Keywords: basin modeling, passive margin, obduction, burial, Raman spectroscopy, thermochronology, thermal maturity

Abstract. We present a study of the pressure and temperature evolution in the passive continental margin under the Oman Ophiolite, using numerical basin models calibrated with thermal maturity data, fluid inclusion thermometry and low-temperature thermochronometry, and building on the results of recent work on the tectonic evolution. Because the Oman Mountains experienced only weak post-obduction overprint, they offer a unique natural laboratory for this study.

Thermal maturity data from the Adam Foothills constrain burial in the basin in front of the advancing nappes to at least 4 km. Peak temperature evolution in the carbonate platform under the ophiolite depends on the burial depth and only weakly on the temperature of the overriding nappes which have cooled during transport from the oceanic subduction zone to emplacement. Fluid-inclusion thermometry yields pressure-corrected homogenization temperatures of 225 to 266 °C for veins formed during progressive burial, 296-364 °C for veins related to peak burial and 184 to 213 °C for veins associated with late-stage strike-slip faulting. In contrast, the overlying Hawasina nappes have not been heated above 130-170 °C, as witnessed by only partial resetting of the zircon (U-Th)/He thermochronometer.

In combination with independently determined temperatures from solid bitumen reflectance, we infer that the fluid inclusions of peak-burial-related veins formed at minimum pressures of 225-285 MPa. This implies that the rocks of the future Jebel Akhdar Dome were buried under 8-10 km of ophiolite on top of 2 km of sedimentary nappes, in agreement with thermal maturity data of solid bitumen reflectance and Raman spectroscopy.

Rapid burial of the passive margin under the ophiolite results in sub-lithostatic pore pressures, as indicated by veins formed in dilatant fractures in the carbonates. We infer that overpressure is induced by rapid burial under the ophiolite. Tilting of the carbonate platform in combination with overpressure in the passive margin caused fluid migration towards the south in front of the advancing nappes.

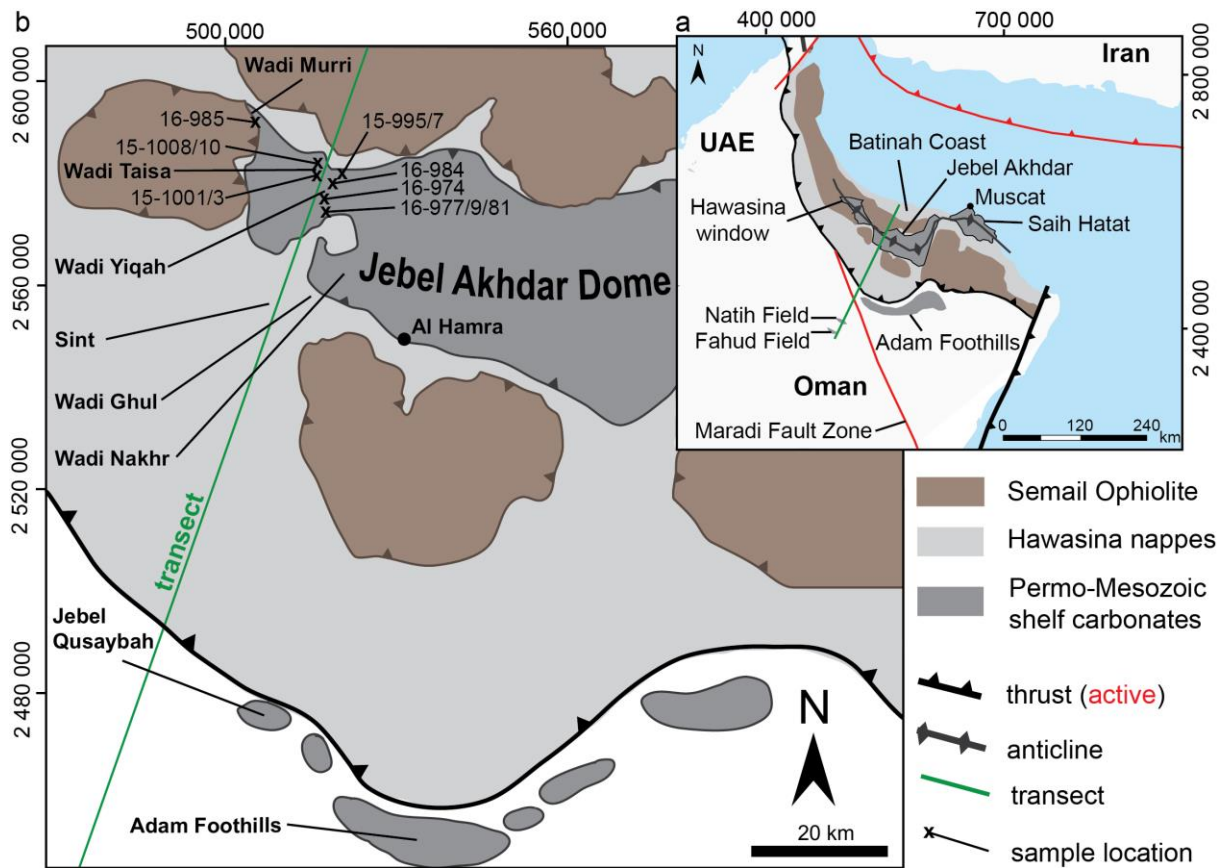

Exhumation of the Jebel Akhdar as indicated by our zircon (U-Th)/He data and in agreement with existing work on the tectonic evolution, started as early as the late Cretaceous to early Cenozoic, linked with extension above a major listric shear zone with top-to-NNE shear sense. In a second exhumation phase the carbonate platform and

40 obducted nappes of the Jebel Akhdar Dome cooled together below c. 170 °C between 50 and 40 Ma, before the
41 final stage of anticline formation.

42 **1. Introduction**

43 The Permian-Mesozoic platform sediments of north Oman (Figure 1; e.g. Beurrier et al., 1986; Glennie et al.,
44 1974; Lippard et al., 1982) with hydrocarbon accumulations in the southern foreland of the Jebel Akhdar Dome
45 (Figures 1 and 2) are overlain by the Semail ophiolite nappe complex, the largest and best-preserved ophiolite on
46 Earth. Limited tectonic extension after obduction followed by uplift, folding and deep erosion and the present-day
47 arid climate formed exceptional exposures in three tectonic windows and in the foreland fold-and-thrust belt of
48 the Oman Mountains (Figure 1). The structural and tectonic evolution of the Oman Mountains has been one main
49 focus of our group in the last 15 years (e.g. Arndt et al., 2014; Gomez-Rivas et al., 2014; Grobe et al., 2016, 2018;
50 Hilgers et al., 2006; Holland et al., 2009a; Virgo et al., 2013a, 2013b) and was investigated in many other studies
51 focusing on tectonic history (Breton et al., 2004; Cooper et al., 2014; Glennie et al., 1973, 1974; Grobe et al., 2018;
52 Loosveld et al., 1996; Searle, 2007), stratigraphic sequences (Van Buchem et al., 2002; Grelaud et al., 2006;
53 Homewood et al., 2008), geodynamic modelling (Duretz et al., 2015), hydrocarbon source rocks (Van Buchem et
54 al., 1996; Philip et al., 1995; Scott, 1990) and reservoir rocks (Arndt et al., 2014; De Keijzer et al., 2007; Koehrer
55 et al., 2011; Virgo et al., 2013a). Less well known is the temperature and pressure evolution of the subophiolite
56 passive margin units and the subsequent cooling history of the Jebel Akhdar (Aldega et al., 2017; Grobe et al.,
57 2018; Hansman et al., 2017; Poupeau et al., 1998; Saddiqi et al., 2006). This information is vital for our
58 understanding of the time-temperature history of overthrust margins and would allow to further constrain
59 obduction dynamics and forebulge migration. Combining peak temperature evolution with cooling ages links the
60 burial history with phases of orogeny.

 64 **Akhdar and Saih Hatat as well as the Adam Foothills. Brown areas show the exposed Semail Ophiolite, black lines**
 65 **denote the obduction fronts of Semail and Masirah ophiolites, red lines denote lithosphere-scale, active faults. The**
 66 **modeled transect (black line) crosscuts the Jebel Akhdar window and continues to the Natih and Fahud oil fields in the**
 67 **southwestern mountain foreland. b) Geologic map of the Jebel Akhdar window with the location of the modeled transect**
 68 **(solid black line) and the locations of thermal maturity data (x).**

69 In other orogens, peak temperatures related to nappe emplacement were reconstructed by analyzing thermal
 70 maturity of finely dispersed organic material (e.g. Teichmüller and Teichmüller, 1986; Zagros: Mashhadi et al.,
 71 2015; Holy Cross Mountain: Schito et al., 2017; Eastern Alps: Lünsdorf et al., 2012; Southern Alps: Rantitsch and
 72 Rainer, 2003; Apennines: Reutter et al., 1988). However, the number of studies of thermal and pressure effects on
 73 overthrust sedimentary basins is limited and modeling approaches to reconstruct such large scale overthrusts are
 74 increasing but still few (e.g. Aldega et al., 2018; Deville and Sassi, 2006; Ferreiro Máhlmann, 2001; Jirman et al.,
 75 2018; Oxburgh and Turcotte, 1974; Roure et al., 2010; Schito et al., 2018; Wygrala, 1989). In these studies, a main
 76 difficulty is to differentiate between temperature history of overthrusting and overprinting by later phases of
 77 orogeny. In the Oman Mountains, peak temperatures reached by obduction have not been overprinted. The whole
 78 Permian-Mesozoic sequence of the carbonate platform below the ophiolite is well exposed, providing outcrop to
 79 study the pressure and temperature history of this rapidly buried passive-margin sequence.

80 In this paper we present new thermal maturity, thermochronology and fluid inclusion data, and integrate them in
 81 a numerical basin model of the pressure-temperature evolution along a transect extending from the undeformed
 82 passive margin sequence in the south to the Batinah coast in the north (Figure 2). This helps to constrain
 83 temperature and pressure conditions of maximum burial, and the time of dome formation and exhumation linked
 84 to the structural and tectonic evolution of the area (Grobe et al., 2018). Our results for the Oman Mountains can
 85 be used to understand more deformed orogens, shed light to fluid migration in the early stages of orogeny and on
 86 exhumation related to orogenic collapse.

88 **Figure 2: Structural transect used for modeling the Jebel Akhdar Dome and its southern foreland (Al-Lazki et al., 2002;**
 89 **Filbrandt et al., 2006; Searle, 2007; Warburton et al., 1990). Highlighted are the locations of the pseudo-wells (black**
 90 **circles) in Wadi Nakhr, Wadi Yiqah and at Jebel Qusaybah, Adam Foothills, which were used for model calibration.**
 91

92 2. Geological setting

93 2.1. Tectonic setting

94 Along the northeastern coast of Arabia, the NW-SE oriented Oman Mountains form a more than 400 km long
 95 anticlinal orogen (Figure 1). The mountain belt consists of allochthonous sedimentary and ophiolitic nappes thrust
 96 onto a Permian-Mesozoic passive continental margin (Breton et al., 2004; Glennie et al., 1973; Loosveld et al.,
 97 1996; Searle and Cox, 2002).

