**Abstract.** The effects of ~~important~~ changes in slope gradient on turbidity currents velocity have been investigated in different deep-sea systems both in modern and ancient environments. However, the impact of subtle gradient changes ( $<0.5^\circ$ ) on sedimentary processes along deep-sea fans still needs to be clarified. The Ogooue Fan, located in the northeastern part of the Gulf of Guinea, extends over more than 550 km westwards of the Gabonese shelf and passes through the Cameroun Volcanic Line. Here, we present the first study of acoustic data (multibeam echosounder and 3.5 kHz, very-high resolution seismic data) and piston cores covering the deep-sea part of this West African system. This study documents the architecture and sedimentary facies distribution along the fan. Detailed mapping and near-seafloor seismic dataset reveal the influence of subtle slope gradient changes ( $< 0.2^\circ$ ) along the fan morphology. The overall system corresponds to a well-developed deep-sea fan, fed by the Ogooue River 'sedimentary load, with tributary canyons, distributary channel-levee complexes and lobes elements. However, variations in the slope gradient due to inherited salt-related structures and the presence of several seamounts, including volcanic islands, result in a more complex fan architecture and sedimentary facies distribution. In particular, turbidity currents derived from the Gabonese shelf deposit across several interconnected intraslope basins located on the low gradient segments of the margin ( $<0.3^\circ$ ). The repeated spill-overs of the most energetic turbidity currents have notably led to the

incision of a large mid-system valley on a higher gradient segment of the slope ( $0.6^\circ$ ) connecting an intermediate sedimentary basin to the more distal lobe area. Distribution and thickness of turbidite sand ~~beds~~ is highly variable along the system, however, turbidite sands preferentially deposit on the floor of the channel and the most proximal depositional areas. The most distal depocenters receive only the upper parts of the flows, mainly composed of fine-grained sediments. The Ogooue deep-sea fan is predominantly active during periods of low sea-level because the canyon heads are separated from terrestrial sediment sources by the broad continental shelf. However, the northern part of this system appears active during sea-level highstands. ~~This feature is due to one~~ deeply incised canyon, the Cape Lopez Canyon located on a narrower part of the continental shelf, which receives sediments transported by the longshore drift.

Keywords: Ogooue Fan, Gulf of Guinea, complex slope profile, turbidity currents, stepped slope

## 1 Introduction

Deep-sea fans are depositional sinks that host stratigraphic archives of Earth history and environmental changes (Clift and Gaedicke, 2002; Fildani and Normark, 2004; Covault et al., 2010, 2011), and are also important reservoirs of natural resources (Pettingill and Weimer, 2002). Therefore, considerable attention has been given to the problems of predicting architectures and patterns of sedimentary facies distribution in submarine fans. First models concerning the morphologies of these systems described submarine fans as cone-like depositional areas across unconfined basin floors of low relief and gentle slope gradient (Shepard and Emery, 1941; Shepard, 1951; Dill et al., 1954; Menard, 1955; Heezen et al., 1959). However, the development of numerous studies realized on both fossil and modern fans showed that topographic complexity across the receiving basin can strongly influence the organization of architectural elements of submarine fans (Normark et al., 1983; Piper and Normark, 2009). A wide range of geometries and architectural features due to topographic obstacles has been described

56 in the literature. Among these features are ponded and intra-slope mini-basin due to  
57 three-dimensional confinement (Prather, 2003; Prather et al., 2012, 2017; Sylvester et  
58 al., 2015) or tortuous corridors created by topographic barriers (Smith, 2004; Hay,  
59 2012). Spatial changes in slope gradients are also important as they cause gravity flows  
60 to accelerate or decelerate along the slope (Normark and Piper, 1991; Mulder and  
61 Alexander, 2001) allowing the construction of successive depocenters and sediment  
62 bypass areas (Smith, 2004; Deptuck, 2012; Hay, 2012). These stepped-slopes have been  
63 described along modern systems such as the Niger Delta (Jobe et al., 2017), the Gulf of  
64 Mexico (Prather et al., 1998, 2017) or offshore Angola (Hay, 2012), but also in ancient  
65 systems such as the Annot Sandstone Formation (Amy et al., 2007; Salles et al., 2014),  
66 the Karoo Basin (Spychala et al., 2015; Brooks et al., 2018) or the Lower Congo basin  
67 (Ferry et al., 2005).

