9 10 11 **Abstract**

12
13 Analogue modellers investigating extensional tectonics often use different machines, set-ups
14 and model materials, so that direct comparisons of results from different studies can be
15 challenging. Here we present a systematic comparison of crustal-scale analogue experiments
16 using simple set-ups simulating extensional tectonics, involving either a foam base, a rubber
17 base, rigid basal plates or a conveyor base to deform overlying brittle-only or brittle-viscous
18 models. We use X-ray computed tomography (CT) techniques for a detailed 3D analysis of
19 internal and external model evolution.

20
21 We find that our brittle-only experiments are strongly affected by the specific set-up, as the
22 materials are directly coupled to the model base. Experiments with a foam or rubber base
23 undergo distributed faulting, whereas experiments with a rigid plate or conveyor base
24 experience localized deformation and the development of discrete rift basins. Pervasive
25 boundary effects may occur due to extension-perpendicular contraction of a rubber base.
26 Brittle-viscous experiments are less affected by the experimental setup than their brittle-only
27 equivalents as the viscous layer acts as a buffer that decouples the brittle layer from the base.
28 Brittle-viscous plate base and conveyor base experiments only localize deformation with high
29 brittle-to-viscous thickness ratios that increases brittle-viscous coupling. This effect is further
30 enhanced by higher strain rates.

31
32 Our set-ups are most appropriate for investigating crustal-scale extension in continental and
33 selected oceanic settings. Specific combinations of set-up and model materials may be used
34 for studying young or old regions, or wide or narrow extension. Here, natural factors as
35 temperature variations, extension rate, water content and lithology should be carefully
36 considered. We hope that our experimental overviews may serve as a guide for future
37 experimental studies of extensional tectonics.

38 39 40 41 **1. Introduction**

42 43 1.1 Analogue experimental set-ups for investigating extensional tectonics

44
45 Tectonic analogue modellers have historically used different experimental apparatus and model
46 materials to investigate continental extension. These experiments have provided the scientific
47 community with highly valuable insights in the evolution of basins and initial rift structures.
48 However, a robust comparison between various experiments is challenging, because of the
49 variety of experimental set-ups and model materials that have been used. Experiments have,
50 for example, used set-ups involving (a combination of) basal foam bars, basal rubber sheet,
51 rigid basal plates or conveyor belt style basal sheets with moving sidewalls to deform model
52 materials (e.g. Allemann et al. 1989; Acocella et al. 1999; Bahroudi et al. 2003; Amilibia et al.
53 2005; Alonso-Henar et al. 2015; Philippon et al. 2015). Alternatively, extension can be achieved
54 through gravitational gliding or spreading, in which case no moving sidewalls or an extending
55 base needs to be applied (e.g. Gartrell 1997; Fort et al. 2004; Acocella et al. 2005). Analogue
56 materials used to simulate brittle parts of the lithosphere include, among others, quartz or
57 feldspar sand, silica flour, microbeads, and (kaolinite) clay (Hubbert 1951, Elmohandes 1981;
58 Serra & Nelson 1988; Clifton & Schlichte 2001; Autin et al. 2010; Abdelmalak et al. 2016, Fig.

59 1). Pure silicone oils and silicone putties are frequently used as analogues for ductile parts of
60 the lithosphere (Basile & Brun 1999; Michon & Merle 2000; Sun et al. 2009, Fig. 1).

61
62 Vendeville et al. (1987) present experiments that highlight several factors controlling the
63 geometry of fault systems in extensional tectonics. The study used rubber sheet set-ups with a
64 brittle sand layer for homogeneous thin-skinned deformation, brittle-viscous gravity-spreading
65 models resting on a solid base, and experiments with the whole brittle-viscous lithospheric
66 analogue floating on a simulated asthenosphere (Fig. 1). The results provide a first impression
67 of the differences between these set-ups, revealing the correlation between fault spacing and
68 layer thickness in brittle materials, rift localisation in brittle-viscous settings and isostatic effects,
69 such as tilted margins due to the influence of an asthenosphere (Fig. 1). Yet the many
70 experimental parameters were widely different from experiment to experiment, making a
71 quantitative comparison difficult.

72
73 Allemand & Brun (1991) test the influence of material layering, but using a conveyor belt set-up
74 to achieve both symmetric and asymmetric extension with a velocity discontinuity (VD). The
75 basal sheets diverge, representing a fracture in the underlying (not-simulated) brittle
76 lithospheric mantle. Asymmetric extension is shown to generate strongly asymmetric rift
77 geometries, in both brittle and brittle-viscous models. The rifts under symmetric extension
78 conditions also develop a degree of structural asymmetry. Model parameters such as layer
79 thickness, material properties and extension velocities are however not clearly defined, again
80 making again a direct comparison of these experiments challenging.

81
82 Brun (1999) summarises extension experiments with a focus on layer rheology and extension
83 velocity. He shows that increasing extension velocities in crustal-scale brittle-viscous conveyor
84 belt models increase viscous strength and brittle-viscous coupling, favouring widespread
85 deformation or wide rifting. By contrast, low extension velocities lead to localized extension or
86 narrow rifting. A similar effect is obtained by changing the brittle-to-viscous thickness ratio: a
87 high ratio of 3:1 leads to high coupling and wide rifting, whereas a small ratio of 1:1 leads to low
88 coupling and narrow rifting. On a lithospheric scale however, the behaviour of the upper mantle
89 becomes important as well (Fig. 1); a single fracture in a strong upper mantle layer may induce
90 narrow deformation in the overlying crustal layers, whereas a weak upper mantle promotes
91 distributed deformation. The models also suggest that within such wide rifts, local weaknesses
92 can account for the development of core complexes. Next to providing a summarizing scheme
93 similar to Brun (1999), Corti et al. (2003) show how magma presence can control graben
94 initiation in narrow rifts and cause a wide rift to shift in core complex mode. The authors also
95 describe the additional effects of oblique extension and multiple extension phases on rift
96 evolution. However, the models presented in both review articles come from numerous studies
97 and are often performed with sometimes very different techniques and parameters.

98
99 The additional significance of VDs in the brittle upper mantle was investigated by Michon &
100 Merle (2000; 2003) by means of brittle-viscous base plate experiments, where the VD is
101 situated at the edge of the plate. A single VD leads to asymmetric extension and the
102 development of a single rift, whereas a double VD experiment may form two or more rift basins,
103 depending on the initial distance between the VDs. This is valid for high strain rates, as low
104 strain rates focus deformation (narrow rifting), decreasing the number of rift basins. Apart from
105 the varying strain rates and VDs, the other parameters such as model size, materials and layer
106 thickness remained fixed.

107
108 Schreurs et al. (2006) compared results of a brittle-viscous plate base extension experiment
109 that was run by five analogue laboratories. The overall experimental set-up was kept as similar
110 as possible using, for example, the same foil to cover the base of the apparatus, the same
111 extension velocity and the same viscous material (PDMS). But differences occurred in brittle
112 materials (different types of sand and a wet clay) and model width. This study illustrated the
113 overall large-scale structural similarities, but also showed differences in fault dip angle and fault
114 spacing, that were related to differences in model materials and/or model set-up.

115

116 1.2 Analogue materials used in extension experiments

117

118 Brittle, Mohr-Coulomb type materials have very similar internal friction angles with respect to
119 their natural analogues (ranging between ca. 25° and 40°, Klinkmüller et al. 2016; Schellart &
120 Strak 2016). Granular materials such as dry quartz sand have a very low cohesion and are
121 considered a good analogue for large-scale models aiming at the whole brittle crust or the crust
122 and lithospheric mantle (Fig. 1). By contrast, high-cohesion materials, such as silica flour and
123 clay ($C = 40\text{--}750$ Pa, Eisenstadt & Sims 2005; Guerit et al. 2016), are better suitable for
124 modelling the uppermost kilometres of the crust where cohesion is an important rheological
125 factor. Intermediate cohesions can be obtained by mixing granular materials (Abdelmalak et al.
126 2016; Montanari et al. 2017). Low-friction microbeads allow the modelling of structural
127 weaknesses or weak crustal lithologies (e.g. Colletta et al. 1991; Panien et al. 2005). The
128 density of brittle analogue materials depends on the specific density, the grain size and
129 handling techniques, as well as water content (for clays), but lies generally between ca. 1400-
130 1800 kg/cm³ (e.g. Krantz 1991; Eisenstadt & Sims 2005; Klinkmüller et al. 2016).

131

132 Pure silicone oils consist of polydimethylsiloxane (PDMS), are transparent, have a density of ca.
133 1000 kg/m³ (Weijermars & Schmeling 1986) and a Newtonian viscosity between c. 10³ Pa·s
134 and 10⁵ Pa·s at room temperature and at typical experimental deformation rates (Rudolf et al.
135 2015; Schellart & Strak 2016). Silicone putties are mixtures of polyborondimethylsiloxane
136 (PBDMS) and inert fillers (Weijermars, 1986), and have higher densities than pure silicone oils.
137 Examples of opaque silicone putties commonly used in analogue modelling include Rhodorsil
138 Gomme GS1R (Cobbold & Quinquis, 1980), Rhodorsil Silbione 70009 (Nalpas & Brun, 1993)
139 and Dow Corning DC3179 (Dixon and Summers, 1985). Their density range varies between c.
140 1140 and 1420 kg/m³ and they display Newtonian viscosities between c. 10⁴ and 4·10⁵ Pa·s at
141 room temperature (e.g., Casas et al., 2001; Cagnard et al., 2006; Konstantinovskaya et al.,
142 2007). It should be noted that the viscosity of silicone-based materials can in some cases
143 strongly depend on temperature (Cagnard et al. 2006) and also aging processes have an effect
144 on silicone behaviour (Rudolf et al. 2015 and references therein). Pure silicone oils and silicone
145 putties can be mixed with for instance sand or metallic powders to modify the material's density
146 and viscosity (e.g. Calignano et al. 2015; Zwaan et al. 2016). Other substances, such as
147 paraffin and gelatin mixtures can be applied when power-law or temperature-dependent
148 rheological behaviour is required (e.g. Zulauf & Zulauf 2004; Boutelier & Oncken 2011). In
149 lithosphere-scale models, the weak ductile behaviour of the asthenospheric mantle is simulated
150 with low viscosity materials, such as honey, glucose syrup or even pure water (Mart & Dauteuil
151 2000; Chemenda et al. 2002; Schellart et al. 2002; 2003; Molnar et al. 2017). These normally
152 exhibit Newtonian behaviour. Further details and references concerning the above-mentioned
153 and other analogue model materials can be found in a comprehensive review article by
154 Schellart & Strak (2016).

