### 33 **Abstract**

34 We investigate the pore space of rock samples with respect to different petrophysical parameters using  
35 various methods, which provide data upon pore size distributions, including micro computed tomography  
36 ( $\mu$ -CT), mercury intrusion porosimetry (MIP), nuclear magnetic resonance (NMR), and spectral induced  
37 polarization (SIP). The resulting cumulative distributions of pore volume as a function of pore size are  
38 compared. Considering that the methods differ with regard to their limits of resolution, a multiple length  
39 scale characterization of the pore space geometry is proposed, that is based on a combination of the results  
40 from all of these methods. The approach is demonstrated using samples of Bentheimer and Röttbacher  
41 sandstone. Additionally, we compare the potential of SIP to provide a pore size distribution with other  
42 commonly used methods (MIP, NMR). The limits of resolution of SIP depend on the usable frequency  
43 range (between 0.002 Hz and 100 Hz). The methods with similar resolution show a similar behavior of the  
44 cumulative pore volume distribution in the overlapping pore size range. We assume that  $\mu$ -CT and NMR  
45 provide the pore body size while MIP and SIP characterize the pore throat size. Our study shows that a  
46 good agreement between the pore radii distributions can only be achieved if the curves are adjusted  
47 considering the resolution and pore volume in the relevant range of pore radii. The MIP curve with the  
48 widest range in resolution should be used as reference.

### 51 **1 Introduction**

52 Transport and storage properties of reservoir rocks are determined by the size and arrangement of the pores.  
53 Different methods have been developed to determine the pore size distribution of rocks. These methods are  
54 based on different physical principles. Therefore, it can be expected that the methods recognize different  
55 geometries and sizes. Additionally, the ranges of pore sizes that are resolved by the methods are different  
56 (Meyer et al., 1997). Rouquerol et al. (1994) reported that no experimental method provides the absolute  
57 value of parameters such as porosity, pore size, surface area, and surface roughness.

58 Our study of pore space analysis is based on the following methods: micro computed tomography ( $\mu$ -CT),  
59 mercury intrusion porosimetry (MIP), nuclear magnetic resonance (NMR), and spectral induced  
60 polarization (SIP). The first three methods can be regarded as standard methods to derive a pore size  
61 distribution. The use of SIP in this field has been reported only recently (Revil et al., 2014; Zhang et al.,  
62 2017).

63 We are aware that further methods can be applied for the characterization of pore size distribution, e.g.  
64 synchrotron-radiation-based computed tomography (Peth et al., 2008), focused ion beam tomography  
65 (Keller et al., 2011), transmission electron microscopy (Gaboreau et al., 2012), scanning electron

66 microscopy (SEM),  $^{14}\text{C}$  labeled methylmethacrylate method (Kelokaski et al., 2005), and gas adsorption  
67 and desorption method (BET) (Avnir and Jaroniec, 1989).

68 A variety of studies has been performed to compare the pore size distribution resulting from different  
69 experiments. For example, Mesquita et al. (2016) matched NMR  $T_2$  distributions and capillary pressure  
70 curves of carbonate samples using a coupled dual porosity model to estimate the surface relaxivity. Daigle  
71 and Johnson (2016) applied percolation theory to determine the pore size distributions combining NMR  
72 and capillary pressure measurement. Zhang and Weller (2014) investigated the fractal behavior of the pore  
73 volume distribution by capillary pressure curves and NMR  $T_2$  distributions of sandstones. Considering the  
74 differences in fractal dimension resulting from the two methods, they concluded a differentiation into  
75 surface dimension and volume dimension.

76 An enhanced pore space analysis using different methods should be able to provide a better description of  
77 the pore space geometry over a wide range of pore sizes. Our study presents an approach to describe and  
78 quantify the pore space geometry of porous material by combining the results of methods with different  
79 resolution. Samples of Bentheimer and Röttbacher sandstone are investigated by  $\mu$ -CT, MIP, NMR, and  
80 SIP. The resulting pore size distributions are connected to each other to get two different pore radii  
81 distributions, one for the pore body radius and one for the pore throat radius. The comparison of the two  
82 curves enables the determination of the ratio between pore body and pore throat radius. Finally, the fractal  
83 dimension of the pore volume distribution is determined for the two samples.

## 84 **2 Methodology**

85 The pore size distribution resulting from different methods has to be compared and evaluated. We prefer a  
86 comparison based on the cumulative volume fraction of pores  $V_c$ , which is expressed by

$$87 \quad V_c = \frac{V(< r)}{V_p}, \quad (1)$$

88 with  $V_p$  being the total pore volume, and  $V(< r)$  the cumulative volume of pores with radii less than  $r$ . A  
89 graph displaying the logarithm of  $V_c$  versus the logarithm of the pore radius offers the advantage that the  
90 slope of the curves is related to the fractal dimension of the pore volume (Zhang and Weller, 2014).