68 On stepped-slopes where structural deformation is very slow, sediment erosion and  
69 deposition are the dominant processes that control the short-term evolution of slope. In  
70 these systems, the slope gradient variations play a key role and studies have shown that  
71 subtle gradient changes can have an important impact on flow velocity and consequently  
72 deep-sea fans organization (e.g. Kneller, 1995; Kane et al., 2010; Stevenson et al.,  
73 2013). However, despite the growing numbers of studies describing these systems, the  
74 impact of subtle changes in slope gradient on deep-sea fans organization still needs to  
75 be better ~~apprehended~~ understood.

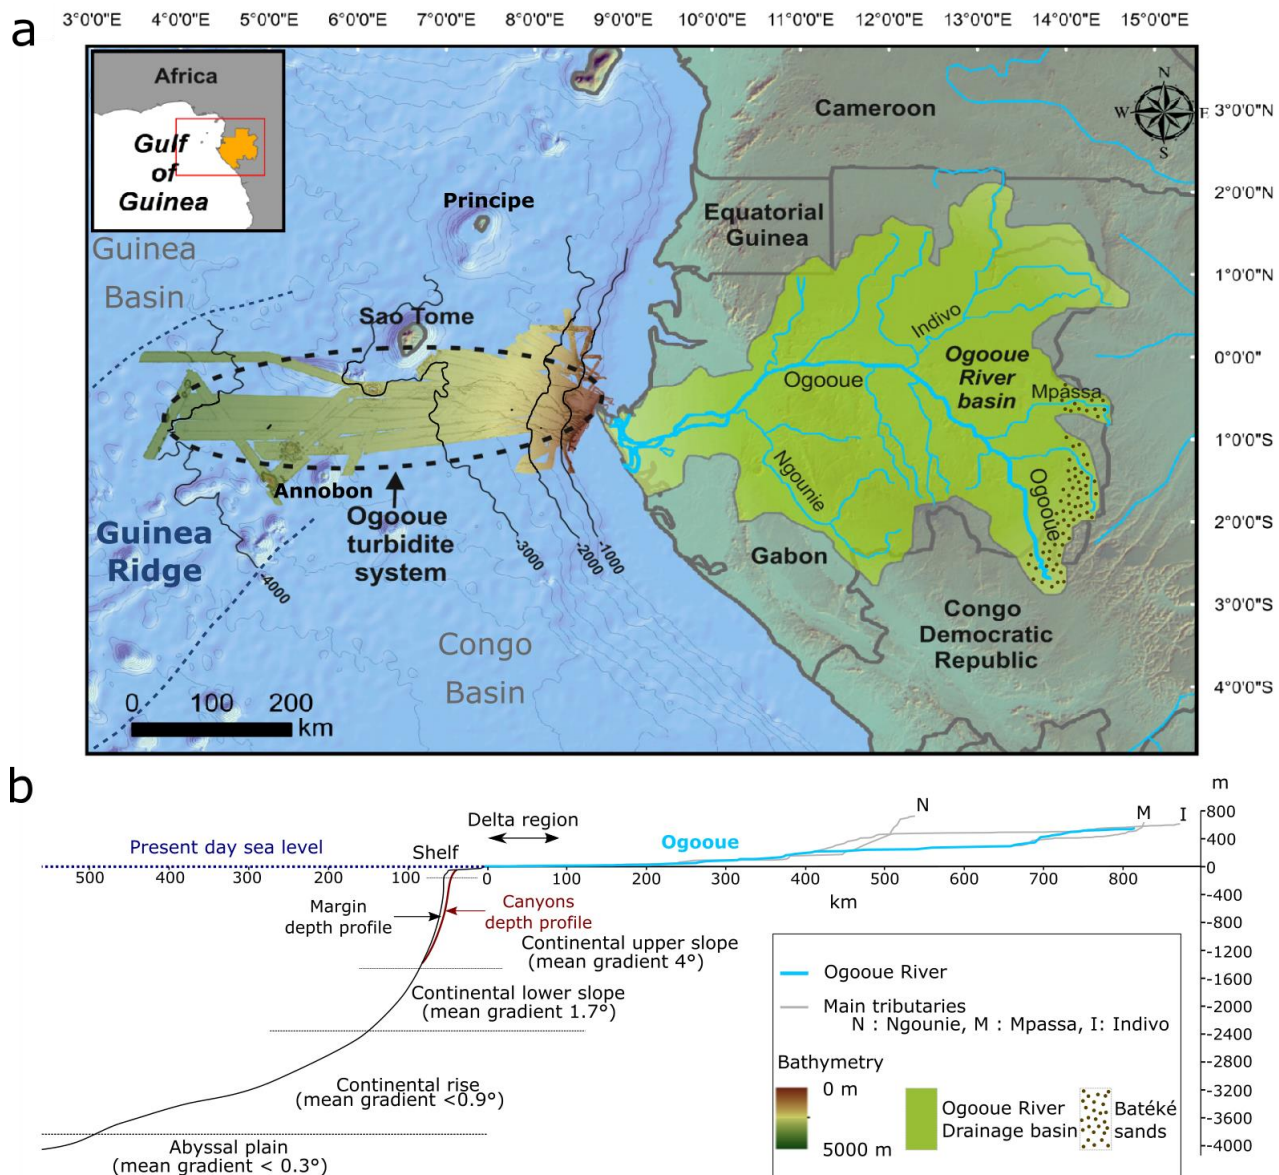

76 The modern Ogooue Fan provides a new large-scale example of the influence of subtle  
77 gradient changes on deep-sea sediment routing. This system, which results from the  
78 sediment discharge of the Ogooue River, is the third largest system of the Gulf of Guinea  
79 after the Congo and the Niger fans (Séranne and Anka, 2005). However, in contrast to  
80 these two systems that have been the focus of many studies (Droz et al., 1996, 2003;  
81 Babonneau et al., 2002; Deptuck et al., 2003, 2007), the Quaternary sediments of the  
82 Gabon passive margin have been relatively poorly studied, especially in its deepest parts  
83 (Bourgoin et al., 1963; Giresse, 1969; Giresse and Odin, 1973). The regional survey of  
84 the area by the SHOM (Service Hydrographique et Océanographique de la Marine) in