98 This continental margin was formed during opening of the Neotethyan ocean (Loosveld et al., 1996) and the
 99 formation of the Permian-Mesozoic Hawasina Basin (Béchenec et al., 1988; Bernoulli et al., 1990). The initiation
 100 of subsea thrusting of the future Semail Ophiolite onto the Arabian Plate at 97-92 Ma, is recorded by U-Pb
 101 geochronology (Rioux et al., 2013, 2016; Warren et al., 2005) and $^{40}\text{Ar}/^{39}\text{Ar}$ dating of the metamorphic sole
 102 (Hacker et al., 1996). The advancing ophiolite caused a flexural forebulge that moved southwestwards through the
 103 passive margin during the Upper Cretaceous (Robertson, 1987). Forebulge migration induced up to 1100 m of
 104 uplift of the Permian-Mesozoic Arabian Platform and erosion of the Cretaceous platform sediments (Searle, 2007),
 105 causing the Wasia-Aruma Break (Robertson, 1987).

106 During this convergence, parts of the Hawasina ocean sediments and volcanic units became detached and accreted
 107 in front of and beneath the ophiolite nappe (Béchenec et al., 1988, 1990; Glennie et al., 1974; Searle et al., 2003;
 108 Warburton et al., 1990). Palinspastic reconstructions of the Hawasina Nappes locate the position of the initial
 109 ophiolite thrusting 300-400 km offshore the Arabian coast (Béchenec et al., 1988; Glennie et al., 1974).

110 In the carbonate platform, burial under the advancing nappes led to generation of overpressure cells and formation
 111 of three crack-seal calcite vein generations (Gomez-Rivas et al., 2014; Grobe et al., 2018; Hilgers et al., 2006;
 112 Holland et al., 2009a; Virgo, 2015). The highest grades of metamorphism is recorded by eclogites exposed in As
 113 Sifah (Figure 1a), at c. 79 Ma (Warren et al., 2003).

114 The sedimentary record in the Batinah coast and the foreland, as well as laterite formation on top of the ophiolite
 115 suggest subaerial exposure and a slow-down or stopped obduction before lower marine conditions were restored
 116 in the Maastrichtian (Coleman, 1981; Forbes et al., 2010; Nolan et al., 1990). This slowdown might relate to the
 117 formation of the Makran subduction zone (Agard et al., 2005; Grobe et al., 2018; Hassanzadeh and Wernicke,
 118 2016; Jacobs et al., 2015; Mouthereau, 2011) preserving the early stage of the obduction orogen in Oman.

119 In the Jebel Akhdar, post-obduction extension took place along ductile top-to-NNE shear zones, at 64 ± 4 Ma
 120 (Grobe et al., 2018; Hansman et al., 2018), followed by NW-SE striking normal fault systems (Al-Wardi and

121 Butler, 2007; Fournier et al., 2006; Grobe et al., 2018; Hanna, 1990; Hilgers et al., 2006; Holland et al., 2009a,
122 2009b; Loosveld et al., 1996; Mattern and Scharf, 2018; Virgo, 2015).

123 Renewed Arabia-Eurasia convergence during the Cenozoic formed the three dome structures. Timing of formation
124 and exhumation of the Jebel Akhdar Dome is still debated. Stratigraphic arguments for a late Cretaceous doming
125 are Maastrichtian rocks unconformably deposited on Hawasina (Bernoulli et al., 1990; Fournier et al., 2006;
126 Hanna, 1990; Nolan et al., 1990), while inclined Miocene strata at the northern fringes of the dome points to a
127 Miocene doming (Glennie et al., 1973). Consequently, some models suggest a two-phased exhumation in
128 Cretaceous and Miocene (Grobe et al., 2018; Searle, 1985, 2007), in agreement with thermochronological
129 constraints and an interpreted two-stage cooling with possible reheating in late Miocene (Poupeau et al., 1998;
130 Saddiqi et al., 2006). More recent studies, however, have shown that the data can also be explained by a cooling-
131 only scenario with exhumation in the Eocene (Hansman et al., 2017). This is in agreement with recent structural
132 observations suggesting early dome formation and later amplification of the structure (Grobe et al., 2018).

133 **2.2. Stratigraphic sequence**

134 Sediments in the Jebel Akhdar area consist of a pre-Permian sequence (Autochthonous A, Figure 3) unconformably
135 overlain by a Permian-Mesozoic sequence (Autochthonous B, Figure 3; Beurrier et al., 1986; Breton et al., 2004;
136 Glennie et al., 1974; Rabu et al., 1990). During the late Cretaceous, Hawasina nappes and the Semail Ophiolite
137 were emplaced onto the passive margin, and neo-autochthonous rocks of Cenozoic age were deposited on top of
138 the ophiolite after obduction (Béchenec et al., 1988; Forbes et al., 2010; Loosveld et al., 1996).

139

140 **Figure 3: Stratigraphy of the Jebel Akhdar area with its two passive margin sequences Autochthonous A and B**
 141 **overthrust by Hawasina and Semail Nappes and unconformably overlain by neo-autochthonous units. Thermal**
 142 **calibration data is shown: ZHe ages (Table 2) show two different grain age clusters. Peak burial temperatures from**
 143 **organic matter maturity (Table 1) outline the temperature increase with stratigraphic age. Temperatures shown relate**
 144 **to the measurements and related uncertainties of the calculations (U = Unit, P =Period). Note that the Semail and**
 145 **Hawasina nappes are shown in their structural rather than stratigraphic positions; lithological data is compiled from**
 146 **Beurrier et al. (1986), Loosveld et al. (1996), Terken et al. (2001) and Forbes et al. (2010).**

147 Autochthonous A deposits are exposed in the Jebel Akhdar window down to the Mistal Fm. (Beurrier et al., 1986).
 148 Black limestones of the Hajir Fm., mudstone rich carbonate beds of the Mu'aydin Fm. and lime- and dolostones
 149 of the Kharus Fm. conformably overlie the Mistal Fm. (Beurrier et al., 1986; Glennie et al., 1974). Platform break-
 150 up is recorded by laminated cherts and volcanoclastics of the Fara Fm. (Beurrier et al., 1986) followed by an
 151 unconformity representing a gap from Cambrian to Permian times (Loosveld et al., 1996). After establishment of
 152 the Neotethyan Ocean during the Permian, northern Oman returned to stable passive margin conditions and the
 153 carbonate platform of the Autochthonous B developed, with the Akhdar Group at its base (Koehrer et al., 2010;
 154 Pöppelreiter et al., 2011). This is unconformably overlain by limestones with clastic interlayers of the Jurassic
 155 Sahtan Group (Beurrier et al., 1986; Pratt et al., 1990). Limestones with marly, frequently organic-rich
 156 intercalations of the Cretaceous Kahmah (Habsi et al., 2014; Vahrenkamp, 2010) and Wasia groups (Grelaud et
 157 al., 2006; Homewood et al., 2008; Philip et al., 1995) form the youngest platform sediments (Robertson, 1987;
 158 Warburton et al., 1990).

159 The obduction-related moving forebulge and associated uplift ended passive margin deposition and eroded the
160 topmost Wasia Group (Natih Fm.) in the Jebel Akhdar (Figure 3), and deeper in the Saih Hatat region. Deposition
161 in the foredeep basins in front and behind the forebulge was dominated by the syn- and postorogenic,
162 conglomerate-rich sediments of the Muti Fm., Aruma Group (Beurrier et al., 1986; Robertson, 1987). Towards the
163 south, in the Adam Foothills, this laterally grades to calcareous foreland sediments of the Fiqa Fm. (Forbes et al.,
164 2010; Robertson, 1987; Warburton et al., 1990).
165 Hawasina sediments accreted in front and beneath the ophiolite represent marine slope and basin facies, time
166 equivalent to the Autochthonous B (Béchenec et al., 1990). They are defined as four age-equivalent groups
167 (Hamrat Duru, Al Aridh, Kawr and Umar) representing carbonatic turbidite deposits (Hamrat Duru Group),
168 radiolarian cherts and platform carbonates (Al Aridh Group), platform carbonates (Kawr Group) and interbedded
169 carbonates and volcanics (Umar Group, Béchenec et al., 1990). After obduction of oceanic crust onto the passive
170 margin, neo-autochthonous evaporites and carbonates of the Paleocene to Eocene Hadhramaut Gp. and bivalve-
171 rich dolomites and limestones of the Oligo- to Pliocene Fars Group were deposited south of the mountains
172 (Béchenec et al., 1990; Forbes et al., 2010). Paleogeographic reconstructions show that the Oman Mountains had
173 high relief after obduction, followed by a low relief landscape until the early Eocene (Nolan et al., 1990). In the
174 middle Eocene marine transgression caused widespread deposition of limestones, as witnessed e.g. by the Seeb
175 and Ruwaydah Formations (Nolan et al., 1990). Post Eocene times show renewed relief development and
176 continued uplift until recent times (Glennie et al., 1974; Searle, 2007).

177 **2.3. Previous paleothermal data of the Autochthon**

178 Only limited paleo-temperature data are available from the carbonate platform (Fink et al., 2015; Grobe et al.,
179 2016; Holland et al., 2009a; Stenhouse, 2014). Peak-burial temperatures of 226-239 °C for the top of the platform
180 were measured using solid bitumen reflectance (also referred to as pyrobitumen reflectance) and Raman
181 spectroscopy of carbonaceous material (RSCM) in the Jebel Akhdar (Grobe et al., 2016). Results indicate peak-
182 burial temperatures of 266 to 300 °C (Grobe et al., 2016; Table 1). Temperature estimates based on RSCM and
183 solid bitumen reflectance (Grobe et al., 2016) yielded similar temperatures for the southern flank of 248-280 °C
184 for the Nahr Umr, 226-239 °C for the Natih B and 172-206 °C for the Muti, respectively (Table 1, Figure 3).
185 Vein crystallization temperatures of 166-205 °C at the top of the Natih A (near Al Hamra) were measured by
186 quartz-calcite thermometry in veins formed during ophiolite-induced burial (Gen. III of Grobe et al., 2018), and
187 approximately 255 °C for veins associated with a later normal fault network (Gen V of Grobe et al., 2018;
188 Stenhouse, 2014). Fluid inclusions (FI) of bedding parallel pinch-and-swell veins (top-to-NNE shear after peak
189 burial, Gen. IV of Grobe et al., 2018) show uncorrected minimum trapping temperatures of 134-221 °C in the
190 lower beds of the Sahtan Group at Wadi Nakhr (Holland et al., 2009a). Reflectance measurements of solid-
191 bitumen-containing veins in the Wadi Ghul (Gen I of Grobe et al., 2018), which are interpreted to be associated
192 with fluid mobilization during forebulge migration, show maximum temperatures of 230 °C (Fink et al., 2015).
193 Vitrinite reflectance data of Mozafari et al. (2015) shows temperatures of c. 140 °C for the Natih B in the Jebel
194 Qusaybah, Adam Foothills, an area not overthrust by the ophiolite complex.

195 **2.4. Temperature evolution of the Semail Ophiolite nappe / Allochthon**

196 Initial intra-oceanic ophiolite thrusting and associated metamorphism at its sole took place at peak temperatures
197 of 840 ± 70 °C at 97-92 Ma measured at several locations in the Oman Mountains (Gnos and Peters, 1993; Hacker

198 and Mosenfelder, 1996; Rioux et al., 2013; Searle and Cox, 2002; Warren et al., 2003). At 90-85 Ma the base of
199 the ophiolite cooled to 350 ± 50 °C (white mica Ar/Ar dating, Gnos and Peters, 1993). At around 80 Ma the deepest
200 burial of the Oman margin beneath the ophiolite was reached (Hacker and Mosenfelder, 1996; Warren et al., 2005)
201 with temperatures in the metamorphic sole below 300 °C (Le Metour et al., 1990; Saddiqi et al., 2006). A
202 lithospheric scale thermo-mechanical model of the thrusting in northwestern Oman includes a thermal anomaly
203 c. 100 km northwest offshore the Arabian margin to initiate subsea thrusting (Duretz et al., 2015).