155

156 1.3 This study

157

158 The analogue modelling work summarized above reveals a trend from a rather qualitative
159 modelling approach to a more quantitative approach. Older studies tend to present a range of
160 models with widely different parameters (for materials and set-up), which are often not fully
161 described. By contrast, newer studies often specify such data in much detail, allowing repetition
162 by analogue and also numerical means. Yet direct comparisons between the various methods
163 remains challenging, especially since these methods aim to simulate different tectonic settings
164 (see also sections 2.2 and 2.3). In theory, the scaling principles that have elevated analogue
165 modelling from a qualitative to a quantitative method can be applied to compute how models
166 should compare to each other (e.g. Hubbert 1937; Ramberg 1981; Weijermars & Schmeling
167 1986). In practice, however, such calculations remain approximate. Different material handling
168 techniques (laboratory traditions, the human factor) or climatic conditions (room temperature,
169 humidity) may influence material behaviour and thus model results with the same set-up can
170 vary from laboratory to laboratory (e.g. Krantz 1991; Schreurs et al. 2006, 2016; Rudolf et al.
171 2015). Furthermore, our understanding of experimental material rheology may be incomplete or
172 poorly constrained since some parameters are difficult to properly determine (Eisenstadt &

173 Sims 2005; Dooley & Schreurs 2012). Thus the need for reference studies of lithospheric
174 extension with standardized model parameters remains and to our knowledge no such work is
175 available to date.

176
177 The aim of this study is to systematically compare a series of simple crustal-scale, normal-
178 gravity laboratory experiments involving commonly used set-ups and to discuss the tectonic
179 settings to which these would apply. We use either a foam base, a rubber base, rigid base
180 plates or “conveyor belt” style plastic sheets as a mechanism to deform the overlying brittle or
181 brittle-viscous model materials. This forms a total of 8 reference set-ups. Various additional
182 sub-set-ups serve to examine, among others, the effects of varying extension velocity, layer
183 thickness and brittle-to-viscous thickness ratio. We also apply X-ray computed tomography
184 (XRCT or CT) for obtaining a highly detailed 3D view of internal as well as external model
185 evolution.

186

187

188 2. Materials and methods

189

190 2.1 Material properties

191

192 We ran brittle (single-layer) and brittle-viscous (two-layer) experiments to simulate a brittle
193 upper crust and a complete brittle-ductile crust, respectively (Fig. 2). Reference brittle-only
194 experiments contain a 4 cm thick layer of fine quartz sand ($\phi = 60\text{-}250\ \mu\text{m}$). The sand is sieved
195 from ca. 30 cm height into the experimental apparatus to guarantee a sand density of ca. $1560\ \text{kg/m}^3$.
196 The sand is flattened using a scraper at every cm thickness during preparation of the
197 experiment, causing slight density variations, which subsequently appears on CT images as a
198 “layering” (Fig. 2f, g). The reference experiments with a brittle-ductile set-up are built of an
199 additional 4 cm thick, near-Newtonian viscous layer (viscosity $\eta = \text{ca. } 1.5 \cdot 10^5\ \text{Pa}\cdot\text{s}$; stress
200 exponent $n = 1.05$) consisting of a 1:1 weight mixture of SGM-36 Polydimethylsiloxane (PDMS)
201 silicone and corundum sand ($\rho_{\text{specific}} = 3950\ \text{kg/m}^3$, Panien et al. 2006; Zwaan et al. 2016;
202 Carlo AG 2018). The obtained density of the viscous material (ca. $1600\ \text{kg/m}^3$) is close to that
203 of the overlying quartz sand layer ($1560\ \text{kg/m}^3$). This results in a density profile that avoids
204 buoyant rise of the viscous material that would occur for pure, low density PDMS ($\rho = 960$
205 kg/m^3). Further material properties are listed in Table 1.

206

207 2.2. Experimental design

208

209 The experimental apparatus consist of a fixed base and two longitudinal sidewalls, which can
210 move outward independently from each other above a fixed support table, controlled by precise
211 computer-guided stepper motors. The initial width of the experiment is 30 cm in all set-ups,
212 which is considerably less than the model length (as specified below). This high length-to-width
213 ratio diminishes the influence of boundary effects of the short sidewalls. Through modification
214 of the apparatus we can use four different methods to transfer deformation from the base of the
215 set-up to the overlying experimental materials: by applying either a foam base or rubber sheet
216 base for a distributed deformation setting, or a base of rigid plates or conveyor belt system for
217 focussed deformation (Fig. 2). The confinement along the short sidewalls varies according to
218 the set-up, as explained below. Since the various set-ups differ significantly, we also specify
219 which type of tectonic setting or crustal rheology is simulated (Fig. 3). An additional overview of
220 the similarities and differences between our set-ups by means of (relative) velocities and shifts
221 in reference frames is provided in Appendix A (Fig. A1).

222

223 2.2.1. Distributed deformation set-ups

224

225 A foam base (F series experiments) induces distributed deformation (e.g. Schreurs & Colletta
226 1998; Schlagenhauf et al. 2008; Zwaan et al. 2016, Zwaan & Schreurs 2017). An 8 cm thick
227 RG 50 Polyurethane foam base is first compressed between the sidewalls with the model
228 subsequently constructed on top (Fig. 2a-c). As the sidewalls move apart during an experiment,
229 the foam expands, causing deformation in the overlying materials (Fig. 2b, c). Rubber sidewalls

230 at the short ends of the set-up confine the materials, with the distributed extension of the rubber
231 decreasing boundary effects there (Fig. 2a). All foam base experiments have a length of 79 cm
232 for an initial length-to-width ratio of 2.6.

233
234 For the rubber base set-up (R series experiments) a 1.5 mm thick Neoprene rubber sheet is
235 spanned between the two long sidewalls (e.g. Vendeville et al. 1987; Bahroudi et al. 2003;
236 Bellahsen et al. 2003; Bellahsen & Daniel 2005; Fig. 2d-f). Note that this is slightly different
237 from set-ups applying a rubber sheet between two rigid base plates that are subsequently
238 moved apart (e.g. McClay & White 1995, McClay et al. 2002; Corti et al. 2007; Henza et al.
239 2010). We use a full rubber base for our experiments in order to allow a comparison with the
240 foam base set-up. When the long sidewalls move apart, the rubber sheet is stretched and
241 extends uniformly with a constant velocity gradient, causing distributed deformation (Fig. 2e, f).
242 The sides of the set-up are free, that is, not confined by any sidewall that may influence the
243 experiments, for the experiments with only a brittle layer. The short sidewalls of the brittle-
244 ductile rubber base experiments are enclosed by a sand talus so that the viscous material
245 cannot escape sideways (Fig. 2d). Since the large forces involved in stretching a large rubber
246 sheet may cause damage to the experimental apparatus, the length of the rubber base
247 experiments is kept to 50 cm. Therefore, the initial length-to-width ratio is 1.7.

248
249 Previous authors have applied a rubber or foam base with an overlying brittle layer to model
250 distributed thin-skinned extension (e.g. Bahroudi et al. 2003; Schlagenhauf et al. 2008). In
251 nature, distributed extension in the brittle crust could develop in a setting with high brittle-ductile
252 coupling between a brittle upper crust and a strong ductile lower crust (Fig. 3a), either due to
253 high strain rates or high viscosity (Brun 1999, Buiter et al. 2008; Zwaan et al. 2016). Note that
254 the sub-crustal mantle has no influence in this case. By contrast, a set-up with brittle-viscous
255 layers on top of a rubber or foam base would simulate a normal brittle-ductile crust on top of a
256 viscously deforming weak mantle (Fig. 3b). This setting, in which the strength of the lithosphere
257 is determined by the brittle crust (Bürgman & Dresen 2008), can be expected in a hot
258 lithosphere, for instance above a mantle plume (Saunders et al. 1992; Burov et al. 2007) or
259 after a phase of crustal thickening and radiogenic heating (Brun 1999).

