves and NMR T_2 distributions
83 of sandstones. Considering the differences in fractal dimension resulting from the two methods, they
84 concluded a differentiation into surface dimension and volume dimension. Additionally, the fractal
85 dimension is used in methods of permeability prediction (e.g. Pape et al., 2009).

86 **2 Theory**

87 The pore size distribution resulting from different methods has to be compared and evaluated. We prefer a
88 comparison based on the cumulative volume fraction of pores V_c , which is expressed by

$$89 \quad V_c = \frac{V(< r)}{V_p}, \quad (1)$$

90 with V_p being the total pore volume, and $V(< r)$ the cumulative volume of pores with radii less than r . A
91 graph displaying the logarithm of V_c versus the logarithm of the pore radius offers the advantage that the
92 slope of the curves is related to the fractal dimension of the pore volume (Zhang and Weller, 2014).

93 Fractal theory is applied to describe the structure of geometric objects (Mandelbrot, 1977, 1983). At
94 molecular size and microscopic range, surfaces of most materials including those of natural rocks show
95 irregularities and defects that appear to be self-similar upon variation of resolution (Avnir et. al, 1984). A
96 self-similar object is characterized by similar structures at different scales. The regularity of self-similar
97 structures can be quantified by the parameter of fractal dimension D . Pape et al. (1982) first proposed a
98 fractal model (the so called ‘pigeon-hole model’ or ‘Clausthal Concept’) for the geometry of rock pores.
99 Fractal dimension describes the size of geometric objects as a function of resolution. This parameter has
100 proved to be useful in the comparison of different methods that determine distributions of pores in
101 sandstones and carbonates (e.g. Zhang and Weller, 2014, Ding et al., 2017).

102 From MIP, the entry sizes of pores and cavities, which is referred to as pore throat radius r_t , can be
103 determined according to the Washburn-equation (Washburn, 1921)

$$104 \quad r_t = -\frac{2 \cdot \gamma \cdot \cos \theta}{P_c}, \quad (2)$$

105 with $\gamma = 0.48$ N/m being the surface tension of mercury, $\theta = 140^\circ$ the contact angle between mercury and
106 the solid minerals, and P_c the pressure of the liquid mercury that is referred to as capillary pressure.

107 Starting with low pressure, the pores with larger pore throats are filled with mercury. While increasing the
108 pressure, the pores with smaller throats are filled. Reaching a certain pressure level P_c , a cumulative
109 volume of mercury (V_{Hg}) has intruded into the sample that corresponds to the pore volume being accessible
110 by pore throat radii larger or equal r_t according to Eq. (2). Figure 1 shows a 2D image of the pore space of
111 sample BH5-2 (information is given in Section 3) indicating the pore throat radius r_t as measured by MIP

112 by red arrows. Fluid flow properties, and hence the injection pressure of mercury, solely depends upon the
 113 narrowest pore diameter in the flow path that corresponds to the pore throat diameter. The cumulative
 114 volume of mercury V_{Hg} corresponds to the pore volume $V(>r_t)$. It should be noted that the volume of larger
 115 pores, which are shielded by narrower throats, is attributed to the pore throat radius (e.g. Kruschwitz et al.,
 116 2016). Knowing the total pore volume V_p , the saturation of the sample with mercury S_{Hg} can be determined.
 117 A conventional capillary pressure curve displays the relationship between the saturation of the sample with
 118 mercury S_{Hg} as a function of capillary pressure P_c (e.g. Thomeer, 1960). Using the following simple
 119 transformations

$$120 \quad S_{Hg} = \frac{V_{Hg}}{V_p} = \frac{V(>r_t)}{V_p} = \frac{V_p - V(<r_t)}{V_p} = 1 - V_c, \quad (3)$$

121 the cumulative volume fraction of pores V_c as defined in Eq. (1) can be determined as a function of r_t .
 122 The NMR relaxometry experiment records the decay of transversal magnetization. The measured
 123 transversal decay curve is decomposed in a distribution of relaxation times $b(T_2)$. The individual relaxation
 124 time T_2 is attributed to a pore space with a certain surface to volume ratio A/V by

$$125 \quad \frac{1}{T_2} = \rho \left(\frac{A}{V} \right), \quad (4)$$

126 with ρ being the surface relaxivity. Considering that for a capillary tube model with cylindrical pores of
 127 radius r , the surface to volume ratio equals $2/r$, we get the following linear relationship between pore radius
 128 r and relaxation time T_2 (e.g. Kleinberg, 1996):

$$129 \quad r = 2\rho T_2. \quad (5)$$

130 It should be noted that the NMR method resolves the radius r_b that corresponds to the maximal distance to
 131 the pore wall. It can be represented by the pore radius of the largest sphere that can be placed inside this
 132 pore as shown in Figure 1.