204 **2.5. Petroleum system elements**

205 Several petroleum systems developed in the carbonate platform of northern Oman with important source rock
206 horizons in the Natih Fm. (Members B and E). Both members contain Type I/II kerogen with total organic carbon
207 contents up to 15 % in the Natih B and up to 5 % in the Natih E, respectively (Terken, 1999). Source rock maturity
208 is restored based on biomarker analysis to c. 0.7 %VR within the Fahud reservoir and c. 0.9 %VR in the Natih
209 reservoir (Terken, 1999). In the southern mountain foreland Natih oil generation started in the middle Cretaceous
210 and continuous until present (Terken, 1999). Ophiolite obduction in the Jebel Akhdar area of northern Oman led
211 to over-mature Natih source rocks (Grobe et al., 2016). The Natih is classified as supercharged, laterally drained,
212 foreland petroleum system (Terken et al., 2001). However, the thermal impact of the moving forebulge and the
213 importance of tectonic processes for fluid migration below and in front of the obduction orogen are not clear. At
214 least three different generations of solid bitumen particles in veins and source rocks on the southern slope of the
215 Jebel Akhdar suggest pulses of hydrocarbon generation and migration in front of the Oman Mountains (Fink et al.,
216 2015; Grobe et al., 2016). In central Oman, Shu'aiba and Tuwaiq oils are produced out of Kahmah and Sahtan
217 Group reservoirs, sealed by argillaceous shales of the Nahr Umr Fm. (Terken et al., 2001). All these units are well-
218 exposed in the Oman Mountains.

219 **3. Methods**

220 **3.1. Raman spectroscopy of carbonaceous material**

221 To determine levels of thermal maturity, over 100 dark, unweathered and organic-rich samples were taken from
222 different stratigraphic units in the Jebel Akhdar (Sahtan Group, Kharaib Fm., Shu'aiba Fm., Nahr Umr Fm., Natih
223 Fm., Muti Fm., Figure 3). Based on total organic carbon (TOC) content as determined by Grobe et al. (2016), 13
224 samples were selected for thermal maturity analysis on surfaces cut perpendicular to bedding. Results were used
225 to calibrate peak-burial temperatures of the numerical basin models. The organic particles lack sufficient size or
226 surface quality for reflectance measurements and are therefore investigated by confocal Raman spectroscopy of
227 carbonaceous material. The technique measures vibrational energies of chemical bonds which change during
228 temperature induced reorganization of amorphous carbonaceous material (kerogen) to graphite (e.g. Aoya et al.,
229 2010; Beyssac et al., 2002; Kouketsu et al., 2014; Mair et al., 2018). Measurements were conducted at the
230 Geoscience Center, Göttingen, on a Horiba Jobin Yvon HR800 UV spectrometer attached to an Olympus BX-41
231 microscope and a 100× objective. A high-power diode laser with a wavelength of 488 nm and an output power of
232 50 mW was installed and a D1 filter avoided sample alteration by heating. Each spectral window (center at
233 1399.82 cm^{-1} , grid of 600 lines/mm) was measured 5 to 10 times for 2 to 10 seconds with a Peltier CCD detector
234 at activated intensity correction. For quality control, the 520.4 cm^{-1} line of a Si-wafer was measured every 30

235 minutes without observable drift of the measurements. To transform the measured data into VR_r values the scaled
236 total area (STA) approach of Lünsdorf (2016) was applied with the equation of Grobe et al. (2016):

$$237 \quad VR_r = -\frac{STA - 280.13}{24.71} \quad [\%]$$

238 Absolute errors of the applied calibration are in the order of ± 40 °C, based on comparing neighboring samples
239 (Grobe et al., 2016) we can resolve the relative differences down to ± 30 °C which also represents the residual
240 error interpreted to relate to within-sample heterogeneity (Lünsdorf et al., 2017; Nibourel et al., 2018).

241 **3.2. Fluid inclusion thermometry**

242 Doubly-polished wafers (c. 200 μm thick) of four vein samples (FI-N1, -N2, -M1, -M2) have been prepared
243 according to the procedure described by Muchez et al. (1994). Fluid inclusion (FI) petrography and
244 microthermometry was performed to analyze the temperature-pressure conditions and fluid's salinity. FIs represent
245 paleofluids accidentally trapped in a crystalline or amorphous solid during crystallization, lithification or both
246 (Diamond, 2003). If unaffected by later changes, trapping pressure and temperature is given by the homogenization
247 temperature (Barker and Goldstein, 1990). Based on the time of trapping primary (mineral growth), secondary
248 (fracture-related) and pseudosecondary inclusions are distinguished (Barker and Goldstein, 1990; Diamond, 2003;
249 Goldstein, 2001; Van Den Kerkhof and Hein, 2001):

250 Two calcite vein samples of the Natih Fm. (FI-N1 and 2, Locations Figure 4) represent conditions related to early
251 burial (FI-N2, structural generation I of Grobe et al., 2018), and burial beneath the ophiolite (FI-N1, structural
252 generation III of Grobe et al., 2018). Two quartz-rich calcite veins of the Muti Fm. (FI-M1 and 2, Locations Figure
253 4) are related to late, NE-SW striking strike slip faults (generation IX of Grobe et al., 2018). FI assemblages were
254 defined and fluid inclusions measured with a Linkam THMSG600 thermostage (accuracy ± 0.1 °C) attached to an
255 Olympus BX60 microscope at the KU Leuven, Belgium. Calibration was performed using CO_2 , $\text{H}_2\text{O-NaCl}$, $\text{H}_2\text{O-}$
256 KCl , and H_2O standards. Homogenization temperatures (T_h) were measured prior to temperatures of complete
257 freezing (T_f), first melt (T_{fm}), and complete melting of ice ($T_{m(ice)}$) to avoid stretching or leakage due to the volume
258 increase during ice formation. All measured temperatures were recorded during heating, except for the freezing
259 temperature (T_f). Pressure corrections of T_h were conducted with the program FLINCOR (Brown, 1989) for
260 280 and 340 MPa, assuming 8 to 10 km of ophiolite overburden (see model results, $\rho = c. 3070 \text{ kg/m}^3$) and 2 km
261 of Hawasina Nappes ($\rho = c. 2450 \text{ kg/m}^3$), and for 45 MPa, assuming 2 km of sedimentary overburden (Al-Lazki et
262 al., 2002; Grobe et al., 2016). Fluid salinities were calculated from the $T_{m(ice)}$ values considering a $\text{H}_2\text{O-NaCl}$
263 composition (Bodnar, 1993), which is based on the T_{fm} values.

264 **3.3. Thermochronometry**

265 Zircon (U-Th)/He (ZHe) dating allows to reconstruct the thermal history of the topmost few kilometers of the
266 Earth's crust. Helium retention in less metamict zircon crystals is sensitive in the temperature range between c. 130
267 and 170 °C, i.e. the zircon partial retention zone (PRZ, Reiners, 2005). 11 rocks sampled above (Muti Fm., Matbat
268 Fm. of the Hamrat Duru Group and Trondjemite of the Semail nappes), below (Mistal Fm., Muaydin Fm., Fara
269 Fm.) and within (Sahtan Gp.) the carbonate platform were selected for ZHe dating. Zircon crystals were released
270 using high voltage pulse crushing (<http://www.selfrag.com>) and concentrated by standard mineral separation
271 processes (drying, dry sieving, magnetic and heavy liquid separation). Three to eight clear, intact, euhedral single
272 crystals were selected per sample and transferred into platinum micro-capsules. They were degassed under high

273 vacuum by heating with an infrared diode and extracted gas purified using a SAES Ti-Zr getter at 450 °C. Helium
274 was analyzed with a Hiden triple-filter quadrupole mass spectrometer. Degassed zircons were subsequently
275 dissolved in pressurized teflon bombs, spiked and U, Th and Sm measured with a Perkin Elmer Elan DRC II ICP-
276 MS equipped with an APEX micro flow nebulizer.
277 Time-temperature histories were reconstructed using the HeFTy 1.8.3 software package (Ketcham, 2005) applying
278 kinetic zircon properties of Guenther et al. (2013). For samples with reset zircons the only constraint used was a
279 minimum temperature above 200 °C between deposition and the calculated ZHe age. Thermal modeling was
280 conducted until 100 statistically good time-temperature paths were achieved (goodness of fit: 0.5, value for
281 acceptable fit: 0.05). In cases where this was not possible, at least 10,000 independent paths were calculated.

282 **3.4. Numerical basin modeling**

283 Structural evolution was palinspastically reconstructed starting from the present-day profile using Move 2D
284 (2016.1, Midland Valley Exploration). Geometries and relative ages of the structures were supplemented with
285 subsurface data (Al-Lazki et al., 2002; Filbrandt et al., 2006; Searle et al., 2004; Warburton et al., 1990). The
286 reconstruction workflow is based on restoring the pre-deformation layer continuity as follows: (1) faulted layers
287 in the southern foreland were restored, (2) doming was retro-deformed by vertical simple shear, before (3) normal
288 faults in the Jebel Akhdar were restored. This sequence is based on our tectonic model (Grobe et al., 2018). The
289 resulting geometries were used as pre-thrusting input geometries for 2D PetroMod 2014.1 (Schlumberger) basin
290 modeling, enabling thermal maturity reconstruction for vitrinite reflectance values of 0.3 to 4.7 % by the use of
291 the EASY % Ro approach (Sweeney and Burnham, 1990). The numerical basin model is based on a conceptual
292 definition of events. Based on this sequence of events (sedimentation, erosion, hiatus) a forward, event-stepping
293 modeling was performed, starting with the deposition of the oldest layer. Subsequent deposition and burial is
294 leading to differential compaction of the single rock units. For each event lithologies and related petrophysical
295 rock properties were assigned (Figures S1, S2).

296 For our conceptual model the following sequence of events was implemented (Figure 3): (1) passive margin
297 carbonate sedimentation from Permian until late Cenomanian times (Forbes et al., 2010; Loosveld et al., 1996),
298 interrupted by a short erosional period at the Triassic-Jurassic boundary (Koehrer et al., 2010; Loosveld et al.,
299 1996), (2) a moving forebulge associated with a paleo-water depth increase in its foredeep and erosion of the top
300 of the carbonate platform in the north of the transect (Robertson, 1987), (3) the emplacement of allochthonous
301 sedimentary nappes and (4) subsequent, stepwise obduction of the ophiolite with deepest burial reached at c. 79 Ma
302 (Warren et al., 2005). Modelling ophiolite obduction as rapid emplacement accounts for burial related heat effects
303 in the carbonate platform underneath but does not allow to fully restore the temperatures within the ophiolitic or
304 sedimentary nappes. The area of the Adam Foothills, represented in the transect by Jebel Qusaybah, is a relic of
305 the moving forebulge not overthrust by allochthonous units – this was used to calibrate burial depth of the foredeep
306 at this point in the transect. The area to the south of the Adam foothills is unaffected by foredeep sedimentation,
307 but also lacks thermal calibration data. Absolute ages, thicknesses, lithologies and related petrophysical properties
308 as well as source rock properties were associated according to results of our own field mapping and the compiled
309 data from Forbes et al. (2010; Figure S1).