261 2.2.2. Localized deformation set-ups

262
263 The plate base set-up (P series experiments) involves two 3 mm thick rigid plastic plates that
264 are fixed to the long sidewalls (Fig. 2g-h) (e.g. Allemand & Brun 1991; Tron & Brun 1991; Brun
265 & Tron 1993; Bonini et al. 1997; Keep & McClay 1997; Michon & Merle 2000). When these
266 plates move apart with the long sidewalls, velocity discontinuities (VD) develop at the basal
267 edges of the plates. The support table below the plates prevents material from escaping (Fig.
268 2e, f). The short sidewalls are confined by a similar plate system that is fixed to the horizontal
269 plates, thus moving in sync and creating the same boundary conditions as at the base of the
270 apparatus (Fig. 2g). In contrast to the set-ups applying distributed extension described above,
271 the rigid base plates allow both symmetric and asymmetric extension (Fig. 2e, f). In the former
272 case, two moving VD's occur as the edges of both non-overlapping plates move apart, whereas
273 the latter case results in only one VD (similar to Michon & Merle 2000, see also Fig. A1). The
274 initial length of the base plate experiments is 90 cm, so that the length-to-width ratio is 3.
275 Although we did not measure the boundary friction of the plastic plates with quartz sand, it is
276 likely to be close to the values reported by Panien et al. 2006 for plastic and PVC: ca. 20.7°.

277
278 The final set-up is a modified version of the plate base set-up involving a "conveyor belt" type of
279 deformation (C series experiments) (e.g. Allemand & Brun 1991; Tron & Brun 1991; Dauteuil &
280 Brun 1993; Keep and McClay 1997; Román-Berdiel et al. 2000). Sub-mm thick plastic sheets
281 or foil ("Alkor" foil 120010 formerly produced by Alkor-Venilia and now available as "Gekkofix
282 11325" www.gekkofix.com; Klinkmüller et al. 2016) are fixed to the plate base set-up and are
283 led down through a slit in the support table, along the central axis of the experiment (Fig. 2j-l).
284 When the long sidewalls move apart, the sheets are pulled upward through the slit (Fig. 2k, l).
285 In contrast to the plate base experiments, a single VD occurs, which remains located at the
286 centre of the experiment. Since this is true for both symmetrical and asymmetrical experiments

287 (Fig. 2k, l), the two setups are different. But the asymmetric set-up is, after a switch of
288 reference frame, the same as the asymmetric plate base set-up (Fig. A1) and should thus
289 produce an identical result. The same sheet system is applied on the short sidewalls in order to
290 have a continuous confinement (Fig. 2j). These sheet base experiments have the same length-
291 to-width ratio as the base plate experiments, i.e. 3. The angle of boundary friction of the foil
292 with quartz sand lies between 15° and 21° (Schreurs et al. 2016).
293

294 Both the base plate and conveyor base experimental designs involve localized deformation at
295 VD. These VD simulate a fault in a strong layer underlying the experimental materials. In the
296 case of our brittle-only experiments, this would translate to a fault at the base of the upper crust.
297 In order to have a fault in the lower crust, the latter needs to behave in a brittle fashion, which
298 in our case would be expected in an old, cool crust (Fig. 3c). On a smaller scale, one can also
299 interpret the VD as a reactivated basement fault affecting overlying strata (e.g. Acocella et al.
300 1999; Ustaszewski et al. 2005). Concerning our brittle-viscous crustal set-up, the VD translates
301 to a fault in a strong upper mantle (e.g. Allemand & Brun 1991; Michon & Merle 2000). Such a
302 setting can be expected in a young stable lithosphere with a strong brittle mantle (Fig. 3d).
303

304 2.3. Additional experimental parameters

305
306 For every experimental set-up, we test brittle-only materials and brittle-viscous layering, with a
307 reference layer thickness of 4 cm, so that brittle-only and brittle-viscous experiments are 4 cm
308 and 8 cm thick, respectively. However, for specific experiments, we either apply a 4 cm thick
309 brittle-viscous layering, or we modify the brittle-to-viscous thickness ratio by decreasing the
310 thickness of the viscous layer to 2 or 1 cm, in order to capture the effects that a different crustal
311 layering may have on extensional structures (details in Table 2). This decrease in viscous layer
312 thickness can be either due to a thinner, viscous lower crust, assuming that the brittle crustal
313 thickness remains the same (Fig. 3g, h), or an increase in brittle crustal thickness with a
314 constant Moho depth. In both cases, this would result in a relative strengthening of the
315 lithosphere with respect to the default layering.
316

317 We also apply “seeds” to localize deformation in several experiments (Fig. 2, Table 2). These
318 seeds are 1 cm thick, semi-cylindrical viscous rods of the previously described
319 PDMS/corundum sand mixture that are placed at the base of the brittle layer. The seeds are
320 continuous and stretch along the full axis of the experiment. They form weak zones where
321 deformation may localise, since the strong sand cover is locally thinner and thus weaker (e.g.
322 Zwaan et al. 2016). Although we acknowledge that surface processes can influence rift
323 evolution (e.g. Burov & Cloetingh 1997; Bialas & Buck 2009; Zwaan et al. 2017), we neither
324 apply erosion nor sedimentation in our experiments, since we aim to directly evaluate
325 differences in experimental results obtained by differences in simple experimental set-ups.
326

327 Our reference extension velocity is 8 mm/h, with both long sidewalls moving 4 mm/h for
328 symmetrical extension, or a single sidewall moving 8 mm/h for asymmetrical extension (Fig. 2).
329 Considering a reference duration of 5 h, the total extension equals 40 mm (or ca. 13%, given
330 an initial width of ca. 30 cm). In addition, we varied extension velocity for selected experiments.
331 In the case of the brittle-only experiments, this should not affect the brittle deformation
332 structures because of the time-independent behaviour of sand. For brittle-viscous experiments
333 however, variations in extension velocity are equivalent to variations in effective linear viscosity
334 and will thus affect the relative strength contrast between the brittle and viscous materials (Fig.
335 3e, f). In the experiments with a foam or rubber base, a strengthening of the viscous material,
336 due to an increase in extension velocity, translates to a strengthening of the hot lithosphere
337 with increased brittle-ductile coupling but still a relatively weak mantle (compare Fig. 3b with
338 Fig. 3e). In the base plates or conveyor set-up equivalent, a higher extension velocity would
339 would then represent a normal crust with increased coupling with respect to the reference
340 settings (Fig. 3f).
341

342 A thin (ca. 0.5 mm thick) grid made of dark (corundum) sand with a 4 x 4 spacing applied to the
343 surface of each experiment allows a first-order assessment of surface deformation by means of

344 top view images, without influencing the experimental results. Furthermore, every component
 345 of the machine around the experiment consists of X-ray transparent materials to allow for CT-
 346 scanning and various experiments are analysed with CT-techniques to reveal their 3D internal
 347 evolution (Fig. 2b). Most experiments marked in Table 2 as “CT-scanned” were a rerun of
 348 previous tests performed without CT scanning. Various other experiments were also repeated
 349 and did indicate little structural variation, thus good reproducibility is ensured (Table 2, details
 350 presented in Appendix B, Figs. B1, B2).

351
 352

353 2.4. Scaling

354

355 We calculate stress ratios ($\sigma^* = \sigma_{\text{experiment}} / \sigma_{\text{nature}}$) using (Hubbert 1937; Ramberg 1981): $\sigma^* =$
 356 $\rho^* \cdot h^* \cdot g^*$ where ρ^* , h^* and g^* represent the density, length and gravity ratios respectively.
 357 The strain rate ratio $\dot{\epsilon}^*$ is derived from the stress ratio σ^* and the viscosity ratio η^*
 358 (Weijermars & Schmeling 1986): $\dot{\epsilon}^* = \sigma^* / \eta^*$. The velocity ratio v^* and time ratio t^* can be
 359 obtained as follows: $\dot{\epsilon}^* = v^* / h^* = 1/t^*$. Natural values for lower crustal viscosity may have a wide
 360 range depending on the specific tectonic setting ($\eta = 10^{19}$ - 10^{23} Pa·s, e.g. Buck 1991; Brun
 361 1999; Bürgman & Dresen 2008). We assume an intermediate lower crustal viscosity of 10^{21}
 362 Pa·s, which is in line with recent findings (Shinevar et al. 2015, and references therein). An
 363 hour in our experiments thus translates to 0.84 Ma in nature and our reference velocity (8
 364 mm/h) converts to a velocity of ca. 0.5 mm/y in nature, close to typical values for initial
 365 continental rifting (1-5 mm/y, e.g. Saria et al. 2014). The scaling parameters are summarized in
 366 Table 3.

367

368 To ensure dynamic similarity between brittle natural and experimental materials, we calculate
 369 the ratio R_s , which is a function of gravitational stress and cohesive strength (C) (Ramberg
 370 1981; Mulugeta 1998): $R_s = (\rho \cdot g \cdot h) / C$. When adapting an intermediate cohesion of ca. 8
 371 MPa for upper crustal rocks, we obtain a R_s value of 67 for both nature and our experiments.
 372 This cohesion is relatively low compared to the ca. 20-40 MPa measured for continental rocks
 373 (e.g. Handin 1969; Jaeger & Cook 1976; Twiss & Moores 1992), but should be reasonable
 374 given that the strength of the earth’s crust is generally reduced due to previous phases of
 375 tectonic activity. For viscous materials, the Ramberg number R_m applies (Weijermars &
 376 Schmeling 1986): $R_m = \text{gravitational stress} / \text{viscous strength} = (\rho \cdot g \cdot h^2) / (\eta \cdot v)$. Our
 377 experimental and the equivalent natural R_m values are the same at 75.