85 2005 and 2010, during the OpticCongo and MOCOSÉD cruises, provided the first  
86 extensive dataset on the Ogooué deep-sea fan, from the continental shelf to the abyssal  
87 plain.

88 The objective of this paper is to document the overall fan morphology, and to link its  
89 evolution with the local changes in slope gradients or topographic obstacles present in  
90 the depositional area. This study contributes to the understanding of the impact of subtle  
91 slope gradient changes on deep-water systems and can be used to develop predictive  
92 models for systems located on stepped-slope with low to very low gradient changes  
93 ( $< 1^\circ$ ).

96  
97 **Figure 1: a) The Ogooué sedimentary system from source (river and drainage basin) to sink (Quaternary turbidite**  
98 **fan). b) Channel depth profile of the Ogooué River (blue) and its main tributaries (grey) and mean depth profile**  
99 **along the Gabonese margin.**

100 The continental margin of the Gulf of Guinea formed during the rifting that occurred  
101 within Gondwana craton in Neocomian to lower Aptian times. Syn-rift deposits are  
102 buried by mid-late Cretaceous transgressive sediments consisting initially of evaporites,  
103 which have created salt-related deformations of the margin sediments, followed by  
104 platform carbonates (Cameron and White, 1999; Mougamba, 1999; Wonham et al.,  
105 2000; Séranne and Anka, 2005). Since the Late Cretaceous, the West African margin