133 Another approach to derive a pore size distribution is based on the SIP method. Relations between grain or
 134 pore size and IP parameters have been reported in a variety of studies (e.g. Slater and Lesmes, 2002; Scott
 135 and Barker, 2003; Binley et al., 2005; Leroy et al., 2008; Revil and Florsch, 2010). Polarization effects of
 136 natural material are caused by different charging and discharging processes of some polarizing elements
 137 such as grain surface, pore throat, membrane, and electrical double layer. Following an approach proposed
 138 by Schwarz (1992), the complex conductivity of an individual polarization element can be presented by a
 139 Debye model. It is assumed that the recorded spectra result from a superposition of polarization processes
 140 characterized by different relaxation times. This approach has been adopted to generate synthetic spectra of
 141 electrical conductivity from distributions of grain sizes (e.g. Revil and Florsch, 2010) or pore sizes (e.g.
 142 Niu and Zhang, 2017).

143 A decomposition of the spectra is needed to derive the relaxation time distribution. Florsch et al. (2014)
 144 demonstrated that a variety of models can be used as kernel for the decomposition of the spectra. Revil et al.
 145 (2014) compare the results of Debye and Warburg decomposition. Their argumentation, which is based on
 146 mechanistic grain size models describing the polarization of charged colloidal particles and granular
 147 material, supports the application of the Warburg decomposition that results in a narrower distribution of
 148 polarization length scales. It should be noted that a uniform grain size does not automatically generate a
 149 uniform pore size. Besides it can be clearly seen by the scanning electrode microscopy images that the
 150 investigated sandstones feature a distinct range of both, grain and pore (throat) sizes. Considering that the
 151 pore size and not the grain size controls the polarization of sandstones, as observed by different authors (e.g.
 152 Scott and Barker, 2003; Niu and Revil, 2016), a wider distribution of length scales can be expected.
 153 According to our opinion, there are no clear indications for superiority of the Warburg decomposition. Up
 154 to now, a theoretical model that confirms the validity of the Warburg model in describing the polarization
 155 of a simple pore space geometry has not been presented. Therefore, we prefer to use the Debye
 156 decomposition, which has proved to be a useful tool in the processing of IP data in both time and frequency
 157 domain (e.g. Terasov and Titov, 2007; Weigand and Kemna, 2016). The algorithm described by Nordsiek
 158 and Weller (2008) provides the electrical relaxation time distribution as well as the total chargeability from
 159 complex conductivity spectra.

160 According to the assumption that the electrical relaxation time and pore size are related to each other, the
 161 specific chargeability at a certain relaxation time corresponds to the pore volume attributed to a certain pore
 162 size, and the total chargeability is attributed to the total pore volume of the sample. The volume fraction V_c
 163 corresponds to the ratio of cumulative chargeability to total chargeability. To transform the relaxation time
 164 distribution into a pore size distribution, we adopt the approach proposed by Schwarz (1962) and applied
 165 by Revil et al. (2012) for the Stern layer polarization model:

$$166 \quad r = \sqrt{2\tau D_{(+)}} , \quad (6)$$

167 with $D_{(+)}$ being the diffusion coefficient of the counter-ions in the Stern layer and τ being the relaxation
 168 time. Originally, this equation describes the relation between the radius of spherical particles in an
 169 electrolyte solution and the resulting relaxation time. Though it remains arguable whether the radius of
 170 spherical grains can be simply replaced by the pore radius (Weller et al., 2016), we generally follow this
 171 approach. Additionally, we assume a constant diffusion coefficient $D_{(+)} = 3.8 \times 10^{-12} \text{ m}^2/\text{s}$ as proposed by
 172 Revil (2013).

173 The signal amplitude at a given relaxation time corresponds to the pore volume related to the pore radius
 174 determined by Eq. (6). Considering the experience that the polarization is related to the specific surface
 175 area per unit pore volume (e.g. Weller et al., 2010), we assume that the IP signals are caused by the ion-
 176 selected active zones in the narrow pores that are comparable with the pore throats. Their size is quantified
 177 by the pore throat radius r_t . Following the procedure proposed by Zhang et al. (2017), the cumulative

178 volume fraction V_c corresponds to the ratio of cumulative chargeability to total chargeability. Considering
179 the restricted range of pore radii (0.1-25 μm) resolved by SIP, a correction of the maximum V_c becomes
180 necessary.

181 **3 Samples and methods**

182 For this study, two different sandstone samples have been used: first, a Bentheimer sandstone, sample
183 BH5-2. The shallow-marine Bentheimer sandstone was deposited during the Early Cretaceous (roughly 140
184 million years ago) and forms an important reservoir rock for petroleum (Dubelaar et al., 2015). This
185 sandstone is widely used for systematic core analysis due its simple mineralogy and the quite homogeneous
186 and well-connected pore space. It is composed out of 92% quartz, contains some feldspar and about 2.5
187 vol.-% of kaolinite (Peksa et al., 2015), which is a direct alteration product of the potassium-bearing
188 feldspar minerals. Accordingly, surface area as well as surface relaxivity values are mostly controlled by
189 the kaolinite for this rock.

190 Secondly, a Röttbacher sandstone, sample RÖ10B, has been used. The Röttbacher sandstone is a fine-
191 grained, more muscovite-illite containing, and rather homogeneous material that was deposited during the
192 Lower Triassic era (roughly 250 million years ago). It is suitable for solid stonework and has been widely
193 used as building material for facades as well as for indoor and outdoor flooring. The Röttbacher sandstone
194 was included in a study on the relationship of pore throat sizes and SIP relaxation times reported by
195 Kruschwitz et al. (2016). This sandstone consists mostly of quartz, but features a higher amount of clay
196 minerals than the Bentheimer sample. Additionally, Fe-bearing minerals (e.g. haematite) have been formed
197 during its arid depositional environment, giving this sandstone a distinct reddish color. Accordingly,
198 surface area as well as surface relaxivity are dominated by the clay and Fe-bearing minerals and should be
199 significantly different than for the BH5-2 sample.