91 Fractal theory is applied to describe the structure of geometric objects (Mandelbrot, 1977, 1983). At  
92 molecular size and microscopic range, surfaces of most materials including those of natural rocks show  
93 irregularities and defects that appear to be self-similar upon variation of resolution (Avnir et. al, 1984). A  
94 self-similar object is characterized by similar structures at different scales. The regularity of self-similar  
95 structures can be quantified by the parameter of fractal dimension  $D$ . Pape et al. (1982) first proposed a  
96 fractal model (the so called ‘pigeon-hole model’ or ‘Clausthal Concept’) for the geometry of rock pores.  
97 Fractal dimension describes the size of geometric objects as a function of resolution. This parameter has

98 proved to be useful in the comparison of different methods that determine distributions of geometric objects  
99 (e.g. Zhang and Weller, 2014, Ding et al., 2017).

100 The experimental methods used in this study include digital image analysis based upon micro computed  
101 tomography ( $\mu$ -CT), mercury intrusion porosimetry (MIP), nuclear magnetic resonance (NMR), and  
102 spectral induced polarization (SIP).

103 The  $\mu$ -CT method can only resolve the part of the pore space with pore sizes larger than the spatial  
104 resolution of the 3D image. Considering a voxel size of 1.75  $\mu\text{m}$  of the 3D data set, and a minimum  
105 extension of pores of two voxels in one direction, which can be separated by the algorithm, a minimum  
106 pore size of 3.5  $\mu\text{m}$  (or minimum pore radius of 1.75  $\mu\text{m}$ ) has to be regarded as effective resolution limit of  
107  $\mu$ -CT. Therefore, the pore volume determined by  $\mu$ -CT does not take into account the pore space with radii  
108 smaller than 1.75  $\mu\text{m}$ . For this study, a nanotom S 180 X-ray  $\mu$ -CT equipment (GE sensing and inspection  
109 technologies) has been used. For pore network separation, a combination of manual thresholding and  
110 watershed algorithms has been applied to achieve the qualitatively best separated pore space. Additionally,  
111 separation results have been cross checked with the images of scanning electrode microscopy (SEM). More  
112 details on the digital image analysis workflow can be found in Halisch et al. (2016). The digital image  
113 analysis of the 3-D  $\mu$ -CT data sets provide for each individual pore the volume and the pore radius of the  
114 largest sphere that can be placed inside this pore (maximum inscribed sphere method). The resulting  
115 equivalent pore radius is referred to as pore body radius  $r_b$ . Adding up the pore volumes starting with the  
116 lowest pore radius yields the cumulative volume fraction of pores  $V_c$  (Eq. (1)) as a function of the pore  
117 body radius  $r_b$ .

118  
119 From MIP, the entry sizes of pores and cavities, which is referred to as pore throat radius  $r_t$ , can be  
120 determined according to the Washburn-equation (Washburn, 1921)

$$121 \quad r_t = -\frac{2 \cdot \gamma \cdot \cos \theta}{P_c}, \quad (2)$$

122 with  $\gamma = 0.48 \text{ N/m}$  being the surface tension of mercury,  $\theta = 140^\circ$  the contact angle between mercury and  
123 the solid minerals, and  $P_c$  the pressure of the liquid mercury that is referred to as capillary pressure. The  
124 MIP experiments have been conducted with the PASCAL 140/440 instrument from Thermo Fisher  
125 (Mancuso et al., 2012), which covers a pressure range between 0.015 MPa and 400 MPa corresponding to a  
126 pore throat radius range from (at best) 1.8 nm to 55  $\mu\text{m}$ . The samples have been evacuated before the MIP  
127 experiment. Starting with low pressure, the pores with larger pore throats are filled with mercury. While  
128 increasing the pressure, the pores with smaller throats are filled. Reaching a certain pressure level  $P_c$ , a  
129 cumulative volume of mercury ( $V_{Hg}$ ) has intruded into the sample that corresponds to the pore volume  
130 being accessible by pore throats radii larger or equal  $r_t$  according to Eq. (2). The volume  $V_{Hg}$  corresponds to  
131 the pore volume  $V(>r_t)$ . It should be noted that the volume of larger pores, which are shielded by narrower

132 throats, is attributed to the pore throat radius (e.g. Kruschwitz et al., 2016). Knowing the total pore volume  
 133  $V_p$ , the saturation of the sample with mercury  $S_{Hg}$  can be determined. A conventional capillary pressure  
 134 curve displays the relationship between the saturation of the sample with mercury  $S_{Hg}$  as a function of  
 135 capillary pressure  $P_c$  (e.g. Thomeer, 1960). Using the following simple transformations

$$136 \quad S_{Hg} = \frac{V_{Hg}}{V_p} = \frac{V(> r_t)}{V_p} = \frac{V_p - V(< r_t)}{V_p} = 1 - V_c, \quad (3)$$

137 the cumulative volume fraction of pores  $V_c$  as defined in Eq. (1) can be determined as a function of  $r_t$ .