378

379

380 3. Results

381

382 3.1. Foam base experiments (F series)

383

384 Fig. 4 shows the results of two brittle-only foam base experiments. Experiment F1 (without
 385 seed) develops no distinct features except for significant boundary effects along the
 386 longitudinal sidewalls towards the end of the experiment (Fig. 4a). In contrast, the seed in
 387 experiment F4 localizes deformation in the centre of the experiment, although faulting along the
 388 long sidewalls is also visible at the surface (Fig. 4b). The CT data from experiment F4 (with
 389 seed) reveals the evolution of these structures in more detail (Fig. 4c-e). After ca. 60 min (8
 390 mm) of extension, a graben starts forming above the seed and becomes visible at the surface
 391 after 120 min (16 mm of extension, Fig. 4d, f). This main rift structure continues developing
 392 towards the end of the experiment (Figs. 4e, g). The CT images show how additional faulting
 393 occurs: first along the sidewalls (Fig. 4d, f), later on throughout the experiment so that at the
 394 end of the experiment, pervasive sidewall-parallel striking normal faulting is omnipresent (Fig.
 395 4e, g). Note that this distributed faulting is not visible on the top view images due to the low
 396 fault offsets at the surface that do not cast shadows on the model surface (Fig. 4b), and may
 397 very well be present in the experiment without seed as well (F1, Fig. 4a). In Experiment F4, the
 398 brighter tones at the rift shoulders visualise local uplift: parts of the experiment that are uplifted
 399 present less of a barrier to the X-rays since these pass through less material, which shows up

400 as a brighter colour on CT images. It is however important to stress that these brighter colours
401 do not represent a specific altitude.

402
403 The evolution of foam base experiments with a brittle-viscous layering is summarized in Fig. 5.
404 Experiment F5, without a seed, forms no central graben (Fig. 5a). Instead, all deformation is
405 concentrated as boundary effects along the long sidewalls. By contrast, experiment F7, with a
406 seed, produces a well-developed symmetric graben structure. Still also this set-up produces
407 some minor faulting along the long sidewalls (Fig. 5b). CT images illustrate the 3D evolution of
408 experiment F7 (Fig 3c-g). Soon after initiation (30 min, 4 mm extension), a central graben
409 structure with two main boundary faults develops above the seed. As the experiment
410 progresses, this structure continues evolving: the rift basin grows deeper and the brittle
411 material situated between the initial boundary faults starts breaking up due to internal faulting
412 (Fig. 5d, f). Some boundary effects develop, but are relatively minor with respect to the central
413 graben structure (Fig. 5d-g). Towards the end of the experiment the brittle sand is almost
414 breached by the upwelling viscous layer (Fig. 5e g). In this experiment, deformation is strongly
415 focussed on the rift structure and no distributed faulting can be distinguished. As in the brittle-
416 only set-up with a seed (F4), this experiment also develops rift shoulder uplift, as indicated by
417 the bright colours at the model surface (Fig. 5e).

418

419

420 3.2. Rubber base experiments (R series)

421

422 The surface evolution of two selected rubber base experiments built of only sand is depicted in
423 Fig. 6. Experiment R1 (Fig. 6a, a') has no seed to localize deformation and, as a consequence,
424 deformation focuses along the sidewalls. In addition, remarkable conjugate faults develop at
425 the end of the experiment (300 min, 40 mm of extension), but are not well visible on the top
426 view images due to poor lighting conditions (Fig. 6a). However, an additional phase of
427 extension (30 min at 40 mm/h) helps to highlight these conjugate faults (Fig. 6a'). In contrast to
428 experiment R1, experiment R5 contains a viscous seed that focuses faulting along the central
429 axis of the experiment (Fig. 6b). As a result, this experiment develops a central graben
430 structure. Similar to experiment R1, well-defined conjugate faults occur as well.

431

432 The CT-derived 3D images (Fig. 6c-g) reveal how deformation localizes along the seed and the
433 sidewall in the initial stages of experiment R5, forming a cylindrical rift structure (Fig. 6d).
434 However, after some 20-25 mm of extension, conjugate sets of vertical strike-slip faults start
435 developing (Figs. 6f), which become pervasive toward the end of the experiment (Figs. 6e, g).
436 This curious feature is the result of along-strike compression, as the orthogonally extending
437 rubber sheet contracts perpendicular to the extension direction (Fig. 6a'). Yet the graben
438 structures continue to evolve toward the end of the experiment run (Fig. 6e, g). The brighter
439 colours on the surface seen in Fig. 6g again indicate rift shoulder uplift.

440

441 Fig. 7 shows results of four brittle-viscous rubber base experiments. Experiment R7, without
442 seed, produces no clear surface structures except for the strong boundary effects along the
443 sidewalls (Fig. 7a). In contrast, experiment R8, with seed, experiences early fault localization
444 (after 30 min a rift becomes visible at the surface), which continues evolving towards the end of
445 the experiment (Fig. 7b). However, also this experiment develops strong boundary effects
446 along the long sidewalls and at the corners, where some viscous material flows into the gap
447 between the original sand buffer and the retreating sidewalls. The rift structure is best
448 developed in the centre of the experiment and dies out towards the short sidewalls, involving
449 slight block rotation of the sand layer in the four corners of the experiment (Fig. 7b).

450

451 Experiment R9 at an increased extension velocity of 80 mm/h (Fig. 7c) produces a central rift
452 that is quite similar to the rift in experiment R8 (Fig. 7b), even though no seed is included.
453 Significantly higher extension velocities (480 mm/h in experiment R10) result in strongly
454 distributed deformation with multiple rifts (Fig 5d). The three experiments without a seed at
455 different extension rates (Fig. 7a, c, d) examine the effect of decreased strength contrast
456 between the brittle and viscous layers. We will discuss this further in discussion section 4.4.

457 3.3. Plate base experiments (P series)

458

459 Experiments P1 and P2 consist of a brittle sand layer on top of plastic-covered rigid base
460 plate(s) (Figs. 1g, 8a, b). In experiment P1 we apply symmetric extension, whereas in
461 experiment P2 extension is asymmetric. Both experiments initially develop a rift above the
462 velocity discontinuity along the central axis of the experiment. However, with continued
463 extension experiment P1 develops a graben with a central horst block in the middle, which
464 does not develop in experiment P2 (Fig. 8a, b). Otherwise, both grabens have the same width.
465 No boundary effects occur along the long sidewalls.

466

467 Fig. 8c-g shows the results of the brittle-viscous base plate experiments. Experiments P3 and
468 P7 are following symmetrical and asymmetrical extension, respectively. No seed is included.
469 The structural evolution is similar for both experiments. Rifting initiates at the short sidewalls,
470 where both the base plates and confining plates are moving apart (Figs. 1h, 8c, d). These rifts
471 propagate slightly towards the centre of the experiment, but strong boundary effects along the
472 long sidewalls take up much of the extension there and no continuous rift structure develops in
473 the centre of the experiment (Fig. 8c, d). As a result, block rotation takes place on both sides of
474 the propagating rifts. The surface structures are largely the same in both experiments,
475 suggesting that the application of symmetric or asymmetric extension does not have a
476 significant influence in this set-up.

477

478 The application of a seed on top of the viscous layer (Exp. P10, in symmetric extension) results
479 in early localization and rift development along the central axis of the experiment (Fig. 8e). This
480 structure continues developing throughout the experiment, yet more extension is
481 accommodated towards the short sidewalls than the middle section, where boundary effects
482 along the long sidewalls take up a larger part of the deformation, similar to experiments P3 and
483 P7 (Fig. 8c, d).

484

485 The thick viscous layer in experiments P3 and P7 likely dampens the influence of the basal
486 boundary condition on the sand layer. We therefore run further tests with half the layer
487 thickness for the viscous material, keeping the same brittle-to-viscous ratio (2 cm brittle and 2
488 cm viscous material, without seed). These experiments did not produce a continuous graben
489 structure either. However, experiment P9, with a higher 80 mm/h extension velocity (and again
490 2 cm brittle and 2 cm viscous layers, without seed), produces interesting basin geometries (Fig.
491 8f, g). Instead of developing a simple rift structure, the viscous layer at the centre of the
492 experiment is strongly stretched, creating a depression with continuous rift basins at its margin
493 due to what seems to be passive downbending (Fig. 8g). Secondary graben structures develop
494 further away from the central depression, indicating a degree of distributed deformation.
495 Notably, no boundary effects occur along the long sidewalls, in contrast to the other brittle-
496 viscous plate base experiments.

497

498

499 3.4. Conveyor base experiments (C series)

500

501 Fig. 9 shows the results of the conveyor base set-up with only a brittle layer (experiments C1
502 and C3). Both experiments develop a large rift structure along the central axis of the
503 experiment (Fig. 9a, b), rather similar to the plate base experiments P1 and P2 (Fig. 8a, b). We
504 do, however, not observe a difference between the symmetrical and asymmetrical set-ups.