200 The experimental methods used in this study include digital image analysis (DIA) based upon micro
201 computed tomography ($\mu\text{-CT}$), mercury intrusion porosimetry (MIP), nuclear magnetic resonance (NMR),
202 and spectral induced polarization (SIP).

203

204 For this study, a nanotom S 180 X-ray $\mu\text{-CT}$ equipment (GE sensing and inspection technologies) has been
205 used. The sample size for $\mu\text{-CT}$ scanning is 2mm diameter and 4 mm length. For pore network separation, a
206 combination of manual thresholding and watershed algorithms has been applied to achieve the qualitatively
207 best separated pore space. Additionally, separation results have been cross checked with the images of
208 scanning electrode microscopy (SEM). More details on the DIA workflow can be found in Halisch et al.
209 (2016). The DIA of the 3-D $\mu\text{-CT}$ data sets provide for each individual pore the volume and the pore radius
210 of the largest sphere that can be placed inside this pore (maximum inscribed sphere method, e.g. Silin and
211 Patzek, 2006) as indicated by the blue circles in Figure 1. Note that Figure 1 displays a 2-D slice with

212 circles. The DIA is performed in 3-D volumes and provides spheres. The resulting equivalent pore radius is
213 referred to as pore body radius r_b . Though the true extent of the pore is not caught properly, the derived r_b
214 from DIA is a good estimate of the average radius. Adding up the pore volumes starting with the lowest
215 pore radius yields the cumulative volume fraction of pores V_c (Eq. (1)) as a function of the pore body radius
216 r_b . The μ -CT method can only resolve the part of the pore space with pore sizes larger than the spatial
217 resolution of the 3D image. Considering a voxel size of 1.75 μm of the 3D data set, and a minimum
218 extension of pores of two voxels in one direction, which can be separated by the algorithm, a minimum
219 pore size of 3.5 μm (or minimum pore radius of 1.75 μm) has to be regarded, as for this study, the CT
220 resolution limit is 1.75 μm . Therefore, the pore volume determined by μ -CT does not take into account the
221 pore space with radii smaller than 1.75 μm .

222

223 The MIP experiments have been conducted with the PASCAL 140/440 instrument from Thermo Fisher
224 (Mancuso et al., 2012), which covers a pressure range between 0.015 MPa and 400 MPa corresponding to a
225 pore throat radius range from (at best) 1.8 nm to 55 μm . The samples have been evacuated before the MIP
226 experiment.

227

228 The NMR experiments have been performed with a Magritek Rock Core Analyzer equipment operating at a
229 Larmor frequency of 2 MHz at room temperature ($\sim 20^\circ\text{C}$) and ambient pressure. After drying at 105°C for
230 more than 24 hours in vacuum, the samples have been fully saturated with tap water with a conductivity of
231 about 25 mS/m. NMR measurements can be calibrated to get the porosity of the sample. The early time
232 decay signal corresponds to the total water content. The range of resolved pore body radii depends on the
233 used value of surface relaxivity. The amplitude b attributed to an individual relaxation time T_2 is related to
234 the volume fraction of pores with the respective pore radius. Considering the larger pores, the resulting
235 radius corresponds to r_b . The smaller pore throats with lower volume yield a lower signal at shorter
236 relaxation times. The cumulative volume fraction of pores V_c is determined by adding up the individual b
237 values starting from the smallest relaxation time and normalizing to the total sum of all b values.

238

239 Complex conductivity spectra were recorded using a four-electrode sample holder as described by Schleifer
240 et al. (2002). The spectra were acquired with the impedance spectrometer ZEL-SIP04 (Zimmerman et al.,
241 2008) in a frequency range between 0.002 Hz and 45 kHz at a constant temperature of about 20°C .
242 Considering that the complex conductivity spectra are affected by electromagnetic coupling effects,
243 Maxwell Wagner relaxation and dielectric effects at higher frequencies and by a lower signal to noise ratio
244 for lower frequencies, we focus on the frequency range between 0.01 Hz and 100 Hz. The samples were
245 fully saturated with a sodium-chloride solution with a conductivity of 100 mS/m. At least two
246 measurements were performed for each sample to verify the repeatability. Considering the limited

247 frequency interval, the SIP method solely resolves a range of pore radii that depends on the diffusion
248 coefficient. Hence, using $D_{(+)} = 3.8 \times 10^{-12} \text{ m}^2/\text{s}$ in Eq. (6), we get a range of pore radii between 0.1 μm and
249 10 μm . Smaller pore sizes are hidden by Maxwell Wagner relaxation and dielectric effects that are not
250 easily related to pore geometry.