310 Thermal boundary conditions of the model have been defined for each time step by the basal heat flow (HF) and
311 the sediment water interface temperature (SWIT), representing the upper thermal boundary (Figure S3). To
312 account for active margin tectonics and uplift and exhumation of the Jebel Akhdar, we assume an increase in basal

313 heat flow since the late Cretaceous. The resulting heat flow trend (Figure S3, Terken et al., 2001; Visser, 1991)
314 has been assigned to the entire transect and was tested in the sensitivity analysis. Paleo-surface temperatures were
315 estimated based on Oman's paleo-latitude (after Wygrala, 1989) corrected by the effect of the paleo-water depth
316 (PWD) derived from the facies record (Van Buchem et al., 2002; Immenhauser et al., 1999; Immenhauser and
317 Scott, 2002; Koehrer et al., 2010; Pratt et al., 1990; Robertson, 1987). This assumes that a possible heat source
318 from the ophiolite itself does not significantly affect the temperature evolution of the top of the carbonate platform
319 (see discussion).

320 This set-up has been iterated until modeling results fit the thermal calibration data (Table 1). From VR_r calculations
321 peak-burial temperatures were determined following the approach of Barker and Pawlewicz (1994). For calibration
322 of the numerical basin models, data was supplemented by thermal maturity and peak-burial temperature data of
323 63 Natih B source rock samples, taken around the Jebel Akhdar Dome (Grobe et al., 2016), and data from the
324 Adam Foothills on Jebel Qusaybah (Mozafari et al., 2015).

325 Main modelling uncertainties derive from the uncertainty in thickness of paleo-overburden (Muti Fm., Ophiolite,
326 Hawasina Nappes) and uncertainty of paleo-basal heat flow. Present-day heat flow was calibrated by data and
327 borehole temperatures of Visser (1991) and Rolandone et al. (2013) and peak-burial temperatures determined by
328 Raman spectroscopy and solid bitumen reflectance data (Table 1). From surface samples and their position in the
329 stratigraphic column various pseudo-wells were created (e.g. Nöth et al., 2001) and used as control points for the
330 2D model (Figure 2). The model was used for sensitivity analyses of different input parameters.

331 4. Results and Interpretation

332 4.1. Thermal maturity and host rock burial temperatures

333 New Raman spectroscopy data of the northern flank are shown in Table 1 and give scaled total areas of 78-172.
334 This correspond to peak temperatures of 270-300 °C in the Shu'aiba Fm., 268-305 °C in the Kahmah Group, 283-
335 286 °C in the Sahtan Group, 270-288 °C in the Nahr Umr Fm. and c. 266 °C at the base of the Natih Fm. Based
336 on the calculation to VR_r and temperature an absolute error of ± 30 °C has to be considered for the single values.
337 Thermal maturity data of the Natih Fm. show solid bitumen reflectances of 2.95-3.72 % for the southern flank of
338 the Jebel Akhdar (Fink et al, 2015, Grobe et al., 2016), 3.32 % BR for the northern flank (Grobe et al., 2016) and
339 a single measurement of 1.1 % VR exists for the Jebel Qusaybah (Mozafari et al., 2015).

340 Calculated peak temperatures for the autochthonous Cretaceous deposits in the Jebel Akhdar range between 225
341 and 305 °C (± 30 °C, error of the calibration), two Jurassic samples 283 and 286 °C (± 30 °C). Temperatures are
342 generally higher on the northern flank (grey boxes, Figure 3) of the Jebel Akhdar and slightly increase with
343 stratigraphy in the autochthonous. Samples of the Muti Fm. ($178-208 \pm 30$ °C) and the Hawasina nappes ($193-
344 213 \pm 30$ °C) show lower temperatures compared to the autochthonous. A single sample from the Jebel Qusaybah
345 reflects peak temperatures of c. 140 °C (Table 1) in an area that was not overthrust by nappes but buried in the
346 related moving forebulge.

347 **Table 1: Thermal maturity data and calculated peak temperatures of northern Oman (new data highlighted by bold**
348 **sample name). Temperatures from Raman spectroscopy of carbonaceous material are calculated based on the STA**
349 **approach of Lünsdorf (2016) and the equation of Grobe et. al (2016). M/P indicate if measurement was conducted on**
350 **solid bitumen particles (P) or organic rich matrix (M). Errors shown relate to the measurements, calculation errors are**
351 **in the order of ± 30 °C. Data in brackets is interpreted to be too low (Nahr Umr) or too high (Natih Vein, Fink et al.**
352 **2015).**

353

354 **4.2. Thermochronology**

355 Results of the ZHe dating are shown in Figures 3 and 4; time-temperature paths modeled with HeFTy are included
356 in the electronic supplement (Figures S4 and S5). Samples from the carbonate platform (stratigraphically older
357 than Muti Fm.) have been entirely reset after deposition, as witnessed by Neogene apparent ages. Similarly, cooling
358 ages from the center of the Jebel Akhdar Dome fall in the range of 48.7 ± 1.8 to 39.8 ± 3.0 Ma (Table 2, Figure
359 4). Sample T4, collected in the Muti Fm., yields an apparent mean age of 93.8 ± 6.9 Ma and samples T5 and T7
360 of the Hawasina Nappes collected at the northern and the southern slope of the dome, show two grain age clusters
361 of $43.0 \pm 3.7 / 99.2 \pm 8.5$ Ma, and $58.9 \pm 7.0 / 106.0 \pm 5.2$ Ma, respectively. In sample T5, an additional single
362 grain age of 172.9 ± 14.9 Ma was obtained.

363

364

365 **Figure 4: Map view of ZHe ages (in Ma).** Data outlines a general cooling between 58.9 ± 7.0 and 39.8 ± 3.0 Ma. Some
 366 samples outside of the dome show two age clusters, with an additional age of c. 100 Ma. Additional temperature data
 367 refers to zircon fission track ages of (*) Saddiqi et al. (2006), Apatite fission track ages of (Δ) Poupeau et al. (1998) and
 368 (+) Mount et al. (1998), and AHe, AFT and ZFT ages of (+, grey) Hansmann et al. (2017). Moreover, the locations of
 369 samples used for fluid inclusion measurements are shown. Colors in the background depict geological units (brown:
 370 ophiolite, pink: Hawasina units, light green: Muti Fm., dark green: Wasia and Kahmah Gp., blue: Sahtan Gp., purple:
 371 Mahil Fm, orange: Saiq Fm, grey: pre-Permian, shaded DEM from Esri, Digital Globe, swisstopo, and the GIS user
 372 Community).

375 These ages indicate a large-scale cooling signal that affects the entire Jebel Akhdar area; the ZHe age pattern and
376 1D thermal models indicate a phase of rapid cooling below 170 °C in the early Cenozoic (58.9 ± 7.0 and
377 39.8 ± 3.0 Ma). The range of modeled cooling paths outline maximum cooling rates of 2-8 °C/Myr. This is
378 followed by slower cooling until the present day.

379 Data from the Muti Fm. and the Hawasina units differ partly from this trend: the apparent ZHe ages of clasts in
380 the Muti sample T4 (mean: 93.8 ± 6.9 Ma) is as old as its respective stratigraphic age (Robertson, 1987). Even
381 though all ages reproduce within error, this indicates partial reset of the ZHe system, as post-depositional reheating
382 above closure temperature would result in younger ages. Samples of the lower Hawasina Nappes contain two grain
383 age clusters. Older ages coincide with higher uranium concentrations suggesting that only the younger ages
384 represent thermally reset zircons. We note that the older ZHe ages of 110-95 Ma coincide with timing of forebulge
385 migration through the area, as independently determined in the stratigraphic record by the Wasia-Aruma Break
386 (Figure 3). This may be either pure coincidence, due to partial resetting of an older grain age population, or may
387 be a grain age population with higher closure temperature witnessing exhumation. We discuss reasons for different
388 resetting temperatures below. However, partial reset of ZHe ages suggests that the Hawasina samples have not
389 experienced temperatures exceeding the partial retention zone (PRZ) of 130-170 °C.

390 A sample from an intrusive body of the Semail Ophiolite yields ZHe ages of 53.7 ± 1.2 Ma (T6) with a modeled
391 cooling path gradually decreasing into the PRZ until c. 55 Ma. This time interval of passing the PRZ is comparable
392 to the Hawasina nappe samples beneath the ophiolite but occurs slightly earlier than cooling of the Autochthonous.
393 Nevertheless, Semail Ophiolite, Hawasina Nappes and the autochthonous margin sequence were affected by the
394 same cooling event that was possibly initiated by exhumation of the Jebel Akhdar Dome.

395 **4.3. Fluid inclusions**

396 The Muti veins' samples FI-M1 and M2 of the southern Jebel Akhdar show evidence of crack and seal processes
397 (youngest parts in the center of the vein, Ma-2010-11b and 14a of Arndt 2015) with blocky quartz grains that
398 contain two kinds of roundish primary FIs with sizes of 3-20 μm . They are mainly aligned along dark zones and
399 are interpreted as growth zones or form bright clusters in the central part of the crystals. A third set of fluid
400 inclusions (FIs) appears in large, grain-crosscutting trails interpreted to be of secondary origin. Calcite crystals
401 within the Natih veins contain bright FIs with sizes of 2-20 μm and are edgy, often rectangular or trapezoidal in
402 shape. Identified primary FIs are aligned parallel to crystal growth zones.

403 All measured FIs are two-phase, liquid-vapor inclusions with ice as last phase to melt. The Muti samples show
404 $T_{\text{fm(ice)}}$ between -5.1 ± 0.5 and -4.6 ± 0.3 °C and $T_{\text{m(ice)}}$ at -2.2 ± 0.2 to -1.9 ± 0.1 °C, the Natih sample T_{fm} of
405 -18.4 ± 1.9 to -20.2 ± 2.1 °C and $T_{\text{m(ice)}}$ of -7.1 ± 0.3 to -8.9 ± 1.8 °C (Table 3). First melting temperatures of all
406 inclusions correspond to an H₂O-NaCl system and complete melting temperatures of ice indicate salinities similar
407 to seawater (3.0 ± 0.5 to 3.5 ± 0.3 wt.-% NaCl eq., Muti Fm., Figure S6) or three times higher (10.3 ± 0.3 to
408 12.5 ± 2.0 wt.-% NaCl eq., Natih Fm., Figure S6).

Primary inclusions in quartz crystals from the Muti Fm. show minimum trapping temperatures of 161 ± 3 to 166 ± 7 °C (Table 3, FI-M2 and middle of FI-M1) with a second primary population of 189 ± 3 °C (sides of vein FI-M1). T_h of secondary inclusions in FI-M1 are above 200 °C. In sample FI-M2, two generations of secondary inclusions were observed, both reflecting lower T_h than the primary inclusions. No hints of necking down, leakage or stretching were observed at the measured inclusions and over 90 % of the measured FIs in one assemblage are in the range of 10-15 °C representing a good quality of the measurements (Goldstein, 2001).