505

506 The results of the brittle-viscous experiments show more diversity than their brittle-only
507 counterparts (Fig. 9c-g). Experiment C4, with symmetrical extension, develops two rifts that
508 originate from the short sidewalls and propagate towards the experiment centre (Fig. 9c). They
509 do however not connect, as boundary effects along the long sidewalls take up most of the
510 deformation in the centre, similar to the structures observed in the plate base equivalents
511 (experiments P3 and P7, Fig. 8c, d). We did not run an asymmetrical extension experiment.
512 Instead, we attempted to reduce the boundary effects along the short sidewalls by applying
513 lubricants or adding a sand buffer as proposed by Tron & Brun (1991) (experiments C5 and C6,

514 respectively). Unfortunately, the boundary effects remained or got worse (See Appendix B, Fig.
515 B1). Furthermore we ran the conveyor base equivalent of experiment P9 (2 cm sand, 2 cm
516 viscous material, Fig. 8f, g), labelled C12, with very similar results to experiment P9 (Fig. B2).
517

518 We also tested the effect of decreasing viscous layer thickness, thus increasing the brittle-to-
519 viscous ratio, in experiments C7 and C8. In experiment C7 (Fig. 9d), the thickness ratio is 2,
520 which does not lead to a significantly different structural evolution compared to the reference
521 setup of experiment C4 (Fig. 9c). However, decreasing the viscous layer thickness further to 1
522 cm (ratio: 4), leads to localization of faulting along the central axis of the experiment during
523 early stages of the experiment, whereas rifting becomes more widespread towards the end of
524 the experiment (C8, Fig. 9e). Tests with higher extension velocities (80 and 40 mm/h for
525 experiments C9 and C10/C11, respectively, see Table 2 and Appendix B, Fig. B2) have shown
526 to improve rift localization, and one such experiment was run in a CT scanner (experiment C11,
527 Fig. 9f, g). These experiments all develop the same features: a double rift system on either side
528 of the VD, which internally grows more complex with time. We also observe the development of
529 further, minor additional rift basins striking parallel. Slight boundary effects occur along the long
530 sidewalls in experiments C10/C11 as well (Fig. 9f, g).
531

532

533

534 4. Discussion

535

536

537 4.1. General structures

538

539 We present a schematic overview of our experimental results in Fig. 10, summarizing the
540 general structures in map view and section, and Table 4, linking these observation with
541 potential natural settings. A clear distinction exists between the brittle-only experiments (left-
542 hand half of upper three rows in Fig. 10) and the brittle-viscous experiments (right-hand half of
543 upper three rows in Fig. 10) since the viscous layer acts as a buffer between the deformation-
544 inducing base and the overlying sand. In the brittle-only experiments, no such buffer exists and
545 deformation induced by the model base is directly transmitted to the overlying sand cover,
546 leading to more distinct structural differences between the experimental series. In addition, the
547 bottom row of Fig. 10 summarizes the structures observed in the high extension velocity
548 experiments and the tests with high brittle-to-viscous ratios. Our experimental results are
549 discussed in more detail below.
550

551 4.2. Brittle-only experiments

552

553 In the foam base experiments, the sand above the foam directly experiences the distributed
554 deformation induced by the expanding foam, causing fault development throughout the
555 experiment, but mainly along the long sidewalls (Figs. 4a, 10a). Schlagenhauf et al. (2008)
556 report similar but more pronounced distributed rifting, possibly enhanced by a higher degree of
557 extension of their foam base (20% vs. our 13%) and a thicker sand pack (8 cm vs our 4 cm).
558 Seeds do localize rift basins in our experiments, but these structures only account for a minor
559 part of the extension as the rifts experience little subsidence with respect to most other
560 experiments (e.g. P1 and P2 in Figs. 8a, b). The brittle-only rubber base experiments produce
561 similar structures to the brittle-only foam base experiments: distributed deformation and a minor
562 axial rift when a seed is applied (Fig. 6). Significant faulting develops at the long sidewalls and
563 migrates towards the centre of the experiment (Fig. 6c-g), which could be explained by stronger
564 strain gradients in the rubber near the sidewalls (Ackermann 1997). A similar effect could
565 possibly occur in the foam base experiments as well, explaining the comparable boundary
566 effects.
567

568 The rubber base experiments also develop conjugate strike-slip faults due to the contraction of
569 the rubber perpendicular to the extension direction (Poisson effect) (Smith & Durney 1992;
570 Venkat-Ramani & Tikoff 2002). Such structures are not always observed in other model studies

571 applying a rubber base set-up (e.g. Vendeville et al. 1987, Fig. 11a). The Poisson effect-related
572 structures we obtain are probably due to the relatively low length-to-width ratio rubber base we
573 use (ca. 1.7). Rubber base models by McClay & White (1995) and McClay et al. (2002) with
574 much higher length-to-width ratios (6 and 4, respectively) do not undergo any visible
575 contraction perpendicular to the extension direction, whereas an experiment by Bahroudi et al.
576 (2003) with a length-to-width ratio of 0.8 develops strong conjugate faulting (Fig. 11b). The
577 faults in Bahroudi et al. (2003) have a normal fault component as well, possibly because the
578 rubber was stretched from one side only. It is furthermore interesting to note that the Poisson
579 effect may occur in very different types of models or materials. Chemenda et al. (2002) for
580 instance, applying an elasto-plastic mixture of various components floating on water to simulate
581 the lithosphere and asthenosphere, also obtain pervasive conjugate faults due to extension-
582 perpendicular contraction.

583
584 Contrary to their rubber and foam base equivalents, a strong localization of faulting above the
585 velocity discontinuity (VD) occurs in the brittle-only plate base and conveyor base experiments
586 (Figs. 8a, b, 9a, b, 10i, j). The plates and sheets translate overlying materials, except at the
587 velocity discontinuity, where extension localises and deep rift basins form. The centre of the rift
588 basins in both the asymmetric and symmetric experiments lies practically at the same level as
589 the experimental base at the end of the experiment (4 cm depth, scaling to a 20 km deep basin
590 in nature, Fig 8i, j). In nature, isostatic compensation would have reduced basin depth. These
591 set-ups may therefore perhaps best be used for investigating initial (small) amounts of
592 extension (e.g. maximum half the thickness of the brittle crust), or larger amounts of extension
593 when significant sedimentation is applied (e.g. Allemand & Brun 1991; Brun & Tron 1993; Keep
594 & McClay 1997). The small horst structure along the axis of the symmetric extension plate base
595 experiment (Figs. 8a, 10i) is likely formed when both plates move away, leaving a small
596 quantity of material behind in the middle. Previous authors have shown the impact extension
597 asymmetry can have on rift geometry by creating strongly asymmetric graben structures
598 (Allemand et al. 1989; Allemand & Brun 1991; Panien et al. 2005, Fig. 11c, d). Yet these effects
599 are not directly observed in our experiments, possibly due to the relatively minor total extension,
600 the lack of syn-rift sedimentation or because we lack the necessary cross-sections as these
601 models were not CT-scanned.

602

603 4.3. Brittle-viscous experiments

604

605 The presence of a viscous layer in our experiments leads to quite different structures with
606 respect to those observed in their brittle-only counterparts (Fig. 10). The brittle-viscous foam
607 and rubber base cases produce basically the same structures: when no seed is present,
608 faulting occurs only along the sidewalls, whereas a seed concentrates deformation, resulting in
609 a central rift structure (Figs. 5a, b, 7a, b, 10c, d, g, h). The decoupling from the foam or rubber
610 base allows the brittle cover to behave as rigid blocks, more or less passively floating on the
611 viscous layer (Zwaan et al. 2017), whereas the sand in the brittle-only experiments is directly
612 coupled to the base, forcing a pervasive type of faulting (Fig. 10a, b, e, f). Due to this
613 decoupling effect of the viscous layer, no conjugate strike-slip fault sets occur in the brittle-
614 viscous rubber base experiments, similar to the experiments of Bellahsen et al. (2003). The fact
615 that the rifts in our rubber base experiments are less developed towards the short ends of the
616 set-up is most likely caused by the use of a sand talus to contain the viscous material there
617 (Figs. 2d, 6, 7b-d). This creates a deformation contrast between the immobile talus and the
618 deforming material above the rubber sheet, an effect that could potentially be reduced by using
619 a rubber sidewall, as in the foam set-up (Fig. 1a).

620

621 In contrast to the brittle-only experiments, the results of the brittle-viscous plate base and
622 conveyor base experiments are quite similar to their foam and rubber base equivalents (Fig.
623 10), most likely due to the tendency of the viscous material to easily spread out when subject to
624 extension. All of these experiments, however, see minor rifting initiating at the short sides of the
625 set-up, because there the model is confined by sidewalls or sheets that move in sync with the
626 long sidewalls, imposing the same boundary conditions there as at the base of the set-up. The
627 resulting additional drag enhances the extensional deformation at these short edges, forcing

628 the development of rifts, which propagate toward the centre of the experiment (Figs. 8c-e, 9c, d,
629 10k). In the centre, however, the viscous spreading mechanism is dominant, so that we
630 observe the same structures as in the other brittle-viscous experiments (Fig. 10). This “short
631 sidewall effect”, which is also present when applying a seed, causing the rifts to be more
632 developed at the short ends of the experiment (Figs. 8e, 10l), may also have occurred in a
633 model by Mart & Dauteuil (2000). Their experiment involves a curious propagating rift system,
634 initiating at the short edge of the set-up, which has a similar plate confinement as in our
635 experiments. In order to reduce this type of boundary effects, higher strain rates can be applied
636 (Fig. 9). The use of a sand talus to confine the short ends of the experiment as suggested by
637 Tron & Brun (1991) does not reduce these boundary effects in our experiments, as the sand
638 has an even stronger rigid relation to the experimental materials as the side plates (or sheets)
639 (experiment C5, Appendix B2).

641 As with the reference brittle-only experiments, we do not observe a clear difference between
642 symmetric and asymmetric extension on the scale of our set-ups. Yet previous authors have
643 shown that asymmetric extension may have an effect in brittle-viscous settings as well. This is
644 however mostly in combination with a relatively thin viscous layer that enhances brittle-viscous
645 coupling (e.g., Allemand et al. 1989). By contrast the relatively thick viscous layer in our
646 reference models acts as a buffer, decoupling the sand from the asymmetrically extending
647 plates or sheets (see also section 4.5).