251

252 Permeability measurements have been performed by using a steady-state gas permeameter (manufactured
253 by Westphal Mechanik, Celle, Germany), using nitrogen as the flowing fluid. This device features a so
254 called “Fancher-type” core holder as described by Rieckmann (1970). With this special type of core holder,
255 significantly lower confining pressures are needed than by using a conventional “Hassler-type” core holder
256 (12 bar for the “Fancher-type” core holder versus min. 35 - 50 bar for the “Hassler-type” core holder),
257 leading to much less initial mechanical influence (compaction) upon the sample material. Measurements
258 have been derived under steady-state flow conditions with accordingly low flow rates in range from 3 to 5
259 ml/min, leading to measured pressure differentials in range from 2 to 7 mbar from sample inlet to outlet.
260 The derived apparent permeability values have been corrected, to address the Klinkenberg-effect of gas
261 slippage (Klinkenberg, 1941; API, 1998). Due to the usage of a steady-state technique with low gas flow
262 rates, we consider that correction of the Forchheimer effect of inertial resistance can be neglected (API,
263 1998).

264 4 Results

265 4.1 Petrophysical properties

266 Figure 2 (A and C) gives 2-D impressions of the pore system of the Bentheimer sandstone sample. The
267 pore space in general is very well connected, featuring many large and open pores (Fig.2, A & C, blue
268 arrows) and can be described as a classical pore body – pore throat – pore body system. Small pores are
269 mostly found within the clayey agglomerations, which act as (macro) pore filling material (Fig. 2, A & C,
270 red arrows) and which are homogeneously distributed throughout the sample material. Figure 2 E gives an
271 impression of the 3-D pore distribution of this sandstone, derived by μ -CT image processing. This
272 favorable structure is directly reflected by the petrophysical properties of this sandstone. The sample
273 investigated in our study is characterized by a porosity of 0.238 measured by MIP, a gas-permeability of
274 $4.25 \times 10^{-13} \text{ m}^2$ determined by steady state permeameter (manufactured by Westphal Präzisionstechnik) with
275 a Fancher type core holder using nitrogen as the flowing fluid, and a specific surface area of 0.3 m^2/g
276 determined by nitrogen adsorption method.

277 Figure 2 (B and D) shows the pore space of the Röttbacher sandstone sample from 2-D imaging techniques.
278 Though the (large) pore space is similar structured as it is for the Bentheimer (pore body-throat-body
279 system, Fig. 2, B & D, blue arrows), it is generally reduced (cemented) by clay minerals and features a

280 significantly higher amount of small pores within (Fig. 2, B & D, red arrows). Accordingly, pore space
 281 related petrophysical properties classify a more compact rock, which is supported by the 3-D pore
 282 distribution, derived by μ -CT image processing (Fig. 2, F). The sample used for this study features a
 283 porosity of 0.166 measured by MIP, which is lower than for the Bentheimer sandstone. The gas-
 284 permeability is $3.45 \times 10^{-14} \text{ m}^2$, which is less than 10 % of the value determined for the Bentheimer
 285 sandstone. The specific surface area has been measured with $1.98 \text{ m}^2/\text{g}$ and is hence nearly seven times
 286 larger than for sample BH5-2, clearly underlining the impact of the clay content. The petrophysical
 287 parameters for both samples are compiled in Table 1, whereas results from X-ray fluorescence analysis are
 288 summarized in Table 2, regarding the most important chemical components of both sandstones that have
 289 been used for this study.

290 4.2 Pore volume fraction

291 We applied the methods μ -CT, MIP, NMR, and SIP to get insight into the pore radius distribution of the
 292 Bentheimer sandstone sample BH5-2. Figure 3 displays the resolved porosity ϕ_r as a function of pore radius
 293 for μ -CT and MIP data. The cumulative pore volume while progressing from larger to smaller pores $V(>r)$
 294 is normalized to the total volume of the sample V_s , and results in the resolved porosity

$$295 \quad \phi_r = \frac{V(>r)}{V_s}, \quad (7)$$

296 which reaches the true porosity ϕ as threshold value for r approaching zero.

297 As shown in Figure 3, the μ -CT method identifies the largest pores with pore body radii of about $100 \mu\text{m}$.
 298 The resolved porosity ϕ_r reaches a value of 0.184 at the limit of resolution of the μ -CT method ($r_b=1.75$
 299 μm). The nearly horizontal curve progression for $r < 17 \mu\text{m}$ indicates that effectively no significant volume
 300 of pores with radii lower than $17 \mu\text{m}$ was detected or quantified by μ -CT and DIA, respectively.
 301 Accordingly, only μ -CT data for $r > 17 \mu\text{m}$ will be taken into account for further analysis.

302 The MIP identifies the largest pore throats with a radius of about $30 \mu\text{m}$. Reaching the limit of resolution of
 303 the MIP, the resolved porosity approaches asymptotically the threshold value of 0.238. Though both
 304 methods μ -CT and MIP yield the pore radius without any adjustable scaling factor, we observe differences
 305 between the two curves $\phi_r(r)$ in Figure 3.