Samples FI-N1 and N2 of the Natih Fm. in the southern Jebel Akhdar (Figure 4) contain primary inclusions hosted by calcite crystals giving T_h of 80 ± 4 , 90 ± 5 and 114 ± 7 °C (Table 3). The latter population is often characterized by elongated, possibly stretched FI, and is not considered for further interpretations. Assuming vein formation during burial (Grobe et al., 2018; Hilgers et al., 2006; Holland et al., 2009a; Virgo, 2015) under 8 to 10 km of ophiolite including partially serpentinized peridotite and 2 km of Hawasina Nappes, results were pressure corrected for 280 and 340 MPa leading to corrected homogenization temperatures of 235 ± 5 and 266 ± 5 °C (FI-N1), and 225 ± 4 and 256 ± 4 °C (FI-N2, Table 3). Signs of strong deformation such as twinning or cleavage were not observed in the measured inclusions; secondary inclusions were present but not measured.

These temperatures represent minimum trapping conditions of a paleo-fluid and do not necessarily represent burial temperatures of the host rock. It should be noted that the analyzed Natih veins formed bedding confined (Grobe et al., 2018; Holland et al., 2009a; Virgo, 2015) and show host rock buffered carbonate isotope signatures (Arndt et al., 2014; Hilgers et al., 2006). This corroborates the idea that analyzed veins were in thermal equilibrium with their host rocks.

FI microthermometry of late strike-slip veins in the Muti Fm. are interpreted to have formed after dome formation (Grobe et al., 2018; Virgo, 2015) at an assumed minimum depth of 2 km (preserved allochthonous thickness). A pressure correction for the related 45 MPa corresponds to minimum fluid trapping temperatures of 184 ± 3 °C (FI-

438 M2) and 213 ± 3 °C (FI-M1) with a later phase of primary inclusions outlining 189 ± 7 °C and even cooler
 439 secondary inclusions of 138 ± 12 to 172 ± 2 °C (FI-M1 and M2, Table 3). These cooler fluid temperatures can be
 440 explained by further exhumation of the Jebel Akhdar and, hence, cooling of the fluids' reservoir during crack-seal
 441 vein formation. Isotope studies on the vein calcite do not support an open system with fluid exchange (Stenhouse,
 442 2014; Virgo and Arndt, 2010), hence, we interpret the formation of strike-slip related veins as having formed
 443 during exhumation following peak burial.
 444 Based on the assumption that fluid and host rock were in thermal equilibrium, we can use maturity data in
 445 combination with fluid inclusion data to estimate the pressure at vein formation. Peak temperatures of the Sahtan
 446 Group revealed by RSCM reached 283 ± 9 to 286 ± 6 °C (Table 1, Figure 5 red line) and enable to solve the
 447 pressure-temperature couples of FIs measured in Sahtan veins formed at deepest burial by Holland et al. (2009,
 448 black line). This results in minimum trapping pressures of 254 ± 30 MPa at times of vein formation (Figure 5 blue
 449 line), which correspond to times close to or at deepest burial of the carbonate platform.

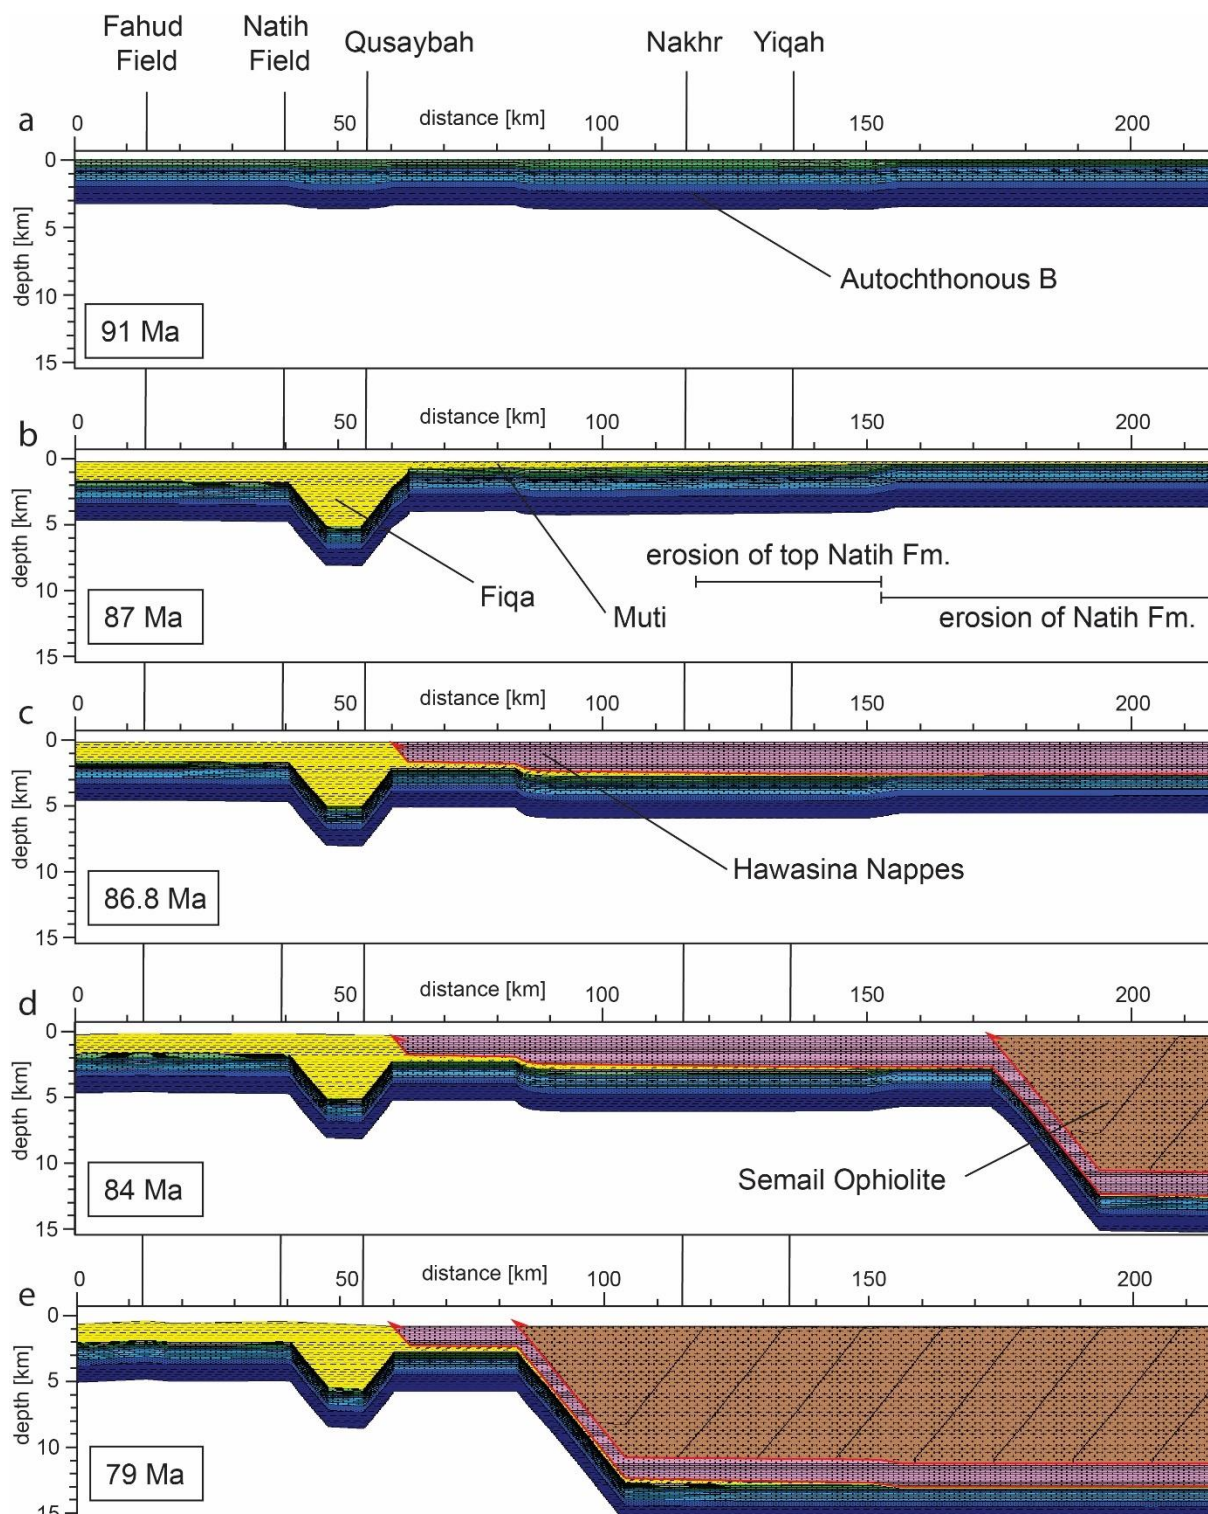

450
 451 **Figure 5: Fluid inclusion isochores (solid black lines) of analyzed fluid inclusion populations with corresponding std.**
 452 **deviations (shaded areas, for Sahtan Group data of Holland et al., 2009, conservatively ± 10 °C are assumed). To estimate**
 453 **the pressure conditions during vein formation, calculated temperatures from thermal maturity data are added for the**
 454 **Sahtan Group (red line with error) and result in minimum trapping pressures of 254 ± 30 MPa during peak burial (blue**
 455 **line with error).**

456 4.4. Basin modeling

457 Numerical basin modeling integrates all data and tests the individual interpretations in the thermal and geodynamic
 458 framework. Deepest burial was constrained with thermal maturity data and exhumation with thermochronological
 459 data. In the following we present our best fit model, considering a mixed ophiolite lithology (Searle and Cox,
 460 2002) consisting of strongly serpentinized peridotites. Then, the sensitivity of important results to changes of
 461 relevant input parameters are discussed.