138  
 139 The NMR relaxometry experiment provides the distribution of the transversal relaxation time  $b(T_2)$ . The  
 140 individual relaxation time  $T_2$  is attributed to a pore space with a certain surface to volume ratio  $A/V$  by

$$141 \quad \frac{1}{T_2} = \rho \left( \frac{A}{V} \right), \quad (4)$$

142 with  $\rho$  being the surface relaxivity. Considering that for a capillary tube model with cylindrical pores of  
 143 uniform radius  $r$ , the surface to volume ratio equals  $2/r$ , we get the following linear relationship between  
 144 pore radius  $r$  and relaxation time  $T_2$  (e.g. Kleinberg, 1996):

$$145 \quad r = 2\rho T_2. \quad (5)$$

146 The NMR experiments have been performed with a Magritek Rock Core Analyzer equipment operating at a  
 147 Larmor frequency of 2 MHz at room temperature ( $\sim 20^\circ\text{C}$ ) and ambient pressure. After drying at  $105^\circ\text{C}$  for  
 148 more than 24 hours in vacuum, the samples have been fully saturated with tap water with a conductivity of  
 149 about 25 mS/m. NMR measurements can be calibrated to get the porosity of the sample. The early time  
 150 decay signal corresponds to the total water content. The range of resolved pore radii depends on the used  
 151 value of surface relaxivity. The amplitude  $b$  attributed to an individual relaxation time  $T_2$  is related to the  
 152 volume fraction of pores with the respective pore radius. Considering the larger pores, the resulting radius  
 153 corresponds to  $r_b$ . The smaller pore throats with lower volume yield a lower signal at shorter relaxation  
 154 times. The cumulative volume fraction of pores  $V_c$  is determined by adding up the individual  $b$  values  
 155 starting from the smallest relaxation time and normalizing to the total sum of all  $b$  values.

156  
 157 Another approach to derive a pore size distribution is based on the SIP method (Revil et al., 2014, Zhang et  
 158 al., 2017). We use the Debye decomposition (Nordsiek and Weller, 2008) to determine the electrical  
 159 relaxation time distribution as well as the total chargeability from complex conductivity spectra. To  
 160 transform the relaxation time distribution into a pore size distribution, we adopt the approach proposed by  
 161 Schwarz (1962) and applied by Revil et al. (2012) for the Stern layer polarization model:

$$162 \quad r = \sqrt{2\tau D_{(+)}}, \quad (6)$$

163 with  $D_{(+)}$  being the diffusion coefficient of the counter-ions in the Stern layer and  $\tau$  being the relaxation  
164 time. Originally, this equation describes the relation between the radius of spherical particles in an  
165 electrolyte solution and the resulting relaxation time. Though it remains discussible whether the radius of  
166 spherical grains can be simply replaced by the pore radius (Weller et al., 2016), we generally follow this  
167 approach. Additionally, we assume a constant diffusion coefficient  $D_{(+)} = 3.8 \times 10^{-12}$  m<sup>2</sup>/s as proposed by  
168 Revil (2013).

169 The signal amplitude at a given relaxation time corresponds to the pore volume related to the pore radius  
170 determined by Eq. (6). Considering the experience that the polarization is related to the specific surface  
171 area per unit pore volume (e.g. Weller et al., 2010), we assume that the IP signals are caused by the ion-  
172 selected active zones in the narrow pores that are comparable with the pore throats. Their size is quantified  
173 by the pore throat radius  $r_t$ . Following the procedure proposed by Zhang et al. (2017), the cumulative  
174 volume fraction  $V_c$  corresponds to the ratio of cumulative chargeability to total chargeability. Considering  
175 the restricted range of pore radii resolved by SIP, a correction of the maximum  $V_c$  becomes necessary.

176 Complex conductivity spectra were recorded using a four-electrode sample holder as described by Schleifer  
177 et al. (2002). The spectra were acquired with the impedance spectrometer ZEL-SIP04 (Zimmerman et al.,  
178 2008) in a frequency range between 0.002 Hz and 45 kHz at a constant temperature of about 20 °C.  
179 Considering that the complex conductivity spectra are affected by electromagnetic coupling effects or other  
180 polarization effects at higher frequencies and by a lower signal to noise ratio for lower frequencies, we  
181 focus on the frequency range between 0.01 Hz and 100 Hz. The samples were fully saturated with a  
182 sodium-chloride solution with a conductivity of 100 mS/m. At least two measurements were performed for  
183 each sample to verify the repeatability. The SIP method solely resolves a range of pore radii that depends  
184 on the diffusion coefficient. Hence, using  $D_{(+)} = 3.8 \times 10^{-12}$  m<sup>2</sup>/s in Eq. (6), we get a range of pore radii  
185 between 0.1 μm and 10 μm.