651 4.4. Velocity effects: wide rifting versus passive downbending and marginal basin formation

652
653 As discussed in section 4.2, the brittle-viscous foam and rubber base experiments without a
654 seed lack the brittle-viscous coupling necessary to transfer deformation to the brittle layer.
655 Stronger coupling can be achieved by either using a material with a higher viscosity or by
656 increasing the extension velocity (which effectively increases viscosity) as in experiments R9
657 and R10 (Fig. 7c, d). A higher viscosity would allow the transfer of distributed extension applied
658 by the base to the brittle layer and thus lead to distributed or wide rifting (Brun 1999; Buiter et al.
659 2008; Zwaan et al. 2016; Figs. 7c, d, 10m, m'). Note that the central rift in experiment R9 is not
660 localized by a seed (Fig. 7c), but probably forms due to some wide rifting effect: the higher the
661 extension velocity (while keeping all other parameters constant), the higher the brittle-viscous
662 coupling and the more rifts develop, as illustrated by experiment R10 (Fig. 7d). Still the type of
663 deformation in these experiments is not as evenly distributed as in their brittle-only equivalents
664 (Figs. 4, 10a, a', b, b', e, e', f, f'), probably since brittle-viscous coupling is not high enough.

666 Considering the results from the high velocity rubber base experiments R9 and R10 (Fig. 7c, d,
667 10m, m'), those of the high velocity brittle-viscous plate/conveyor base experiments P9 (Fig. 8f)
668 and C12 (Fig. B2) may seem somewhat remarkable; instead of developing distributed rifting,
669 these models generate a ‘down-bent’ depression bordered by marginal grabens (Figs. 8f, g,
670 10n, n', B2). It seems that the high extension velocity in P9 and C12 (80 mm/h, translating to
671 320 mm/h for the reference layer thickness) causes high coupling between the viscous layer
672 and the brittle cover, as well as between the viscous layer and the base. The set-ups lead to
673 intense stretching (necking) above the VD(s) and subsequent downward ‘bending’ of the sand
674 cover (Fig. 8g). High coupling between the viscous layer and the base also explains why no
675 apparent boundary effects are visible along the longitudinal sidewalls. The bending of the brittle
676 layer at the edge of the system causes local extension in the sand and the formation of
677 marginal basins. Similar structures can be observed along the Western Escarpment of the Afar
678 (northernmost sector of the East African Rift System) in Ethiopia (e.g. Abbate & Sagri 1969;
679 Chorowicz et al. 1999), possibly caused by loading and bending due to massive diking and
680 underplating in the adjacent rift basin (Corti et al. 2015). Our experiment may suggest that rapid
681 extension of the crust could also cause such basin geometries.

682
683
684

685 4.5. Effects of different brittle-to-viscous ratios

686
687 Our brittle-viscous plate and conveyor base set-ups with the reference brittle-to-viscous
688 thickness ratio fail to produce proper rift basins, in contrast to their brittle-only equivalents
689 (experiments P1, P2, C1 and C2, Figs. 8a-d, 9a,b, 10k). Instead, we either need a seed as in
690 the foam and rubber base experiments (experiment P10, Figs. 8e, 10l), or a high brittle-to-
691 viscous thickness ratio (>2) to localize deformation (experiments C8 and C11, Fig. 9e-g). In the
692 latter case, high extension velocities improve localization (experiment C11, Fig. 9f, g). Yet we
693 obtain double rift structures rather than the single rift basins in the brittle-only experiments.
694

695 Also Tron & Brun (1991) apply a relatively thin viscous layer (brittle-to-viscous ratio of ca. 2)
696 and obtain well-developed rift structures in symmetric extension (Fig. 11f). The thin viscous
697 layer probably increases brittle-viscous coupling, causing the experimental brittle materials to
698 behave as rigid blocks and leading to rift localization near the VD, similar to our brittle-only
699 experiments (Fig. 8a, b, 9a, b). The extension model by Tron & Brun (1991, Fig. 11f) produces
700 the same double rift structure including the additional faults away from the central rifts as our
701 experiment C11 (Fig. 9f, g). Also Keep & McClay (1997) and Schreurs et al. (2006) obtain two
702 rifts with symmetrical extension experiments involving a conveyor or plate base and a brittle-to-
703 viscous ratio of 4 and 6, respectively. A lateral transfer of deformation through the viscous layer,
704 away from the VD is the probable cause of this dual rift arrangement (Michon & Merle 2000;
705 2003, Fig. 11e). This feature seems to occur in asthenospheric-scale models as well
706 (Vendeville et al. 1987, Fig. 1). A single rift structure may form due to factors as higher strain
707 rates (Keep and McClay 1997; Michon & Merle 2000), asymmetric extension or possibly syn-rift
708 sedimentation (e.g. Brun & Tron 1993, Fig. 11f). The formation of a single or dual rift structure
709 is most likely influenced by the viscosity of the viscous layer as well. Experiments with high
710 brittle-to-viscous ratios thus seem to be highly sensitive to various parameters. Whether the
711 various viscous layer thickness ratios mentioned above are realistic depends on the specific
712 tectonic setting that is simulated, as lithospheric rheological profiles are known to vary
713 considerably in extensional settings (e.g. Brun 1999; Burov 2011; Tetreault & Buiter 2017, see
714 also section 4.7).
715

716 4.6. Boundary conditions and boundary effects

717
718 Most of our reference experiments, except for the brittle-only plate and conveyor base
719 experiments, develop some degree of normal faulting along the long sidewalls (Fig. 10). In the
720 brittle-only experiments, this may be due to enhanced local stretching of the rubber base
721 (Ackermann 1997), an effect possibly present in the foam base equivalents as well. The rigid
722 sand layer in the brittle-viscous experiments on the other hand is subject to “inertia”, i.e. an
723 inability to move and extend as easily as the viscous materials, leaving “gaps” along the
724 sidewalls that take up significant amounts of deformation in the experiment (Zwaan et al. 2017).
725

726 Some authors avoid this “inertia” effect by simply ignoring it and focussing on the structures in
727 the centre of the experiment. Others attempt to reduce faulting by applying a viscous layer that
728 does not reach the model sidewalls (Tron & Brun 1991; Schreurs et al. 2006). By narrowing the
729 viscous layer however, the boundaries of the viscous material become rheological contrasts
730 that may trigger faulting themselves, thus causing a new type of boundary effects (e.g. Bonini
731 et al. 1997). This also raises the question what the viscous layer represents in nature, if not a
732 continuous viscous lower crust. Even narrower patches of viscous material, for instance
733 simulating a weak zone in the crust due to magmatism, lead to narrower rift structures (e.g.
734 Brun & Nalpas 1996; Dauteuil et al. 2002) and the seeds in our experiments can be seen as
735 the most extreme exponent of this trend. The width of the structural weakness is also relevant
736 for set-ups involving a rubber base fixed between two base plates (e.g. McClay & White 1995,
737 McClay et al. 2002; Corti et al. 2007; Henza et al. 2010). In such experiments, all deformation
738 occurs above the rubber sheet, with its edges acting as the boundaries of the rift system.
739

740 Our results show that the type of confinement along the short edges of the brittle-viscous
741 experiment forms another important factor generating boundary effects. In the foam base

742 experiments, the rubber sheet sidewalls cause little to no additional deformation, yet the sand
743 talus confinement in the rubber base experiments generates significant boundary effects, and
744 enhanced rifting is associated with the plate base and conveyor base confinements. However,
745 the similarity of the structures in the centre of all our reference brittle-viscous experiments (due
746 to the likely dominance of the viscous spreading mechanism under low brittle-viscous coupling
747 conditions) may suggest that, if the short edge boundary effects can be reduced, the type of
748 extension mechanism would be of little influence under our standardized conditions. Therefore
749 we could perhaps have obtained comparable results for brittle-viscous set-ups even without a
750 method to induce deformation directly at the base of the experimental materials: only moving
751 apart the two longitudinal sidewalls may suffice to cause uniform spreading of the viscous layer
752 (e.g. Le Calvez & Vendeville 2002; Autin et al. 2010, 2013; Marques 2012). However, the
753 results of such experiments may again vary with different strain rates, layering and layer
754 thickness, materials, application of sedimentation etc., highlighting the challenges of directly
755 comparing the results from different modelling studies and the need to specify all relevant
756 parameters and boundary conditions, as well as any resulting boundary effects.

757 758 4.7. Recommendations for extension experiments

759
760 Our extension experiments represent different rheological stratifications and extension
761 conditions (Fig. 3), which may serve as a guide for other modelling studies aiming at
762 investigating extension in specific tectonic settings. We calculated a series of rheological
763 profiles for natural cases to allow a direct rheological comparison to the analogue set-ups (Fig.
764 12). We used the rheological values of Table 3 with laboratory flow laws often used for the
765 lower crust and lithospheric mantle (Hirth & Kohlstedt 2003; Rybacki et al. 2006). We varied
766 extension velocity (0.5 to 10 mm/yr) and Moho temperature (550 and 650 °C). The calculations
767 show that extension velocity has a relatively minor influence on the rheological profile with
768 respect to temperature and dry or wet versions of the flow laws. The plots also indicate that our
769 reference brittle-to-viscous ratio of 1:1, although often used in analogue models (Corti et al.
770 2003 and references therein), is quite low (compare Fig. 12a, with Fig. 12b) and may only
771 occur in a relatively wet and hot lithosphere (Fig. 12f). This may for instance be in accordance
772 with the situation in the East African Rift System (Fadaie & Ranalli 1990; Corti 2009), but a 2:1
773 or 3:1 ratio would fit better with the calculations for a normal-temperature lithosphere (Fig. 12b-
774 d). A strong upper mantle, as inferred for (brittle-viscous) plate and conveyor base set-ups, only
775 occurs in a wet cold lithosphere (Fig. 12) or in a completely dry lithosphere (dotted lines in Fig.
776 12), yet the complete absence of hydrous minerals may be unrealistic (Xia & Hao 2010). Note,
777 however, that our strength profile calculations are based on monomineralic flow laws
778 (anorthosite and olivine, Hirth & Kohlstedt 2003; Rybacki et al. 2006), whereas continental
779 rocks are of course polymineralic. Different rheological profiles for natural settings can be
780 obtained by not only varying the thermal gradient, but also by variations in water content,
781 temperature or by simply using other flow laws. We choose lower crust and mantle flow laws
782 (Rybacki et al. 2006 and Hirth & Kohlstedt 2003, respectively) that are fairly recent and neither
783 overly weak nor strong in comparison with other flow laws.