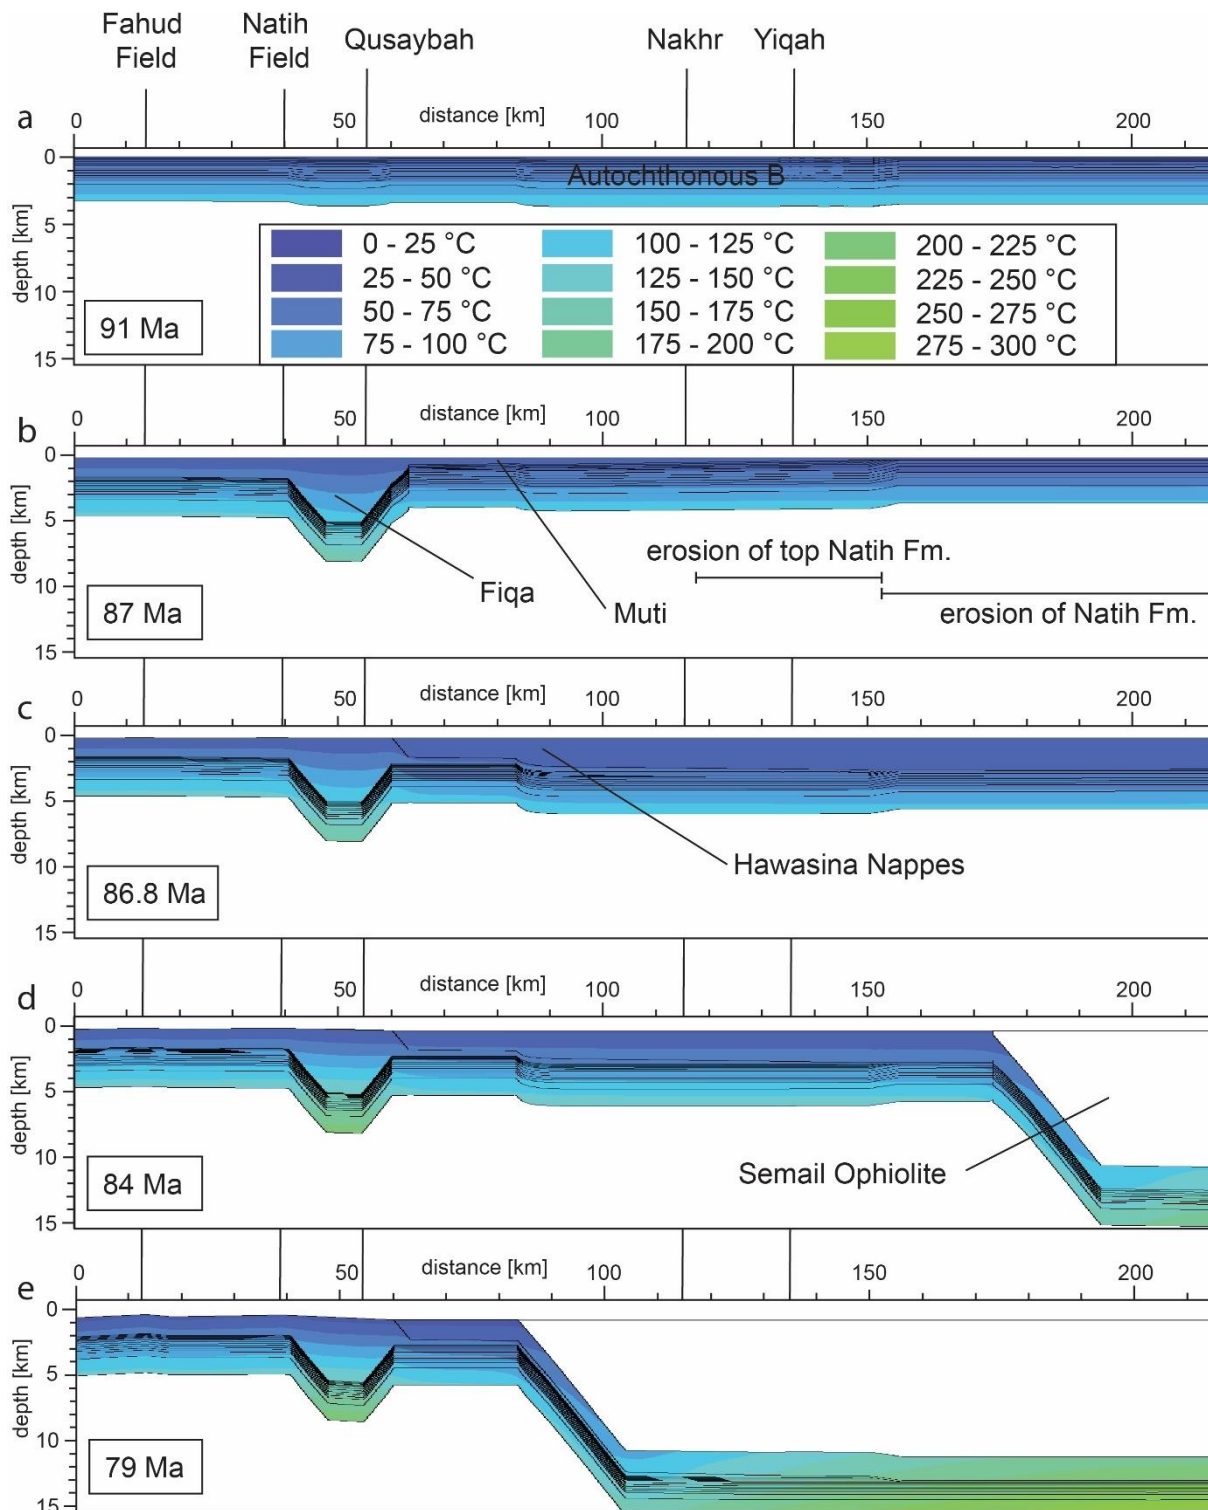

462 Modeled evolution of the transect over time is given in Figures 6 and 7, showing (a) final deposition of the
 463 Autochthonous B, (b) erosion of the Natih Fm. in the North by a moving foredeep (no erosion in S, full erosion in
 464 N), (c) emplacement of 1400 m of Hawasina Nappes, and d-e) ophiolite obduction reconstructed by rapid, stepwise
 465 sedimentation. After maximum burial beneath the ophiolite complex at c. 80 Ma (Warren et al., 2005) exhumation
 466 is assumed to start slightly prior to 55 Ma (Saddiqi et al., 2006) with a rapid phase of cooling below c. 200 °C at
 467 55 Ma leading to lower temperatures in the Jebel Akhdar region. 1D burial plots of two pseudo-wells created out
 468 of point data in Wadi Nakhr and Wadi Yiqah are shown in Figure 8.

 482 **Nakhr and Yiqah (Figures 1, 6 and 7) show two phases of rapid burial related to Hawasina and Semail Nappe**
 483 **emplacement and c. 88 Ma and ophiolite emplacement at c. 78 Ma. Burial in the North (Wadi Yiqah) starts c. 2 Myr**
 484 **earlier due to ophiolite obduction taking place from N to S.**

485 As a model set up only presents one possible solution out of several, sensitivity analyses with varying paleo-
 486 overburden thicknesses (Figures 9 and 10), changing degree of serpentinization of the ophiolite and varying basal
 487 heat flow during deepest burial (Figure 11) are presented and discussed below.

488 Thermal maturity data of the Natih B at Jebel Qusaybah (1.1 % VR_r), Adam Foothills, require peak temperatures
 489 of c. 140 °C (Table 1). Sensitivity analyses of the overburden above the Natih Fm. show that maximum 4 km of
 490 sedimentary overburden (Figures 9a and 10a) is needed to match the calibration data (Figures 9a and 10a).

496 **Figure 10: Sensitivity analysis of paleo-overburden and its influences on thermal maturity in comparison to calibration**
 497 **data (gray area). Data is used to calibrate burial depth of the foredeep at the Jebel Qusaybah (a) and the paleo-ophiolite**
 498 **thickness at the southern flank of the Mountains at Nakhr (b). Its northern counterpart at Yiqah (c) is in agreement**
 499 **with the temperature data of Figure 9, however to mature to be reconstructed by standard maturity modelling (Sweeney**
 500 **and Burnham, 1990).**

501 To restore the former minimum thickness of the Semail Ophiolite, the thickness of the Hawasina Nappes along
 502 the transect was fixed to 2 km, as suggested by the maximum present-day thickness of the Jebel Misht exotics. To
 503 reach the required thermal conditions measured at the entrance of the Wadi Nakhr (Natih B: 2.83-3.72 % VR,
 504 225-260 °C; Grobe et al., 2016), 8-10 km of original, total thickness of strongly serpentinized ophiolite sequence
 505 are needed in addition to the 2 km of Hawasina Nappes (Figures 9b and 10b). These thicknesses are also sufficient
 506 to reach peak temperatures calculated for older stratigraphy at the northern flank of the Jebel Akhdar Dome
 507 (Shu'aiba Fm. at Wadi Yiqah: 270-295 °C by RSCM, Figures 9c and 10c). Modeling results show an earlier
 508 heating and more rapid increase in maturity in the north. We associate this with the 2 Mys earlier onset of obduction
 509 and, hence, a longer burial of the northern carbonate platform (Wadi Yiqah) under the active ophiolite obduction
 510 compared to its southern counterpart (Béchenec et al., 1990; Cowan et al., 2014).

511 Another factor influencing the modeling results is related to the lithology of the overburden and its compaction.
 512 In the special case of burial under an ophiolite, serpentinization of peridotite and its impact on ophiolite density
 513 and thermal conductivity must be considered. Sensitivity analysis of ophiolite serpentinization shows the
 514 temperature and thermal maturity effects on our model (Figure 11). A model-case of ophiolite without any
 515 serpentinized peridotite (0 %-case, $\rho_{\text{ophio}}=3133 \text{ kg/m}^3$) would represent the largest deviation compared to our best-
 516 case model assuming complete ophiolite serpentinization (100 %-case, $\rho_{\text{ophio}}=3069 \text{ kg/m}^3$). This density is based
 517 on Al-Lazki et al. (2002). Even if the upper part of the ophiolite was missing in the Jebel Akhdar area (Nicolas
 518 and Boudier, 2015), this and the field data of Searle and Cox (2002) in the Saih Hatat support strong
 519 serpentinization. A less serpentinized ophiolite means higher densities and related higher thermal conductivities
 520 of the overburden and thus lower peak temperatures in the sediments below. In the case of no serpentinization,
 521 peak temperature of Natih B in the Wadi Nakhr would decrease by c. 60 °C resulting in a maximum thermal
 522 maturity decrease of 1.5 % VR. The best fit model with an ophiolite thickness of 8-10 km would need additional
 523 3 km of overburden at 0 % serpentinization to equally match the measured thermal maturities. Additional
 524 thicknesses of 0.75 km (75 % serpentinization), 1.5 km (50 % serpentinization) and 2.25 km (25 %
 525 serpentinization) apply for lower degrees of serpentinization, respectively (compare Fig. 9).
 526 Results depend strongly on basal heat flow (Figure S3). The best fit model of 40 mW/m² at maximum burial is
 527 typical for a passive continental margin setting. If this heat flow at peak burial would be lowered to 30 mW/m² an
 528 additional amount of 1.2 km of ophiolitic overburden would be required to achieve a match with thermal
 529 calibration data (Figure 11). Increased heat flow values to 50, 60 or 70 mW/m² would result in lowering of
 530 overburden by 1.3, 2.4 and 3.5 km, respectively (Figure 11).

538 **5. Discussion**

539 Evaluating uncertainties in basin and petroleum system models is especially important for complex areas such as
540 the Jebel Akhdar, where sedimentary rocks reached high temperatures and maturities due to deep and rapid burial.
541 In the following, we discuss these uncertainties with respect to temperature and burial history, overpressure build-
542 up and induced fluid flow. For all presented basin models of the study area, the following assumptions apply: (1)
543 decompacting the present-day lithologies does not consider rock volume lost by pressure solution. This is probably
544 of minor importance in our study area as host-rock buffered isotope ratios of the veins were interpreted as local
545 sinks for nearby dissolved calcite (Arndt et al., 2014; Hilgers et al., 2006), so that the overall rock volume remains
546 approximately constant, (2) decompaction only accounts for burial, whereas a possible tectonic compaction is
547 neglected (Neumaier, 2015) and (3) calculated overpressure does not include a rock volume decrease due to
548 pressure solution.

549 **5.1. Burial history**

550 Little is known about the very early phase of burial, before 91 Ma (Figures 6 and 7, Grobe et al., 2018). The
551 assumptions for this period are based on hypotheses on the tectonic evolution of the passive continental margin as
552 well as data on thickness of sedimentary units but are not strongly constrained by geological data.