186

187 The procedures described above result in an individual curve displaying the logarithm of  $V_c$  versus the  
188 logarithm of the pore radius for each method. Previous studies have compared the resulting curves (e.g.  
189 Zhang and Weller, 2014; Zhang et al., 2017; Ding et al., 2017). The slope of the curves was used to get a  
190 fractal dimension. It became obvious that the distribution curves indicate remarkable differences that are  
191 caused by the physical principles of the used methods. The methods differ with regard to their limits of  
192 resolution. The effective resolution of μ-CT is limited by the voxel size. Larger pores can be easily detected.  
193 The MIP yields the widest range of pore radii. The pore radius is directly related to the pressure. A  
194 similarly wide range of pore radii can be resolved by NMR. However, the transformation of the NMR  
195 transversal relaxation time into a pore radius requires the surface relaxivity as scaling factor. In a similar  
196 way, the transformation of the electrical relaxation time resulting from SIP into a pore radius is based on a

197 scaling factor that depends on the diffusion coefficient. Only a restricted range of pore radii can be resolved  
198 by SIP.

199 Beside the range of pore radii, the geometrical extend of the pore radius differ among the methods.  $\mu$ -CT  
200 enables a geometrical description of the individual pore space considering the shape of the pore. The pore  
201 radius can be determined in different ways. We use the average pore radius as an equivalent for the pore  
202 body radius  $r_b$ . MIP is sensitive to the pore throat radius  $r_t$  that enables the access to larger pores behind the  
203 throat. The NMR relaxation time is related the pore body radius  $r_b$ . We assume that the IP signals are  
204 caused by the ion-selected active zones in the narrow pores that are comparable with the pore throats.

205 Regarding the differences of the methods, we present an approach that combines the curves to get more  
206 information on the pore space geometry. Considering the two kinds of pore radii  $r_b$  and  $r_t$ , we use first  $\mu$ -  
207 CT and NMR to generate a combined curve displaying  $V_c$  as a function of  $r_b$ . In the next step, we link the  
208 curves resulting from MIP and SIP to get a curve showing  $V_c$  as a function of the pore throat radius  $r_t$ .

209 It is fundamental that the total pore volume (or total porosity) has to be known. The cumulative pore  
210 volume fraction should only consider the pore volume that is resolved in the regarded range of pore radii.  
211 Considering the resolution of  $\mu$ -CT, only the pore space with radii larger than the voxel size is determined.  
212 The cumulative pore volume fraction at the limit of resolution has to be adjusted to the non-resolved pore  
213 volume. In this way, the  $\mu$ -CT curve gets a fixed position in the  $V_c - r$  plot. Regarding NMR, the relaxation  
214 time  $T_2$  has to be transformed into a pore radius according to Eq. (5). The application of Eq. (5) requires the  
215 knowledge of the surface relaxivity  $\rho$ , which is the necessary scaling factor that causes a shift of the  $V_c - r$   
216 curve along the axis of pore radius. Since NMR method is sensitive to the pore body radius, we expect a  
217 similar  $V_c - r$  curve for NMR and  $\mu$ -CT in the overlapping range of pore radii. The NMR curve is shifted  
218 along the axis of pore radii until a good agreement between the two curves is reached. This procedure  
219 enables the adjustment of the surface relaxivity.

220 MIP is used to generate the curve displaying  $V_c$  as a function of  $r_t$  over a wide range of pore radii. The SIP  
221 curve is fixed at the MIP curve considering the coincidence at the largest pore radius resolved by SIP.

222 The two curves representing  $V_c$  as a function of both  $r_b$  and  $r_t$  are displayed in a double logarithmic plot.  
223 The shift of the two graphs represents the ratio  $r_b/r_t$ . Additionally, the slope of the curves is related to the  
224 fractal dimension.

### 225 3 Sample material

226 For this study, two different sandstone samples have been used: first, a Bentheimer sandstone, sample  
227 BH5-2. The Bentheimer sandstone formation is exposed in outcrops just east of the Dutch-German border  
228 in the vicinity of Bad Bentheim, Germany. The shallow-marine Bentheimer sandstone was deposited  
229 during the Early Cretaceous (roughly 140 million years ago) and forms an important reservoir rock for  
230 petroleum (Dubelaar et al., 2015). This sandstone is widely used for systematic core analysis due its simple

231 mineralogy and the quite homogeneous and well-connected pore space. It is mainly composed out of quartz,  
232 contains some feldspar and about 5 vol.-% of kaolinite, which is a direct alteration product of the  
233 potassium-bearing feldspar minerals. Accordingly, surface area as well as surface relaxivity values are  
234 mostly controlled by the kaolinite for this rock. Figure 1 (A and B) gives 2-D impressions of the pore  
235 system of the Bentheimer sandstone sample. The pore space in general is very well connected, featuring  
236 many large and open pores (Fig. 1, A & B, blue arrows) and can be described as a classical pore body –  
237 pore throat – pore body system. Small pores are mostly found within the clayey agglomerations, which act  
238 as (macro) pore filling material (Fig. 1, A & B, red arrows) and which are homogeneously distributed  
239 throughout the sample material. This favorable structure is directly reflected by the petrophysical properties  
240 of this sandstone. The sample investigated in our study is characterized by a porosity of 0.238, a gas-  
241 permeability of 425 mD and a specific surface area of 0.3 m<sup>2</sup>/g.