784
785 The rheological calculations highlight that one should carefully consider the various factors that
786 may influence the strength of the lithosphere in a given tectonic setting before selecting a
787 specific experimental set-up. It is also important to stress that although the materials involved
788 may only represent the upper parts of the crust, deeper parts of the lithosphere (basement or
789 mantle) are simulated via the chosen experimental extension mechanism (Fig. 3). This is most
790 evident for brittle-only models that are directly coupled to the set-up (Fig. 10). However, we
791 have shown that for low extension velocity brittle-viscous experiments, that aim at representing
792 a hot lithosphere, any extension mechanism should suffice due to the high degree of
793 decoupling (Fig. 10). This decoupling effect could also allow a simple way to model an oceanic
794 lithosphere, which is generally considered to comprise a brittle oceanic crust and a viscous
795 lithospheric mantle (e.g. Benes & Scott 1996). Note, however, that in such set-ups an imposed
796 weakness is necessary to create any rift structure at all (Fig. 10). Since efforts should be made
797 to keep boundary effects to a minimum, we recommend using the foam base method for such
798 brittle-viscous models (see also section 4.6).

799

800 Our set-ups could be extended to include more layers (three or four-layer lithospheres) (e.g.
801 Corti et al. 2003) and an underlying asthenosphere, that would allow an assessment of the
802 effect of isostatic compensation on a stretching lithosphere. In such set-ups, a strong
803 lithosphere would strongly affect rifting processes (Brun 1999; Corti et al. 2003), whereas in the
804 case of a weak lithosphere (Figs. 3b, e, 12b-d, g, h), the (rising) asthenosphere may have an
805 important impact. The presence of an asthenosphere analogue would also allow the vertical
806 motions associated with a major fault or shear zone in the strong upper mantle (e.g. Vendeville
807 et al. 1987, Fig. 1). In the commonly used plate and conveyor base set-ups such a fault is
808 represented by the VD, yet any associated vertical motions are not simulated. The conveyor
809 belt extension mechanism may not be well suited to crustal-scale models, as the continuous
810 “upwelling” of the plastic sheets resembles a convection cell system, which could be taken to
811 simulate sub-lithospheric mantle behaviour. The conveyor base set-up would therefore be more
812 appropriate for lithospheric-scale models. For crustal-scale wide rift experiments we
813 recommend using a plate base set-up.

814

815 It could also be worthwhile to repeat our experiments with other brittle materials and viscous
816 analogues, which may better capture the behaviour of the lithosphere (overview in Schellart &
817 Strak 2016). The use of temperature-dependent materials would allow the inclusion of
818 temperature effects (e.g. Boutelier & Oncken 2011), which can strongly control rifting as shown
819 by numerical simulations (Tetreault & Buitier, 2017). Furthermore, a next necessary step in
820 modelling rift structures is to include surface processes as well (e.g. Burov & Cloetingh 1997;
821 Bialas & Buck 2009; Zwaan et al. 2017).

822

823 We would like to stress the importance of standardized modelling methods and strict lab
824 procedures (e.g. Klinkmüller et al. 2016). Different handling techniques, laboratory conditions
825 and personal preferences may cause variations in, for instance, sand density (e.g. Krantz
826 1991) or rheology of viscous materials (Rudolf et al. 2015) and can have significant effects on
827 model results (Schreurs et al. 2006, 2016). By means of standardized procedures within a
828 modelling group, these variations can be reduced. Yet reproducing the same model results in
829 different laboratories will probably always remain a challenge (see efforts by Schreurs et al.
830 2006, 2016).

831

832

833 5. Conclusion

834

835 We presented a systematic comparison of four setups commonly used for analogue modelling
836 of crustal-scale extension. We examined distributed extension obtained by a foam or rubber
837 base and localised extension by rigid basal plates or conveyor-belt basal sheets. We find that:

838

- 839 1. Brittle-only experiments are strongly affected by the experimental setup, as the materials
840 are directly coupled to the base of the set-up. Foam base or rubber base experiments
841 therefore undergo distributed deformation and wide rifting, whereas plate base or conveyor
842 base experiments experience localized deformation and narrow rifting.
- 843 2. Strong boundary effects may occur due to extension-perpendicular contraction effects
844 during stretching of a rubber base (Poisson effect, e.g. Smith & Durney 1992). This may be
845 mitigated by using a high length-to-width ratio for rubber base set-ups.
- 846 3. Brittle-viscous experiments are less affected by the experimental setup than brittle-only
847 equivalents as the viscous layer acts as a buffer that decouples the brittle parts from the
848 base of the set-up.
- 849 4. Of the brittle-viscous experiments we tested, the least boundary effects occur for a setup
850 involving a foam base and a stretchable rubber sidewall. This sidewall method could also
851 be applied to a rubber base setup to minimize boundary effects. In contrast, the plate base
852 and conveyor base set-ups may experience major boundary effects along their short
853 sidewalls that may prove difficult to mitigate.
- 854 5. The poor rift development in our reference brittle-viscous plate base and conveyor base
855 experiments is linked to relatively low brittle-to-viscous thickness ratio and strain rates.

856 Apart from inserting a structural weakness in the sand, we achieve better localization with
857 higher brittle-to-viscous ratios and higher strain rates, which increase brittle-viscous
858 coupling. High strain rates with reference brittle-to-viscous ratios can also cause intense
859 stretching of the viscous layer and downbending effects, leading to the formation of basins
860 with marginal grabens.

861
862 The significant differences between experimental results obtained with the different set-ups,
863 sometimes due to seemingly small differences in, for instance extension velocity or layer
864 thicknesses, indicate the need to accurately specify model parameters and boundary
865 conditions in order to allow meaningful comparisons between (analogue) modelling studies.
866 The combination of rheological stratification and experimental set-up defines the tectonic
867 setting that is investigated. Our set-ups can be applied to study extension of crustal materials in
868 young, weak or old, strong lithospheres with different levels of basement control. Here factors
869 as temperature, extension rate, water content and lithology should be taken into account (Fig.
870 12). We advise to avoid the conveyor belt method for crustal-scale models.

871
872 Finally we recommend that every laboratory standardize its procedures and methods as much
873 as possible in order to minimize variations due to different handling techniques and personal
874 preferences.

875 876 877 **6.1. Appendix A. Schematic overview of relations between experimental set-ups**

878
879 Fig. A1 provides an overview of the various set-ups and how these compare to each other by
880 means of extension velocities and shifts of reference frames. All symmetric extension set-ups
881 are different: foam/rubber base experiments (Fig. A1a, b) develop an extension gradient,
882 whereas the plate and conveyor base experiments develop velocity discontinuities (Fig. A1d, e
883 and i, j, respectively). Also the plate and conveyor set-ups are different (e.g. a moving and fixed
884 VD occurs in plate base and conveyor base configurations, respectively, as is revealed after
885 applying a shift of reference frame, Fig A1e, j). Asymmetric extension set-ups differ from their
886 symmetric equivalents as well, but are between themselves, after a shift of reference frame,
887 basically the same (Fig. A1g, l).

888 889 890 **6.2 Appendix B. Experimental reproducibility**

891
892 Figs. B1 and B2 show the surface results of repeated experiments in order to evaluate their
893 reproducibility. In most cases, the structures are very similar. Although the boundary effects in
894 P6 and P7 (Fig. B1) do show some variation, the structures in the centre are the same in both
895 cases (no rift). Experiments C4-C6 seem quite different (Fig. B1), but C5 and C6 are tests to
896 reduce boundary effects. As proposed by Tron & Brun (1991), we added sand to confine the
897 short ends of the experiment, but instead of improving the situation this measure increases
898 boundary effects. In C6 (Fig. B1) we added a lubricant (hand soap) between the sides and the
899 model. Since there was no improvement, we aborted the experiment after 120 min. Note that
900 asymmetric brittle-viscous plate base experiment P6 and symmetric brittle-viscous conveyor
901 belt experiment C4 are quite similar, due to viscous decoupling effects. Also asymmetric brittle-
902 only plate/conveyor base experiments P2, C2 and C3 produce the same structures (Fig. B2),
903 since both the plate base and conveyor base set-ups are, after a shift of reference frame,
904 identical in asymmetric extension conditions. The double rift structure in conveyor base
905 experiment C10 is almost identical to the version generated in C11 (Fig. B2), although the
906 curving nature of the normal faults does provide local variations in rift width. High-velocity
907 models P9 and C12 develop very similar structures, although those in the conveyor belt set-up
908 (C12) are better developed than in plate base experiment P9 (Fig. B2). Note that the additional
909 rift basins in C12 are also present in P10, but not very visible due to their less evolved state
910 and the unfavourable lighting conditions.

911
912

913 **7. Author contribution**

914

915 The first author, Frank Zwaan, performed the analogue models and composed the first version
916 of the manuscript. Second author and project supervisor Guido Schreurs assisted with the
917 model interpretation and the finalizing of the manuscript. This study was inspired by a
918 collaboration on numerical-analogue comparisons with third author Susanne Buitter, who
919 helped planning and discussing the model series, provided a comparison to natural strength
920 profiles, and helped in finalizing the manuscript.