553 In Turonian times (Robertson, 1987) a southwest-ward-moving forebulge, related to plate convergence, affected
554 northern Oman. It eroded the northeastern platform edge and migrated southwest-ward to the present-day position
555 of the Adam Foothills (Robertson, 1987). Measured thermal maturities of 1.1 % VR_r were used to reconstruct peak
556 temperatures during burial in Jebel Qusaybah, Adam Foothills to c. 140 °C. Numerical basin modeling results
557 reveal that additional paleo-overburden of maximum 4 km (Natih B, Qusaybah, Figure 10) is required to reach
558 these temperatures. The exhumation history of the Adam Foothills is not well known; our model is based on an
559 interpreted late exhumation during the Miocene (Claringbould et al., 2013). Earlier exhumation would shorten the
560 time span of the rock at higher temperatures (Figure 7), lead to decreased thermal maturity and, hence, would
561 require additional overburden to match the measured thermal maturity data. Therefore, the resulting burial of 4 to
562 4.5 km has to be regarded as minimum value. South of the Adam Foothills basin geometries do not show tilting
563 and are interpreted as not affected by the moving foredeep. Here peak burial was reached under c. 3 km of Fiqā,
564 Hadhramaut and Fars formations. This is based on the assumption that present-day burial equals deepest burial as
565 no thermal calibration data of the area south of Jebel Qusaybah are available, which is in agreement with
566 interpretations of Terken (1999) and Warburton et al. (1990).

567 In case of the Jebel Akhdar, peak temperatures were reached as a consequence of burial below the ophiolite
568 (Loosveld et al., 1996; Searle et al., 2003; Searle, 2007; Warren et al., 2005). Here the sedimentary rocks reached
569 high temperatures and maturities as shown by solid bitumen reflectance, RSCM, FT-IR and Rock-Eval pyrolysis
570 data (Fink et al., 2015; Grobe et al., 2016). Pre-obduction burial by sedimentation is not sufficient for such high
571 thermal maturities, and it likewise cannot be explained by increased basal heat flow before 91 Ma or after 55 Ma.
572 Influence of local hydrothermal effects cannot be excluded, but because the entire Jebel Akhdar reached high
573 temperatures, short-term, local events are unlikely to have been dominant. A regional thermal overprint on the
574 passive margin sediments by warm ophiolite obduction can be excluded and is hence not accounted for in the
575 model. Due to the at least 2 km thick imbricated Hawasina Nappes between the ophiolite and the passive margin
576 sequence, the thermal overprint did not affect the top of the carbonate platform. Limited thermal overprint of the
577 units underlying the ophiolite is supported by the fact that the sediments of the nappes directly below the ophiolite

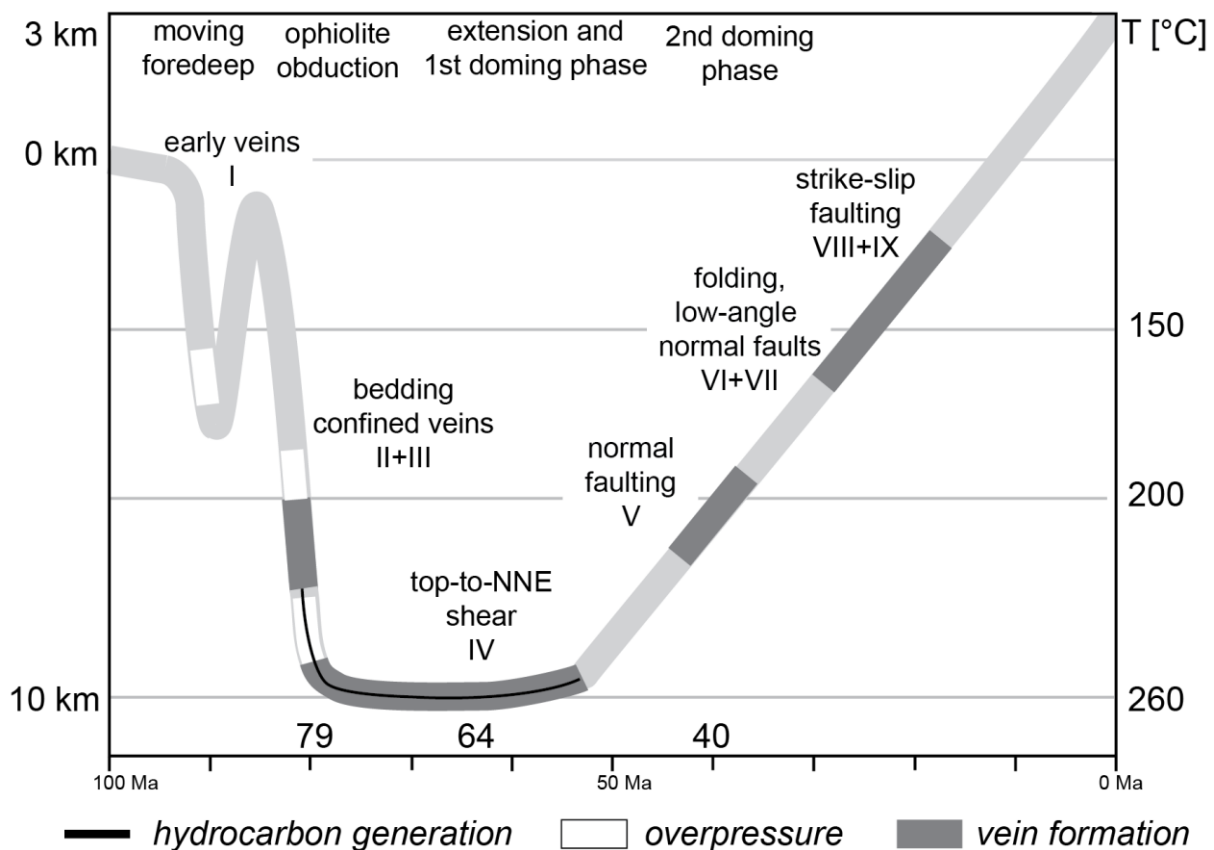

578 do not show signs of regional metamorphism in the Jebel Akhdar region (Searle, 1985). Moreover, the thermal
579 imprint as observed by the metamorphic sole in northern Oman only affects 10's of meters in the sub-thrust
580 Hawasina Nappes (Searle and Cox, 2002) and not the carbonate platform sediments below. This minor overprint
581 is also observed in other areas (e.g. Wygrala, 1989).

582 To reach the measured maturity values in the Jebel Akhdar, a paleo-thickness of the ophiolite in the order of 8-
583 10 km on top of 2 km of Hawasina Nappes is required (Figure 10); this corresponds to 280 to 340 MPa of lithostatic
584 pressure, in rough agreement with the pressure reconstructed by combining fluid inclusion data and independently
585 determined thermal rock maturity temperatures (cf. FI results: 254 ± 30 MPa).

586 Basin modeling indicates that highest temperatures were reached later than deepest burial under the ophiolite
587 (Figure 7), directly prior to exhumation. This difference is interpreted as the time advection needs to heat the rock.
588 Deep burial under the ophiolite represents the only time in the basin's evolution when ductile limestone
589 deformation was possible (Grobe et al., 2018). However, there is uncertainty concerning the exact timing of
590 deepest burial in the Jebel Akhdar (we used 79 Ma according to U-Pb dating of eclogites in the Saih Hatat window;
591 Warren et al., 2005), the related basal heat flow (discussion, Fig. S2) and the beginning of early exhumation (we
592 used 55 Ma, as discussed below). A later exhumation would not be sufficient to match observed thermal maturities
593 with thermometry data. The slightly higher temperatures of the model compared to thermometry data suggest that
594 an even quicker exhumation might have taken place.

595 Our peak temperatures are in agreement with temperatures of c. 200 °C suggested for the top of the carbonate
596 platform by Breton et al. (2004), non-reset zircon fission tracks in the pre-Permian basement indicating peak
597 temperatures up to 280 °C (Saddiqi et al., 2006), and ductile limestone conditions observed at the Jurassic-
598 Cretaceous boundary (Grobe et al., 2018, Figure 7). Moreover, thermal maturities of the same stratigraphic units
599 show similar values along the transect and around the dome (Grobe et al., 2016). Hence, we assume a similar burial
600 history for the entire Jebel Akhdar and were able to refine previous models (Grobe et al., 2016) with the here
601 presented larger dataset. The temperatures used in our models are in contrast with recent results on mixed layers
602 illite-smectite and clay mineral assemblages from the Jebel Akhdar by Aldega et al. (2017) who argue for peak
603 temperatures of 150-200 °C on the northern flank of the Jebel Akhdar and 120-150 °C on the southern flank. These
604 values are incompatible with our solid bitumen and Raman spectroscopy data, as well as with the overmature Natih
605 B source rock on the southern flank (data presented here and in Grobe et al., 2016). Independent data on
606 temperatures from fluid inclusions confirm the higher temperature range. At present, there is no clear explanation
607 for this discrepancy. However, it has been shown that the vitrinite reflectance system is more sensitive to rapid
608 temperature changes than clay mineralogy (e.g. Hillier et al., 1995; Velde and Lanson, 1993). If burial was short
609 enough, the clay minerals may not have time to recrystallize, possibly due to a lack of potassium, whereas vitrinite
610 reflectance increases. Alternatively, we speculate that the clay minerals were transformed during top-to-NNE
611 shearing, thus their state do not show peak burial. Indeed it has been shown that deformation associated with this
612 early extension reaches deeply into the passive margin sequence, and includes the Rayda and Shuaiba Formations
613 (Grobe et al., 2018; Mattern and Scharf, 2018). Furthermore, Aldega et al. (2017) argue that the cooling history
614 proposed by Grobe et al. (2016) indicates temperature in the basement $< 70^{\circ}\text{C}$ during the Eocene-Oligocene, thus
615 not accounting for thermochronological data in pre-Permian basement rocks. In fact, the calibration data we used
616 for the basement indicate rapid cooling at 55 ± 5 Ma (Poupeau et al., 1998; Saddiqi et al., 2006), in agreement with
617 models of Grobe et al. (2016) and the exhumation presented in this work.