242 Secondly, a Röttbacher sandstone, sample RÖ10B, has been used. The Röttbacher sandstone is a fine-  
243 grained, more muscovite-illite containing, and rather homogeneous material that was deposited during the  
244 Lower Triassic era (roughly 250 million years ago). It is suitable for solid stonework and has been widely  
245 used as building material for facades as well as for indoor and outdoor flooring. The Röttbacher sandstone  
246 was included in a study on the relationship of pore throat sizes and SIP relaxation times reported by  
247 Kruschwitz et al. (2016). This sandstone consists mostly of quartz, but features a higher amount of clay  
248 minerals than the Bentheimer sample. Additionally, Fe-bearing minerals (e.g. haematite) have been formed  
249 during its arid depository environment, giving this sandstone a distinct reddish color. Accordingly, surface  
250 area as well as surface relaxivity are dominated by the clay and the Fe-bearing minerals and should be  
251 significantly different than for the BH5-2 sample. Figure 1 (C and D) showcases an impression of the pore  
252 space from 2-D imaging techniques. Though the (large) pore space is similar structured as it is for the  
253 Bentheimer (pore body-throat-body system, Fig. 1, C & D, blue arrows), it is generally reduced (cemented)  
254 by clay minerals and features a significantly higher amount of small pores within (Fig. 1, C & D, red  
255 arrows). Accordingly, pore space related petrophysical properties classify a more compact rock. The  
256 sample used for this study features a porosity of 0.166, which is lower than for the Bentheimer sandstone.  
257 The gas-permeability is 34.5 mD, which is less than 10 % of the value determined for the Bentheimer  
258 sandstone. The specific surface area has been measured with 1.98 m<sup>2</sup>/g and is hence nearly seven times  
259 larger than for sample BH5-2, clearly underlining the impact of the clay content. The petrophysical  
260 parameters for both samples are compiled in Table 1, whereas results from X-ray fluorescence analysis are  
261 summarized in Table 2, regarding the most important mineral components of both sandstones that have  
262 been used for this study.

## 263 4 Results

### 264 4.1 Bentheimer sandstone

265 We applied the methods  $\mu$ -CT, MIP, NMR, and SIP to get insight into the pore radius distribution of the  
266 Bentheimer sandstone sample BH5-2. Figure 2 displays the resolved porosity  $\phi_r$  as a function of pore radius  
267 for  $\mu$ -CT and MIP data. The cumulative pore volume while progressing from larger to smaller pores  $V(>r)$   
268 is normalized to the total volume of the sample  $V_s$  and results in the resolved porosity

$$269 \quad \phi_r = \frac{V(>r)}{V_s}, \quad (7)$$

270 which reaches the true porosity  $\phi$  as threshold value for  $r$  approaching zero.

271 As shown in Figure 2, the  $\mu$ -CT method identifies the largest pores with pore body radii of about 100  $\mu\text{m}$ .  
272 The resolved porosity  $\phi_r$  reaches a value of 0.184 at the limit of resolution of the  $\mu$ -CT method ( $r_b=1.75$   
273  $\mu\text{m}$ ). The nearly horizontal curve progression for  $r < 17 \mu\text{m}$  indicates that no pores with radii lower than 17  
274  $\mu\text{m}$  were detected by  $\mu$ -CT.

275 The MIP identifies the largest pore throats with a radius of about 30  $\mu\text{m}$ . Reaching the limit of resolution of  
276 the MIP, the resolved porosity approaches asymptotically the threshold value of 0.238. Though both  
277 methods  $\mu$ -CT and MIP yield the pore radius without any adjustable scaling factor, we observe differences  
278 between the two curves  $\phi_r(r)$  in Figure 2.

279 Applying the transformation in Eq. (3) for the MIP data and assuming a true porosity of 0.238, the  
280 cumulative volume fraction of pores  $V_c$  can be displayed as a function of pore radius as shown in Figure 3.  
281 The MIP curve gets a fixed position in the plot of Figure 3 without the need for any scaling. It covers a  
282 wide range of pore radii.