921

922

923 **8. Acknowledgements**

924

925 We would like to express our gratitude to Nicole Schwendener for assisting us with the CT-
926 scanning, Marco Herwegh for providing the necessary financial support to upgrade the
927 experimental apparatus and to the engineers from IPEK Rapperswil (Theodor Wüst, Reto
928 Gwerder, Rudolf Kamber, Michael Ziltener and Christoph Zolliker) for realizing these
929 improvements. We thank John Naliboff and Jürgen Adam for supportive discussions and
930 testing of analysis techniques. This project was funded by the Swiss National Science
931 Foundation (grant no. 200021_147046/1).

1404 Table 1. Material properties

1405

Granular materials	Quartz sand^a	Corundum sand^b
Grain size range	60-250 μm	88-175 μm
Density (specific) ^c	2650 kg/m^3	3950 kg/m^3
Density (sieved)	1560 kg/m^3	1890 kg/m^3
Angle of internal peak friction	36.1°	37°
Angle of dynamic-stable friction	31.4°	32°
Cohesion	9 \pm 98 Pa	39 \pm 10 Pa
Viscous material	PDMS/corundum sand mixture^a	
Pure PDMS density (specific) ^a	0.965 kg/m^3	
Weight ratio PDMS : corundum sand	0.965 kg : 1.00 kg	
Mixture density	ca. 1600 kg/m^3	
Viscosity ^d	ca. 1.5 · 10 ⁵ Pa·s	
Type	near-Newtonian ($n = 1.05$) ^e	

1406

1407 ^a Quartz sand, pure PDMS and viscous mixture characteristics after Zwaan et al. (2016)1408 ^b Corundum sand characteristics after Panien et al. (2006)1409 ^c Specific densities of quartz and corundum sands after Carlo AG (2018)1410 ^d The viscosity value holds for model strain rates $< 10^{-4} \text{ s}^{-1}$ 1411 ^e Stress exponent n (dimensionless) represents sensitivity to strain rate

1432 Table 4. Overview of links between our analogue set-ups, the resulting structures observed in
 1433 our experiments and their natural analogues
 1434

Type	Layering	Extension velocity	Brittle-viscous ratio used	Coupling observed in experiments	Natural analogue	Structural style observed in experiments
Foam/Rubber	Brittle	Slow	-	Very high coupling of brittle layer with substratum	Strong ductile lower crust (Fig. 3a)	No seed: wide rifting (Fig. 10a, a') Seed: wide rifting with small localized graben (Fig. 10b, b') NB: Rubber base: conjugate faults may occur! (Fig. 10e, e', f, f')
			1:1	Low coupling between all components*	Weak, hot lithosphere (strong mantle absent) (Fig. 3b)	No seed: only boundary effects (Fig. 10c, c') Seed: localized rifting (Fig. 10d, d')
	Brittle-viscous	Fast	1:1	High coupling between all components	Strong ductile lower crust, but weak ductile upper mantle (Fig. 3e)	No seed: wide rifting (Fig. 10m, m') Seed: wide rifting with a localized graben (e.g. Zwaan et al. 2016)
			4:1	Very high coupling between all components*	Cold lithosphere; Fault in (thick) brittle crust or brittle mantle (Fig. 3c).	Narrow rifting (Fig. 10i, i', j, j')
Plate/Conveyor belt	Brittle	Slow	1:1	Low coupling between all components*	Hot lithosphere with thick ductile lower crust above brittle upper mantle (Fig. 3d)	No seed: wide rifting (Fig. 10k, k) Seed: wide rifting with small localized graben (Fig. 10l, l')
			4:1	High coupling between all components*	Cold lithosphere with thin ductile lower crust above brittle upper mantle (Fig. 3h)	No seed: Wide (double) rifting (Fig. 10o, o') Seed: Not known
	Brittle-viscous	Fast	1:1	Very high coupling between all components*	Hot lithosphere with thick ductile lower crust above brittle upper mantle (Fig. 3f)	No seed: Downbending basin (Fig. 10m, m') Seed: Not known
			4:1	Very high coupling between all components*	Cold lithosphere with thin ductile lower crust above brittle upper mantle (Fig. 3h)	Narrow (double) rifting (Fig. 10p, p') Seed: Not known

1435

Fig. 1. Example of model layering to simulate extension in a stable four-layer lithosphere. Left: strength profile of the natural example, with a brittle upper crust, a ductile lower crust, a strong brittle upper mantle and a ductile lower mantle that blends into the underlying asthenosphere at a temperature of 1300 °C. Middle: model materials representing the various layers: sand for the brittle parts of the lithosphere, viscous silicone (mixtures) for the ductile crust and mantle. The asthenosphere is simulated with a honey or viscous syrup. Right: cross-section at the end of the extension experiment. Adapted from Allemand & Brun (1991) with permission from Elsevier.

C4 (reference layering and extension velocity), (d) model C7 (reference extension velocity, brittle-to-viscous ratio: 2), (e) Exp. C8 (reference extension velocity, brittle-to-viscous ratio: 4) and (f) Exp. C11 (elevated extension velocity: 40mm/h, brittle-to-viscous ratio: 4). Note that the boundary effects (if present) occur on both sides of the model, but may be partially invisible due to shadow. (g) CT section depicting the internal structures of Exp. C11.

Fig. 10. Schematic summary of our experimental results. (a-l) Experiments with reference brittle-to-viscous ratios (1:1) and reference extension velocities (8 mm/h). (* = plate base model result only). All sections shown go through the central part of the model where boundary effects are minimal. (m-p) Additional brittle-viscous experiments with high extension velocities (80 mm/h) and/or high brittle-to-viscous ratios (4:1).

1544 Fig. 11. Examples of previously published analogue models of extensional tectonics. (a) Cross-
 1545 section of a brittle-only rubber base model, as used for homogeneous thin-skinned deformation.
 1546 Note the conjugate fault sets. Adapted from Vendeville et al. (1987) with permission from the
 1547 Geological Society, London. (b) Top view and cross-section of a brittle-only rubber base model
 1548 similar to (a), although developing the conjugate fault sets due to extension-perpendicular
 1549 contraction of the rubber sheet (Poisson effect). Adapted from Bahroudi et al. (2003) with
 1550 permission from Elsevier. (c-d) Cross-sections of brittle-only conveyor base experiments with
 1551 symmetric (c) or symmetrical extension (d), both including syn-rift sedimentation. Here the VD
 1552 may represent a basement structure controlling deformation in the overlying strata. Redrawn
 1553 after Allemand & Brun (1991) with permission from. (e-g) Cross-sections of brittle-viscous
 1554 models with a plate base or conveyor belt set-up, with the VD representing a fracture in the
 1555 strong brittle mantle affecting the overlying crustal analogues. (e) Brittle-viscous plate base
 1556 model with asymmetric extension, illustrating the relation between the velocity discontinuity
 1557 (VD) and the two rift basins. Compare with model C11 (Figs. 9f, g, B2). Redrawn (with
 1558 permission from Elsevier) after Michon & Merle (2003), who investigated the European
 1559 Cenozoic Rift System and the influence of VDs in a strong upper lithospheric mantle. (f)
 1560 Symmetric extension model with conveyor set-up and brittle-viscous layering, designed to
 1561 simulate the influence of a strong mantle on a two-layer crust. Adapted from Tron & Brun

 1563 extension. Note that this experiment includes syn-rift sedimentation and aims to reproduce the
 1564 North Sea Viking Graben. Modified after Brun & Tron with permission from Elsevier (1993).
 1565 Black arrows indicate extensional motion. VD: velocity discontinuity.

 1571 Fig. 12. Strength profiles calculated for our experiments (a) and various natural cases (b-f).
 1572 Reference values for the natural example are $T_{\text{moho}} = 600 \text{ }^{\circ}\text{C}$ and $v = 0.5 \text{ mm/y}$ (b). Extension
 1573 velocity variations are shown in (c) and (d) and variations due to different Moho temperatures
 1574 are depicted in (e) and (f). The crust and mantle flow laws used here are anorthosite dislocation
 1575 creep (Rybacki et al. 2006) and olivine dislocation creep (Hirth & Kohlstedt 2003). Note that the
 1576 filled-in profile represents a wet lithosphere, whereas the dotted profiles delineate a dry
 1577 lithosphere scenario. The horizontal lines indicate various brittle-to viscous ratios (see
 1578 discussion in text).

Fig. A1. Schematic overview of relations between experimental set-ups, illustrated with shifts of reference frame (v = velocity, VD = velocity discontinuity). Compare with Fig. 2. (a-b) Foam/rubber base set-ups, in which the base induces an extension gradient. (c-g) Plate base set-ups. (h-l) conveyor base models. Shifts of reference frame are used to highlight the direct differences between models. Note that most set-ups fundamentally differ as indicated by the (\neq) sign, except for the asymmetric plate base and conveyor base set-ups (f-g, k-l), which are fundamentally the same. The latter are indicated by the (=) sign. Darker colors indicate mobile parts of the set-ups, whereas brighter colors indicate static parts.

Fig. B1. Reproducibility tests. Final top views of experiments F2-F4 (brittle-only, foam base, with seed), F6 and F7 (brittle-viscous foam base, with seed), P6 and P7 (brittle-viscous plate base models, no seed) and C4-C6 (brittle-viscous conveyor base, no seed). Note that C5* and C6** were attempts to decrease boundary effects by replacing part of the basal viscous layer with sand (transparent overlay) or adding a lubricant (hand soap) along the short ends of the set-up, respectively. The former however increased boundary effects, whereas the latter did not significantly change surface structures and was therefore halted after 2 hours. Extension velocities are 8 mm/h in all cases.