618 This exhumation might be a result of the ductile top-to-NNE shearing event (64 ± 4 Ma, Hansman et al., 2018;
 619 Grobe et al., 2018). Its onset marks the exhumation of the carbonate platform after deepest burial. Related peak
 620 temperatures measured in fluid inclusions of bedding parallel veins were estimated to $186\text{--}221$ °C by Holland et
 621 al. (2009) assuming an ophiolitic overburden of 5 km (Sahtan Fm., Wadi Nakhr). If we adjust this pressure
 622 correction for higher values of 280 to 340 MPa accounting for the here elaborated 8 to 10 km of ophiolite and
 623 2 km of sedimentary nappes, trapping temperatures would increase to c. $296\text{--}364$ °C (Table 3), which are in the
 624 order of the maximum burial temperatures as deduced from organic matter maturity.
 625 Figure 12 presents a summary burial graph integrating all presented data in a plot of the temperature evolution
 626 over time. Additional pressure data is gained by fluid inclusion thermometry: These data indicate paleo-fluid
 627 temperatures in the range of 225 ± 4 °C (280 MPa) to 266 ± 5 °C (340 MPa) during burial under the ophiolite
 628 (bedding-confined veins), c. $296\text{--}364$ °C at peak burial (top-to-NNE sheared veins) and 213 ± 3 °C during
 629 exhumation with a later phase of primary inclusion outlining 184 ± 3 to 189 ± 7 °C (both strike-slip related veins).
 630 Temperature decrease within the latter formed parts of the strike-slip veins might relate to a change of fluid source
 631 or to exhumation during vein formation. In combination with our thermochronology data the second possibility
 632 appears more likely and would imply strike-slip faults developed after c. 55 Ma.
 633

634 **— hydrocarbon generation** **□ overpressure** **■ vein formation**
 635 **Figure 12: Summary sketch of burial and exhumation for the top of the carbonate platform (Natih Fm.) integrating all**
 636 **presented datasets. Headings refer to the tectonic phases and captions to the structural generations I-IX (Grobe et al.,**
 637 **2018) and enlarged ages reflect deepest burial reached at c. 79 Ma, the onset of initial dome formation at 64 Ma (top-**
 638 **to-NNE shearing) and rapid exhumation active at 40 Ma. Temperatures on the right are based on RSCM and FI**
 639 **thermometry. Pressure at peak burial is calculated from FI measurements and independently determined temperature**
 640 **data to $p_p = 254 \pm 30$ MPa and $p_L = 340$ MPa. The exhumation history is reconstructed from ZHe ages.**

641 5.2. Exhumation history

642 Our new thermochronology data from the central part of the Jebel Akhdar Dome suggest cooling below the reset
643 temperature of the ZHe thermochronometer (c. 130-170 °C) between 48.7 ± 1.8 and 39.8 ± 3.0 Ma (Table 2,
644 Figure 4). The small variation in cooling ages for the different stratigraphic levels indicates rapid passage of the
645 entire rock suite through the ZHe partial retention zone, and consequently rapid exhumation of the Jebel Akhdar
646 Dome. This Eocene cooling is in agreement with ZHe ages of pre-Permian strata of Hansman et al. (2017) ranging
647 between 62 ± 3 and 39 ± 2 Ma. Apatite fission track (AFT) ages measured in the basement of the Jebel Akhdar
648 range between 55 ± 5 Ma and 48 ± 7 Ma (4 samples, Poupeau et al., 1998) and 51 ± 8 Ma to 32 ± 4 Ma (Hansman
649 et al., 2017). The temperature of resetting the AFT system (i.e. the depth of the base of the partial annealing zone)
650 may vary depending on annealing kinetics. For different apatite crystals this temperature ranges between 100 and
651 120 °C (Carlson et al., 1999; Fitzgerald et al., 2006). Hence, these AFT ages reproduce within error with our ZHe
652 results, despite the fact that both systems are sensitive to different temperature intervals (100-120 °C and 130-
653 170 °C, respectively). This supports the interpretation of rapid exhumation of the Jebel Akhdar at c. 55 Ma. Zircon
654 fission track ages witness cooling of the Jebel Akhdar below c. 260 °C between 96 and 70 Ma (Saddiqi et al.,
655 2006). This implies slow cooling thereafter (c. 100° between 70 and 55 Ma) until rapid exhumation at c. 55 Ma.
656 Earlier exhumation would not result in required thermal maturities as exposure of the rock to highest temperatures
657 would be too short for thermal equilibration. A reheating event in the late Miocene is not required to explain the
658 data.

659 Our ZHe data from the Muti Formation and the Hawasina Nappes show a spread in ages, between 173 and 43 Ma,
660 i.e. partly much older than the ages observed in the stratigraphically lower units in the center of the dome.

661 A spread in (U-Th)/He-ages is often observed, and has been attributed to radiation damage density, uneven
662 distribution of mother isotopes in the dated crystal, broken grains, grain chemistry, among other causes (e.g.
663 Flowers et al., 2009; Guenther et al., 2013). Several studies show that samples from sedimentary rocks are
664 particularly prone to spread in ages (e.g. von Hagke et al., 2012; Ketcham et al., 2018; Levina et al., 2014). This
665 is because transported grains are subject to abrasion, which influences age correction for grain geometry and may
666 obscure presence of inclusions within the crystal. Additionally, dated grains can originate from different sources,
667 and thus have a different chemical composition and a different pre-depositional temperature history. This may
668 result in different reset temperatures, and consequently different grains (or grain age populations) represent
669 different thermochronometers.

670 It is difficult to prove the existence of such multiple thermochronometers, as independent parameters indicative
671 for different kinetics have not yet been established. Indeed, statistical analysis of different grain age populations
672 requires dating of multiple grains (e.g. to be 95 % certain that a population representing 5 % of the grains is not
673 missed 117 single grain ages need to be dated, Vermeesch (2004)). In any case, reproducing ages determined in
674 different samples indicates the data is geologically meaningful, i.e. the observed spread is the result of partial
675 resetting and/or different kinetics and not the result of factors independent of the time-temperature history, such
676 as undetected inclusions or external helium implantation. We thus interpret the system as only partially reset,
677 implying these units were not heated above the reset temperature (approximately 130-170 °C) after deposition.
678 This interpretation is corroborated by unreset ZHe ages in the Hawasina Window (Figure 1, Csontos, pers. comm.).
679 The top of the Natih Formation experienced temperatures above 220 °C. We suggest that this apparent
680 contradiction may be explained by juxtaposition of the colder Muti and Hawasina units against the top of the
681 carbonate platform during extensional top-to-NNE shearing. This implies that at least 50 °C of cooling are

682 associated with post obduction extension, i.e. before doming. A two-stage exhumation history of the Jebel Akhdar
683 Dome has also been inferred from structural data (Grobe et al., 2018; Mattern and Scharf, 2018) and the
684 stratigraphic record (Fournier et al., 2006; Mann et al., 1990). Top-to-NNE shearing is associated with tectonic
685 thinning of the ophiolite (Grobe et al., 2018). This tectonic denudation will also result in cooling, and may explain
686 why so little ophiolite is found in the post-obduction sediments. Additionally, ophiolitic material may have been
687 lost to the Gulf of Oman.

688 **5.3. Pressure evolution**

689 Evolution of pore pressures was modelled (Figures S7 and S8) assuming a seal on top of the Natih Fm.
690 ($k_{\text{Muti}}=10^{-23} \text{ m}^2$). Porosity was lost during Muti deposition in the moving forebulge (top seal) and related burial, the
691 emplacement of the Hawasina Nappes and the ophiolite, which induced compaction and a remaining very low
692 porosity of c. 1 %. Hydrostatic pressure increased with burial under the moving forebulge at 88 Ma to 40 MPa,
693 after Muti deposition to 60 MPa and after ophiolite emplacement to 120 MPa. Calculated pore pressure rise above
694 hydrostatic pressure in response to Hawasina Nappe and ophiolite emplacement.

695 Formation of tensile fractures, as inferred from bedding confined, Mode-I veins in the Natih Fm. (Arndt et al.,
696 2014; Grobe et al., 2018; Holland et al., 2009a; Virgo, 2015), require internal fluid pressures (P_f) exceeding the
697 sum of the stress acting normal on the fracture surface (σ_3) and the tensile stress of the rock (T): $P_f > \sigma_3 + T$, and
698 a differential stress ($\sigma_1 - \sigma_3$) below $4T$ (Secor, 1965). Host-rock buffered vein isotope compositions indicate that
699 the veins were formed by local fluids (Arndt et al., 2014) and, hence, require local overpressure cells.

700 Sensitivity analyses of reduced permeabilities of Muti, Natih and Nahr Umr formations show that overpressure
701 generation, necessary for rock fracturing, requires a very good top seal and also a reduced horizontal permeability
702 of the Natih Fm. of 10^{-23} m^2 (Figure S7 and S8). A top seal on its own is not sufficient for overpressures initiating
703 rock failure. This case results in pore pressures up to 300 MPa within the top Natih and localized overpressures of
704 195 MPa in front of the obducting ophiolite.

705 All results indicate that without low horizontal permeabilities of the Natih Fm. $\leq 10^{-23} \text{ m}^2$ overpressure cells
706 required for vein formation cannot be generated. The reduced permeabilities in the Natih Fm. are necessary to
707 prevent an early, tectonically-driven horizontal pressure release.

708 **5.4. Fluid migration**

709 Numerical basin modeling shows that rapid burial of sedimentary rocks below the ophiolite (88-80 Ma) caused
710 under-compaction, i.e. a porosity too high with respect to burial depth, and consequent pore pressure increase.
711 Two example model results of fluid migration in front of the obducting ophiolite are shown in the electronic
712 supplement Figure S9. If low permeabilities are assigned to the non-source-rock members of the Natih Fm.,
713 migration will mainly take place within the source rocks and at layer interfaces within the Natih Fm. If the complete
714 Natih Fm. has low permeabilities, fluids will leave the source rock vertically first, before lateral migration localizes
715 along layer boundaries. The pressure gradient between overpressures below the allochthonous nappes and the less
716 deeply buried southern foreland initiates tectonically-driven fluid migration in front of the obducting nappes, an
717 idea that was first introduced by Oliver (1986). Solid bitumen accumulations in black stained calcite veins are in
718 agreement with this interpretation (Fink et al., 2015).

719 Dome formation of the Jebel Akhdar anticline around 55 Ma initiated layer tilting and consequent southward
720 migration of the generated hydrocarbons as observed by secondary low reflective solid bitumen generations in
721 Natih veins and host rocks at the southern flank of the Oman Mountains (Fink et al., 2015; Grobe et al., 2016).

722 **6. Conclusions**

723 This study provides insights into the temperature evolution during obduction, prior to subsequent orogenesis.
724 Arabia's passive continental margin was buried to at least 4 km at times of foredeep migration and afterwards
725 under 8-10 km of Semail Ophiolite and 2 km of sedimentary Hawasina Nappes. Deepest burial under the ophiolite
726 resulted in peak temperatures of up to 300 °C (Shu'aiba Fm.) with sub-lithostatic pore pressures. Ophiolite
727 obduction and overpressure cells expelled fluids towards the foreland, through matrix and fracture porosity.
728 ZHe data show cooling associated with forebulge migration, as well as with exhumation of the Jebel Akhdar Dome.
729 Exhumation of the Jebel Akhdar Dome took place in two stages. A first stage is associated with top-to-NNE
730 shearing, which is responsible for at least 50 °C of cooling, as witnessed by juxtaposition of units including
731 partially reset ZHe ages against units that experienced more than 220 °C. ZHe data show the second exhumation
732 phase, associated with doming of the Jebel Akhdar occurred between 49 and 39 Ma.

733 **Author contribution**

734 JLU, RL and AG initiated and planned the study. AG planned and carried out fieldwork as well as thermal maturity
735 measurements (VR, solid bitumen reflectance, Raman spectroscopy), structural interpretations and basin
736 modelling. AG, CvH, JU, ID and FW carried out fieldwork and structural interpretations. FW and ID conducted
737 the thermochronological measurements with help of CvH. PM and AG performed fluid inclusion thermometry.
738 AG and CvH prepared the manuscript with contributions from all co-authors.

739 **Acknowledgements**

740 We acknowledge the highly-appreciated help of Donka Macherey (sample preparation, RWTH Aachen), the team
741 of the KU Leuven (fluid inclusion measurements) and Keno Lünsdorf (Raman spectroscopy, Georg-August-
742 University, Göttingen). Sample crushing was realized by the team of SELFRAG, Switzerland. Wiekert Visser and
743 Victoria Sachse are thanked for fruitful discussions; Gösta Hoffmann and Wilfried Bauer of GUTech are thanked
744 for helping with field logistics. We are grateful for comments of Edwin Gnos, Andreas Scharf, Wolf-Christian
745 Dullo and Mark Handy on earlier versions of this manuscript and the reviews of Massimiliano Zattin, Luca Aldega,
746 Bruce Levell and Federico Rossetti.