283 The curves resulting from other methods have to be adjusted considering the limits of the range of pore  
284 radii. The maximum of the  $\mu$ -CT curve corresponds to  $V_c = 1$  because no larger pore size has been detected  
285 by other methods. The maximum resolved porosity of the sample as detected by MIP reaches 0.238. The  
286 porosity determined by  $\mu$ -CT reaches only 0.184 (Figure 2). This value corresponds to a fraction of 0.773  
287 of the porosity determined by MIP. Therefore, the minimum of the  $\mu$ -CT curve at the pore radius of 17  $\mu\text{m}$   
288 has to be adjusted at  $V_c = 1 - 0.773 = 0.227$ , because this fraction of pore volume is related to pore radii  
289 smaller than 17  $\mu\text{m}$ . The shift of the  $\mu$ -CT curve to larger pore radii in comparison with MIP is observed in  
290 this plot, too.

291 The  $T_2$  relaxation time distribution of sample BH5-2 is plotted in Figure 4. It indicates a distinct maximum  
292 at a relaxation time of 330 ms and two weaker maxima at lower relaxation times. The  $T_2$  relaxation time  
293 distribution is transformed into a curve showing the cumulative intensity as a function of  $T_2$ . The total  
294 intensity is attributed to the total pore volume. The volume fraction  $V_c$  corresponds to the ratio of  
295 cumulative intensity to total intensity. In order to get the curve  $V_c$  as a function of pore radius, the

296 relaxation time  $T_2$  has to be transformed into a pore radius using the surface relaxivity  $\rho$  as scaling factor in  
297 Eq. (5). Since both  $\mu$ -CT and NMR method are sensitive to the pore body radius, we expect a similar  $V_c - r$   
298 - curve in the overlapping range of pore radii. Assuming a coincidence of the two curves at  $V_c = 0.5$ , the  
299 surface relaxivity is adjusted at  $\rho = 54 \mu\text{m/s}$ .

300 Considering the frequency range between 0.01 and 100 Hz and  $D_{(+)} = 3.8 \times 10^{-12} \text{ m}^2/\text{s}$ , the relaxation time  
301 distribution derived from SIP is attributed to a restricted range of pore radii between 0.1  $\mu\text{m}$  and 10  $\mu\text{m}$ .  
302 Assuming that the polarization signals originate from the pore throats, a similarity of pores size  
303 distributions resulting from MIP and SIP can be expected. It should be noted that MIP provides the  
304 distribution for a wider range of pore radii. Therefore, we adjust the value of  $V_c$  at the maximum radius of  
305 the SIP to the corresponding value for the MIP curve.

#### 306 4.2 Röttbacher sandstone

307 The Röttbacher sample was scanned with resolution 1.5  $\mu\text{m}$  by  $\mu$ -CT. As shown in Figure 6, the  $\mu$ -CT  
308 method identifies the largest pores with pore body radii of about 90  $\mu\text{m}$ . The resolved porosity  $\phi_r$  reaches a  
309 value of 0.106 at the limit of resolution of the  $\mu$ -CT method ( $r_b=1.5 \mu\text{m}$ ). The nearly horizontal curve  
310 progression for  $r < 10 \mu\text{m}$  indicates that no pores with radii lower than 10  $\mu\text{m}$  were detected by  $\mu$ -CT.

311 The MIP identifies the largest pore throats with a radius of about 50  $\mu\text{m}$ . Reaching the limit of resolution of  
312 MIP, the resolved porosity gets the value of 0.166. Applying the transformation in Eq. (3) on the MIP data  
313 and assuming a true porosity of 0.166, the cumulative volume fraction of pores  $V_c$  is displayed as a function  
314 of pore radius as shown in Figure 7.

315 We suppose that the MIP method detects the whole pore volume, a porosity of 0.106 recognized by  $\mu$ -CT  
316 corresponds to 63.9% of the total pore volume. Therefore, the minimum of the  $\mu$ -CT curve at the pore  
317 radius of 10  $\mu\text{m}$  has to be adjusted at  $V_c = 1 - 0.639 = 0.361$ , because this fraction of pore volume is related  
318 to pore radii smaller than 10  $\mu\text{m}$ .

319 The  $T_2$  relaxation time distribution of sample RÖ10B is plotted in Figure 4. It indicates a distinct maximum  
320 at a relaxation time of 170 ms. Non-vanishing signals are observed at relaxation times below 0.1 ms. This is  
321 an indication of the existence of very small pores in the Röttbacher sandstone.

322 The position of the NMR curve in the plot of Figure 7 depends on the surface relaxivity  $\rho$ . A coincidence  
323 with the  $\mu$ -CT curve at  $V_c = 0.5$  requires a surface relaxivity of  $\rho = 237 \mu\text{m/s}$  for adjusting the NMR curve.

324 The complex conductivity spectra of the Röttbacher sample are displayed in Figure 5. The processing of the  
325 spectra according to the described algorithm results in the  $V_c - r$  - curve as shown in Figure 7. The SIP  
326 curve is fixed at the value  $V_c = 0.9$  that has been determined by MIP for the maximum pore radius resolved  
327 by SIP ( $r_t = 10 \mu\text{m}$ ).