306 The Röttbacher sample was scanned with resolution $1.5 \mu\text{m}$ by μ -CT. As shown in Figure 4, the μ -CT
 307 method identifies the largest pores with pore body radii of about $90 \mu\text{m}$. The resolved porosity ϕ_r reaches a
 308 value of 0.106 at the limit of resolution of the μ -CT method ($r_b=1.5 \mu\text{m}$). As observed for the Bentheimer
 309 sandstone, the nearly horizontal curve progression for $r < 10 \mu\text{m}$ indicates that no significant volume of
 310 pores with radii lower than $10 \mu\text{m}$ were detected or quantified by μ -CT and DIA, respectively. Accordingly,
 311 only μ -CT data for $r > 10 \mu\text{m}$ will be taken into account for further analysis.

312 4.3 Pore radius distribution

313 The description and quantification of the pore space in three dimensions requires morphological parameters
314 such as length, width, and thickness of individual pore segments. The parameters are extracted by image
315 analysis software from 3-D μ -CT data. We determined the pore length (maximum length of Feret
316 distribution), pore width (minimum width of Feret distribution), and the equivalent diameter of the
317 analyzed pore segment that corresponds to the spherical diameter with equal voxel volume (Schmitt et al.,
318 2016). The minima, maxima, and mean values of the geometrical parameters derived from μ -CT data of the
319 two samples are compiled in Table 3.

320 The procedures described above result in an individual curve displaying the logarithm of V_c versus the
321 logarithm of the pore radius for each method.

322 For Bentheimer sandstone, applying the transformation in Eq. (3) for the MIP data and assuming a true
323 porosity of 0.238, the cumulative volume fraction of pores V_c can be displayed as a function of pore throat
324 radius as shown in Figure 5. The MIP curve gets a fixed position in the plot of Figure 5 without the need
325 for any scaling. It covers a wide range of pore throat radii between 0.0018 and 44.7 μm .

326 The curves resulting from other methods have to be adjusted considering the limits of the range of pore
327 radii. The maximum of the μ -CT curve corresponds to $V_c = 1$ because no larger pore size has been detected
328 by other methods. The maximum resolved porosity of the sample as detected by MIP reaches 0.238. The
329 porosity determined by μ -CT reaches only 0.184 (Figure 3). This value corresponds to a fraction of 0.773
330 of the porosity determined by MIP. Therefore, the minimum of the μ -CT curve at the pore radius of 17 μm
331 has to be adjusted at $V_c = 1 - 0.773 = 0.227$, because this fraction of pore volume is related to pore body
332 radii smaller than 17 μm . The shift of the μ -CT curve to larger pore body radii in comparison with MIP is
333 observed in this plot, too.

334 The T_2 relaxation time distribution of sample BH5-2 is plotted in Figure 6. It indicates a distinct maximum
335 at a relaxation time of 330 ms and two weaker maxima at lower relaxation times. The T_2 relaxation time
336 distribution is transformed into a curve showing the cumulative intensity as a function of T_2 . The total
337 intensity is attributed to the total pore volume. The volume fraction V_c corresponds to the ratio of
338 cumulative intensity to total intensity. In order to get the curve V_c as a function of pore radius, the
339 relaxation time T_2 has to be transformed into a pore radius using the surface relaxivity ρ as scaling factor in
340 Eq. (5). Since both μ -CT and NMR method are sensitive to the pore body radius, we expect a similar $V_c - r$
341 - curve in the overlapping range of pore body radii. Assuming a coincidence of the two curves at $V_c = 0.5$,
342 the surface relaxivity is adjusted at $\rho = 54 \mu\text{m/s}$.

343 The complex conductivity spectra of the Bentheimer sample are displayed in Figure 7. Considering the
344 frequency range between 0.01 and 100 Hz and $D_{(+)} = 3.8 \times 10^{-12} \text{ m}^2/\text{s}$, the relaxation time distribution
345 derived from SIP is attributed to a restricted range of pore radii between 0.1 μm and 10 μm . Assuming that
346 the polarization signals originate from the pore throats, a similarity of pores size distributions resulting

347 from MIP and SIP can be expected. It should be noted that MIP provides the distribution for a wider range
348 of pore throat radii. Therefore, we adjust the value of V_c at the maximum radius of the SIP to the
349 corresponding value for the MIP curve.

350 As shown in Figure 4 for Röttbacher sandstone, the MIP identifies the largest pore throats with a radius of
351 about 50 μm . Reaching the limit of resolution of MIP, the resolved porosity gets the value of 0.166.
352 Applying the transformation in Eq. (3) on the MIP data and assuming a true porosity of 0.166, the
353 cumulative volume fraction of pores V_c is displayed as a function of pore radius as shown in Figure 8.

354 We suppose that the MIP method detects the whole pore volume, a porosity of 0.106 recognized by μ -CT
355 corresponds to 63.9% of the total pore volume. Therefore, the minimum of the μ -CT curve at the pore
356 radius of 10 μm has to be adjusted at $V_c = 1 - 0.639 = 0.361$, because this fraction of pore volume is related
357 to pore body radii smaller than 10 μm .

358 The T_2 relaxation time distribution of sample RÖ10B is plotted in Figure 6. It indicates a distinct maximum
359 at a relaxation time of 170 ms. Non-vanishing signals are observed at relaxation times below 0.1 ms. This is
360 an indication of the existence of very small pores in the Röttbacher sandstone.

361 The position of the NMR curve in the plot of Figure 8 depends on the surface relaxivity ρ . A coincidence
362 with the μ -CT curve at $V_c = 0.5$ requires a surface relaxivity of $\rho = 237 \mu\text{m/s}$ for adjusting the NMR curve.