## 328 5 Discussion

329 The proposed approach in this study results in two pore size distribution curves for the two samples, which  
330 are in good accordance to the general pore space structures as described in section 3 and as visualized in  
331 Figure 1 (A to D). The first curve combines the distributions resulting from  $\mu$ -CT and NMR. The  $\mu$ -CT data  
332 provide a pore radius, which is regarded as pore body radius, without any scaling. The scaling of the NMR-  
333 curve provides an estimate of the surface relaxivity. The surface relaxivity of the Bentheimer sample  
334 reaches 54  $\mu\text{m/s}$ , the corresponding value of the Röttbacher sample is with 237  $\mu\text{m/s}$  much higher. The  
335 higher surface relaxivity in comparison with the Bentheimer sample is clearly justified considering the  
336 larger specific surface area (Table 1) and the significantly higher content of clay and iron-bearing minerals  
337 as indicated in Table 2 (e.g. Keating and Knight, 2010).

338 The two cumulative pore volume distribution curves for the Röttbacher sample (Figure 7) indicate over the  
339 wide range of pore radii a parallel progression with consistently higher values for the pore body radius ( $\mu$ -  
340 CT and NMR) in comparison with the pore throat radius (MIP). The horizontal distance of the two curves  
341 yields the ratio  $r_b/r_t$ . Regarding the median pore radii at  $V_c = 0.5$ , a ratio  $r_b/r_t = 9.13$  is determined.  
342 Considering smaller pores, a ratio  $r_b/r_t = 12.15$  is indicated at  $V_c = 0.05$ .

343 The parallelism of the pore volume distribution curve is less developed for the Bentheimer sample (Figure  
344 3). We observe a clear distance of the two curves in the range of larger pore radii. Regarding the median  
345 pore radii at  $V_c = 0.5$ , a ratio  $r_b/r_t = 2.57$  is determined. For  $V_c < 0.2$ , the slope of the curves decreases and  
346 smaller distances between the curves are observed. The NMR curve in Figure 3 indicates for  $V_c > 0.08$   
347 larger pore radii in comparison with the MIP curve and confirms the relationship  $r_b > r_t$ . The reverse  
348 behavior in the interval  $0.1 \mu\text{m} < r < 0.6 \mu\text{m}$  is possibly caused by the low volume fraction (3%) attributed  
349 to this range of pore radii. It can be expected that the small amount of water in the small pores causes only  
350 weak signals in the NMR relaxometry. Certainly, the resolution of all methods is limited in the range of  
351 pore radii that contains only a small volume of water.

352 Beside the distances between the curves the individual slopes are regarded. The slope ( $s$ ) of the curve  $\log$   
353 ( $V_c$ ) versus  $\log$  ( $r$ ) is related to the fractal dimension  $D$  of the pore volume ( $D = 3 - s$ ) (Zhang and Weller,  
354 2014). We observe a varying slope in the investigated range of pore radii for the Bentheimer sample. The  
355 only range of more or less constant slope, which extends from pore radius  $0.1 \mu\text{m}$  to  $10 \mu\text{m}$ , corresponds to  
356 a fractal dimension  $D_{MIP} = 2.678$  for MIP,  $D_{NMR} = 2.776$  for NMR, and  $D_{SIP} = 2.618$  for SIP.

357 We observe a constant slope of the NMR curve for the Röttbacher sample (Figure 7) in the interval  $0.01$   
358  $\mu\text{m} < r_b < 100 \mu\text{m}$ . A similar slope is observed for the MIP curve in the interval  $0.01 \mu\text{m} < r_t < 10 \mu\text{m}$ .  
359 Considering the overlapping pore throat radii range between  $0.1 \mu\text{m}$  and  $10 \mu\text{m}$ , a fractal dimension  $D$  with  
360 values of 2.640 for MIP, and 2.661 for NMR has been determined. The slightly higher slope of the SIP  
361 curve results in a lower value of fractal dimension ( $D = 2.533$ ).

362 Our approach enables the integration of SIP in the determination of a pore throat size distribution.  
363 Considering the limited frequency range, only a limited range of pore throat radii can be reflected. Using a  
364 fixed diffusion coefficient  $D_{(+)} = 3.8 \times 10^{-12}$  m<sup>2</sup>/s, a range of pore throat radii between 0.1 μm and 10 μm is  
365 resolved. The SIP curve is linked to the MIP curve at  $r = 10$  μm. The proposed procedure results in a fair  
366 agreement between SIP and MIP curves in the overlapping range of pore throat radius for both the  
367 Bentheimer and the Röttbacher sample. In comparison with MIP, a slight overestimation of  $V_c$  is observed  
368 for larger pore throat radii and a underestimation for lower pore throat radii. Considering the two samples  
369 of the presented study, the assumption of a constant diffusion coefficient seems to be justified. Regarding  
370 the discussion on the most relevant parameter that controls the relaxation time, our assumption that the pore  
371 throat radius is related to the relaxation time is supported by the results.