363 The complex conductivity spectra of the Röttbacher sample are displayed in Figure 7. The processing of the
364 spectra according to the described algorithm results in the $V_c - r$ - curve as shown in Figure 8. The SIP
365 curve is fixed at the value $V_c = 0.9$ that has been determined by MIP for the maximum pore radius resolved
366 by SIP ($r_t = 10 \mu\text{m}$).

367 5 Discussion

368 Previous studies have compared the $V_c - r$ - curves resulting from different methods (e.g. Zhang and Weller,
369 2014; Zhang et al., 2017; Ding et al., 2017). The slope of the curves was used to get a fractal dimension. It
370 became obvious that the distribution curves indicate remarkable differences that are caused by the physical
371 principles of the used methods. The methods differ with regard to their limits of resolution. The effective
372 resolution of μ -CT is limited by the voxel size. Larger pores can be easily detected. Nevertheless, even
373 though the derived image (voxel) resolution is quite high (1.75 μm), both sandstone data sets feature no
374 significant volume of pore body radii smaller than 10 μm (BH-5) and 17 μm (RÖ-10), respectively. We
375 assume that this is caused by a complex and sensitive mixture of issues about image resolution, image
376 quality (phase contrast), reliability of the watershed-algorithm concerning the separation of individual pores,
377 and hence of the complexity of the pore structure of small pores. The MIP yields the widest range of pore
378 throat radii. The pore radius is directly related to the pressure. A similarly wide range of pore body radii
379 can be resolved by NMR. However, the transformation of the NMR transversal relaxation time into a pore
380 radius requires the surface relaxivity as scaling factor. In a similar way, the transformation of the electrical

381 relaxation time resulting from SIP into a pore radius is based on a scaling factor that depends on the
382 diffusion coefficient. Only a restricted range of pore radii can be resolved by SIP.

383 Beside the range of pore radii, the geometrical extent of the pore radius differs among the methods. μ -CT
384 enables a geometrical description of the individual pore space considering the shape of the pore. The pore
385 radius can be determined in different ways. We use the average pore radius as an equivalent for the pore
386 body radius r_b . MIP is sensitive to the pore throat radius r_t that enables the access to larger pores behind the
387 throat. The NMR relaxation time is related the pore body radius r_b . We assume that the IP signals are
388 caused by the ion-selected active zones in the narrow pores that are comparable with the pore throats.

389 Regarding the differences of the methods, we present an approach that combines the curves to get more
390 information on the pore space. Considering the two kinds of pore radii r_b and r_t , we use first μ -CT and
391 NMR to generate a combined curve displaying V_c as a function of r_b . In the next step, we link the curves
392 resulting from MIP and SIP to get a curve showing V_c as a function of the pore throat radius r_t .

393 It is fundamental that the total pore volume (or total porosity) has to be known. The cumulative pore
394 volume fraction should only consider the pore volume that is resolved in the regarded range of pore radii.
395 Considering the resolution of μ -CT, only the pore space with radii larger than the voxel size is determined.
396 The cumulative pore volume fraction at the limit of resolution has to be adjusted to the non-resolved pore
397 volume. In this way, the μ -CT curve gets a fixed position in the $V_c - r$ plot. Regarding NMR, the relaxation
398 time T_2 has to be transformed into a pore radius according to Eq. (5). The application of Eq. (5) requires the
399 knowledge of the surface relaxivity ρ , which is the necessary scaling factor that causes a shift of the $V_c - r$
400 curve along the axis of pore radius. Since NMR method is sensitive to the pore body radius, we expect a
401 similar $V_c - r$ curve for NMR and μ -CT in the overlapping range of pore body radii. The NMR curve is
402 shifted along the axis of pore body radii until a good agreement between the two curves is reached. This
403 procedure enables the determination of the surface relaxivity. The proposed alternative method for the
404 determination of surface relaxivity considers the reduction of NMR relaxation time T_2 caused by high clay
405 content and iron-bearing minerals (e.g. Keating and Knight, 2010).

406 MIP is used to generate the curve displaying V_c as a function of r_t over a wide range of pore throat radii.
407 The SIP curve is fixed at the MIP curve considering the coincidence at the largest pore radius resolved by
408 SIP.

409 The two curves representing V_c as a function of both r_b and r_t are displayed in a double logarithmic plot.
410 The horizontal shift of the two graphs represents the ratio r_b/r_t . Additionally, the slope of the curves is
411 related to the fractal dimension.

412 The proposed approach in this study results in two pore size distribution curves for the two samples, which
413 are in good accordance to the general pore space structures as described in section 3 and as visualized in
414 Figure 2 (A to F). The first curve combines the distributions resulting from μ -CT and NMR. The μ -CT data
415 provide a pore radius, which is regarded as pore body radius, without any scaling. The scaling of the NMR-

416 curve provides an estimate of the surface relaxivity. The surface relaxivity of the Bentheimer sample
417 reaches 54 $\mu\text{m/s}$, the corresponding value of the Röttbacher sample is with 237 $\mu\text{m/s}$ much higher. The
418 higher surface relaxivity in comparison with the Bentheimer sample is clearly justified considering the
419 larger specific surface area (Table 1) and the significantly higher content of clay and iron-bearing minerals
420 as indicated in Table 2.