## 372 6 Conclusions

373 Pore radii distributions have been determined by different methods (μ-CT, MIP, NMR, and SIP) for two  
374 sandstone samples. The curves presenting the cumulative distribution of pore volume  $V_c$  as a function of  
375 pore size have proved to be a suitable tool for comparison. It becomes obvious that the distribution curves  
376 indicate remarkable differences that are based on the physical principles of the used methods. The methods  
377 differ with regard to their limits of resolution. The effective resolution of μ-CT is limited by the voxel size  
378 (3.5 μm). Larger pores can be easily detected. The MIP yields the widest range of pore radii. The pore radii  
379 are directly related to the pressure interval. A similar wide range of pore radii can be achieved by NMR.  
380 However, the transformation of the NMR transversal relaxation time into a pore radius requires the surface  
381 relaxivity as scaling factor. In a similar way, the transformation of the electrical relaxation time resulting  
382 from SIP into a pore radius is based on a scaling factor that depends on the diffusion coefficient. Only a  
383 restricted range of pore radii (0.1 μm to 10 μm) can be resolved by SIP.

384 Beside the range of pore radii, the geometrical extend of the pore radius differ among the methods. μ-CT  
385 enables a geometrical description of the individual pore space considering the shape of the pore. The pore  
386 radius can be determined in different ways. We use the average pore radius as an equivalent for the pore  
387 body radius  $r_b$ . MIP is sensitive to the pore throat radius  $r_t$  that enables the access to larger pores behind the  
388 throat. The NMR relaxation time is related to an average pore body radius  $r_b$ . We assume that the IP signals  
389 are caused by the ion-selected active zones in the narrow pores that are comparable with the pore throats.

390 Considering the two kinds of pore radii  $r_b$  and  $r_t$ , we use μ-CT and NMR to generate a combined curve  
391 displaying  $V_c$  as a function of  $r_b$ . A good agreement between the two curves is achieved if they coincide at  
392  $V_c = 0.5$ . This condition is used to determine the surface relaxivity, which is in good accordance to the  
393 investigated surface area and mineralogy of the sample materials. MIP is used to generate the curve

394 displaying  $V_c$  as a function of  $r_t$  over a wide range of pore radii. The SIP curve is fixed at the MIP curve  
395 considering the coincidence at the largest pore radius resulting from SIP.  
396 The two curves representing  $V_c$  as a function of both  $r_b$  and  $r_t$  are displayed in a double logarithmic plot.  
397 The shift of the two graphs represents the ratio  $r_b/r_t$ . Additionally, the slope of the curves is related to the  
398 fractal dimension.  
399 The investigations on the samples demonstrate that the porosity increases using a method with a higher  
400 resolution. Both porosity and pore volume are parameters that depend on the resolution. The fractal  
401 dimension describes the size of geometric objects as a function of resolution. Therefore, the knowledge on  
402 fractal behavior enables upscaling and downscaling of geometric quantities. The Bentheimer sandstone  
403 sample is characterized by a ratio  $r_b/r_t = 2.57$  for the larger pores. A fractal behavior is observed in the  
404 range of pore radii between  $0.1 \mu\text{m}$  and  $10 \mu\text{m}$  with an average  $D = 2.69$  determined for the pore volume by  
405 MIP, NMR, and SIP. The Röttbacher sandstone sample indicates with  $r_b/r_t = 9.13$  a larger ratio between  
406 pore body radius and pore throat in comparison with the Bentheimer sample. An average fractal dimension  
407 of  $D = 2.61$  is determined for the Röttbacher sample.

#### 408 **Acknowledgements**

409 The authors thank Sven Nordsiek (University Bayreuth) for the Debye decomposition of the SIP data,  
410 Dietmar Meinel (BAM, Berlin) for supporting the CT analysis, Carsten Prinz (BAM, Berlin) for providing  
411 the MIP data, and Mike Müller-Petke as well as Raphael Dlugosch (both LIAG) for the acquisition of the  
412 NMR spectra for this study. Dr. Zeyu Zhang thanks Bundesanstalt für Materialforschung und –prüfung  
413 (BAM, Berlin) for the Adolf-Martens-Fellowship that enabled his stay in Germany for the experimental  
414 research.

Figure 1: SEM (A) and 2D (B) CT views upon the minerals and pore structure of the investigated sample of Bentheimer sandstone, and SEM (C) and 2D (D) CT views upon the minerals and pore structure of the investigated sample of Röttbacher sandstone. Blue arrows indicate open pore spaces, red arrows indicate clay agglomerations and pore fillings.