421 The two cumulative pore volume distribution curves for the Röttbacher sample (Figure 8) indicate over the
422 wide range of pore radii a parallel progression with consistently higher values for the pore body radius (μ -
423 CT and NMR) in comparison with the pore throat radius (MIP). The horizontal distance of the two curves
424 yields the ratio r_b/r_t . It should be noted that the ratio r_b/r_t may vary with pore sizes. Most studies consider
425 only a fixed ratio r_b/r_t determined from the dominant pore body size from NMR r_b and the dominant pore
426 throat size from MIP r_t (e.g. Müller-Huber et al., 2018). Regarding the median pore radii at $V_c = 0.5$, a ratio
427 $r_b/r_t = 9.13$ is determined. Considering smaller pores, a ratio $r_b/r_t = 12.15$ is indicated at $V_c = 0.05$.

428 The parallelism of the pore volume distribution curve is less developed for the Bentheimer sample (Figure
429 4). We observe a clear distance of the two curves in the range of larger pore radii. Regarding the median
430 pore radii at $V_c = 0.5$, a ratio $r_b/r_t = 2.57$ is determined. For $V_c < 0.2$, the slope of the curves decreases and
431 smaller distances between the curves are observed. The NMR curve in Figure 5 indicates for $V_c > 0.08$
432 larger pore radii in comparison with the MIP curve and confirms the relationship $r_b > r_t$. The reverse
433 behavior in the interval $0.1 \mu\text{m} < r < 0.6 \mu\text{m}$ is possibly caused by the low volume fraction (3%) attributed
434 to this range of pore radii. It can be expected that the small amount of water in the small pores causes only
435 weak signals in the NMR relaxometry.

436 Beside the distances between the curves the individual slopes are regarded. The slope (s) of the curve \log
437 (V_c) versus \log (r) is related to the fractal dimension D of the pore volume ($D = 3 - s$) (Zhang and Weller,
438 2014). We observe a varying slope in the investigated range of pore radii for the Bentheimer sample. The
439 only range of more or less constant slope, which extends from pore radius $0.1 \mu\text{m}$ to $10 \mu\text{m}$, corresponds to
440 a fractal dimension $D_{MIP} = 2.678$ for MIP, $D_{NMR} = 2.776$ for NMR, and $D_{SIP} = 2.618$ for SIP.

441 The whole curves of the four methods are non-linear and indicate non-fractal behavior. A Maximum
442 Likelihood Estimator approach (MLE) might be relevant to extract the underlying scaling parameters
443 (Rizzo et al., 2017). For example, in the case of the NMR curve of Bentheimer sandstone, the fitting of all
444 data using the MLE reveals that the log-normal distribution is the most likely distribution with the
445 estimated parameters $\mu = 3.43 \mu\text{m}$ and $\sigma = 0.82 \mu\text{m}$. These two scaling parameters are the logarithmic mean
446 and logarithmic standard deviation of the pore radius, respectively. We recognize that the resulting mean
447 radius reaches half value of the effective hydraulic radius ($r_{eff} = 6.97 \mu\text{m}$).

448 We observe a constant slope of the NMR curve for the Röttbacher sample (Figure 8) in the interval
449 $0.01 \mu\text{m} < r_b < 100 \mu\text{m}$. A similar slope is observed for the MIP curve in the interval $0.01 \mu\text{m} < r_t < 10 \mu\text{m}$.
450 Considering the overlapping pore throat radii range between $0.1 \mu\text{m}$ and $10 \mu\text{m}$, a fractal dimension D with

451 values of 2.640 for MIP, and 2.661 for NMR has been determined. The slightly higher slope of the SIP
452 curve results in a lower value of fractal dimension of $D = 2.533$.

453 Our approach enables the integration of SIP in the determination of a pore throat size distribution.
454 Considering the limited frequency range, only a limited range of pore throat radii can be reflected. Using a
455 fixed diffusion coefficient $D_{(+)} = 3.8 \times 10^{-12}$ m²/s, a range of pore throat radii between 0.1 μm and 10 μm is
456 resolved. The SIP curve is linked to the MIP curve at $r = 10$ μm . An extension to lower pore radii would
457 require the integration of higher frequencies. The removal of electromagnetic coupling effects can be one
458 first step to improve the reliability of complex conductivity spectra for frequencies larger than 100 Hz, but
459 it should be regarded that smaller pore sizes are hidden by Maxwell Wagner and dielectric relaxation. The
460 proposed procedure results in a fair agreement between SIP and MIP curves in the overlapping range of
461 pore throat radius for both the Bentheimer and the Röttbacher sample. In comparison with MIP, a slight
462 overestimation of V_c is observed for larger pore throat radii and a underestimation for lower pore throat
463 radii. Considering the two samples of the presented study, the assumption of a constant diffusion
464 coefficient seems to be justified. Though alternative kernels have not been tested, our study confirms that
465 the Debye decomposition provides a relaxation time distribution of complex conductivity spectra that can
466 be transformed in a pore throat size distribution comparable with the resulting curves from MIP. Regarding
467 the discussion on the most relevant parameter that controls the relaxation time, our assumption that the pore
468 throat radius is related to the relaxation time is supported by the results.

469 The investigations by μ -CT, MIP, NMR, and SIP on the sandstone samples have been done in the
470 laboratory. μ -CT and MIP are methods that can only be applied on rock samples. The potential of these
471 methods to derive pore size distributions is well acknowledged. NMR and SIP are methods that can also be
472 performed in boreholes or as field survey. The NMR method has been successfully applied in permeability
473 prediction at the field scale. A variety of permeability prediction models based on SIP parameters has been
474 proposed based on laboratory investigations (e.g. Robinson et al., 2018). First tests have demonstrated their
475 applicability in the field. Most permeability models consider pore size and porosity as the most important
476 parameters. The evaluation of pore sizes of sediments at the field scale is a challenging task for geophysical
477 methods. Our laboratory study has demonstrated the potential of SIP in identifying a pore size distribution.
478 Further investigations with larger sets of samples have to be done to improve the proposed procedure
479 before the pore size distribution can be extracted from high quality complex conductivity field spectra.

480 **6 Conclusions**

481 Pore radii distributions (considering both pore body and pore throat radii) have been determined by
482 different methods (μ -CT, MIP, NMR, and SIP) for two sandstone samples. The curves presenting the
483 cumulative distribution of pore volume V_c as a function of pore size have proved to be a suitable tool for

484 comparison. It becomes obvious that the distribution curves indicate remarkable differences that are based
485 on the physical principles of the used methods. The methods differ with regard to their limits of resolution.
486 The effective resolution of μ -CT is limited by the voxel size (1.75 μm). Larger pores can be easily detected,
487 whereas quantification of small pores and volumes of pores with small radii is severely affected by the
488 image quality and the image processing algorithms. The MIP yields the widest range of pore radii. The pore
489 throat radii are directly related to the pressure interval. A similar wide range of pore radii can be achieved
490 by NMR. However, the transformation of the NMR transversal relaxation time into a pore body radius
491 requires the surface relaxivity as scaling factor. In a similar way, the transformation of the electrical
492 relaxation time resulting from SIP into a pore radius is based on a scaling factor that depends on the
493 diffusion coefficient. Only a restricted range of pore radii (0.1 μm to 10 μm) can be resolved by SIP.
494 Beside the range of pore radii, the geometrical extent of the pore radius differs among the methods. μ -CT
495 enables a geometrical description of the individual pore space considering the shape of the pore. The pore
496 radius can be determined in different ways. We use the average pore radius as an equivalent for the pore
497 body radius r_b . MIP is sensitive to the pore throat radius r_t that enables the access to larger pores behind the
498 throat. The NMR relaxation time is related to an average pore body radius r_b . We assume that the IP signals
499 are caused by the ion-selected active zones in the narrow pores that are comparable with the pore throats.
500 Considering the two kinds of pore radii r_b and r_t , we use μ -CT and NMR to generate a combined curve
501 displaying V_c as a function of r_b . A good agreement between the two curves is achieved if they coincide at
502 $V_c = 0.5$. This condition is used to determine the surface relaxivity, which is in good accordance to the
503 investigated surface area and mineralogy of the sample materials. MIP is used to generate the curve
504 displaying V_c as a function of r_t over a wide range of pore throat radii. The SIP curve is fixed at the MIP
505 curve considering the coincidence at the largest pore radius resulting from SIP.
506 The two curves representing V_c as a function of both r_b and r_t are displayed in a double logarithmic plot.
507 The horizontal shift of the two graphs represents the ratio r_b/r_t . Additionally, the slope of the curves is
508 related to the fractal dimension.
509 The investigations on the samples demonstrate that the porosity increases using a method with a higher
510 resolution. Both porosity and pore volume are parameters that depend on the resolution. The fractal
511 dimension describes the size of geometric objects as a function of resolution. Therefore, the knowledge of
512 fractal behavior enables upscaling and downscaling of geometric quantities. The Bentheimer sandstone
513 sample is characterized by a ratio $r_b/r_t = 2.57$ for the larger pores. A fractal behavior is observed in the
514 range of pore radii between 0.1 μm and 10 μm with an average $D = 2.69$ determined for the pore volume by
515 MIP, NMR, and SIP. The Röttbacher sandstone sample indicates with $r_b/r_t = 9.13$ a larger ratio between
516 pore body radius and pore throat in comparison with the Bentheimer sample. An average fractal dimension
517 of $D = 2.61$ is determined for the Röttbacher sample.

518 **Acknowledgements**

519 The authors thank Sven Nordsiek (University Bayreuth) for the Debye decomposition of the SIP data,
520 Dietmar Meinel (BAM, Berlin) for supporting the CT analysis, Carsten Prinz (BAM, Berlin) for providing
521 the MIP data, and Mike Müller-Petke as well as Raphael Dlugosch (both Leibniz Institute for Applied
522 Geophysics, Hanover) for the acquisition of the NMR spectra for this study. Dr. Zeyu Zhang thanks
523 Bundesanstalt für Materialforschung und –prüfung (BAM, Berlin) for the Adolf-Martens-Fellowship that
524 enabled his stay in Germany for the experimental research.