has recorded clastic sedimentation fed by the denudation of the African continent (Séranne and Anka, 2005). Different periods of major uplift and canyons incision occurred from Eocene to Lower Miocene times (Rasmussen, 1996; Wonham et al., 2000; Séranne and Anka, 2005). The sediments depocenters were located basinward of the main rivers, such as the Niger, Congo, Ogooué or Orange River forming vast and thick deep-sea fans (Mougamba, 1999; Séranne and Anka, 2005; Anka et al., 2009). The Ogooué Fan is located in the northeastern part of the Gulf of Guinea on the Gabonese continental slope. The fan develops on the Guinea Ridge, which separates the two deep Congo and Guinea basins. This region is notably characterized by the presence of several volcanic islands belonging to the Cameroon Volcanic Line (CVL) associated with rocky seamounts (Figure 1a). Geophysical studies of the volcanic line suggest that the volcanic alignment is related to a deep-mantle hot line (Déruelle et al., 2007). All the volcanoes of the CVL have been active for at least 65 Ma (Lee et al., 1994; Déruelle et al., 2007). Ar/Ar dates realized on Sao Tomé and Annobon volcanic rocks evidenced the activity of these volcanic island over much of the Pleistocene (Lee et al., 1994; Barfod and Fitton, 2014). The MOCOSÉD 2010 cruise revealed that numerous mud volcanoes were associated with the toe of the slopes of the volcanic islands (Garlan et al., 2010). They form small topographic highs on the seafloor (< 20 m high and 100 m in diameter) and show active gas venting (Garlan et al., 2010). The Quaternary Ogooué Fan extends westwards over 550 km through the CVL. Overall, the modern slope profile is concave upward, similar to that of many other passive margins. The mean slope gradient shallows from 7° on the very upper slope to < 0.3° in the abyssal plain (Figure 1b). The Gabonese continental shelf, which is relatively narrow, can be divided into two sub-parts: the south Gabon margin presenting a SE-NW orientation and the north Gabon margin presenting a SW-NE orientation. The southern part of the margin is characterized by the presence of numerous parallel straight gullies oriented perpendicular to the slope (Séranne and Nzé Abeigne, 1999; Lonergan et al., 2013). On the north Gabon margin, the area located between 1°00 S and the Mandji Island is incised by several canyons that belong to the modern Ogooué Fan (Figure 2a).

135 North of the Mandji Island, the seafloor reveals numerous isolated pockmarks as well  
136 as sinuous trains of pockmarks. These features are interpreted as the results of fluid  
137 migration from shallow buried channels (Gay et al., 2003; Pilcher and Argent, 2007).  
138 The Ogooue Fan is supplied by the sedimentary load of the Ogooue River, which is third  
139 largest African freshwater source in the Atlantic Ocean (Mahé et al., 1990). Despite the  
140 relatively small size of the Ogooue River basin (215,000 km<sup>2</sup>), the river mean annual  
141 discharge reaches 4,700 m<sup>3</sup>/s due to the wet equatorial climate (Lerique et al., 1983;  
142 Mahé et al., 1990). The Ogooue River flows on a low slope gradient in a drainage basin  
143 covered essentially with thick lateritic soils that developed over the Congo craton and  
144 Proterozoic formations related to Precambrian orogenic belts (Séranne et al., 2008). The  
145 estuary area includes several lakes (Figure 1b) (Lerique et al., 1983) that contribute to  
146 the dominant muddy composition of the particle load of the Ogooue River that is  
147 estimated between 1 and 10 M t/yr. (Syvitski et al., 2005). The limited portion of sand  
148 particles in the river originates mainly from the erosion of the poorly lithified Batéké  
149 Sands located on a 550-750 m high perched plateau that forms the easternmost boundary  
150 of the Ogooue watershed (Séranne et al., 2008) (Figure 1a). On the shelf, recent  
151 fluvial deposits consist of fine-grained sediments deposited at the mouth of the  
152 Ogooue River (Giresse and Odin, 1973). The wave regime along the Gabonese coast  
153 causes sediments to be transported northward. Sedimentary transport linked to  
154 longshore drift ranges between 300,000 m<sup>3</sup>/yr. and 400,000 m<sup>3</sup>/yr. (Bourgoin et al.,  
155 1963) and is responsible for the formation of the Mandji Island, a sandy spit of 50 km  
156 long located on the northern end of the Ogooue Delta (Figure 3). Except for the Cape  
157 Lopez Canyon, located just west of the Mandji Island with the canyon head in only 5 m  
158 water depth (Biscara et al., 2013), the Ogooue Fan is disconnected from the Ogooue  
159 Delta during the present-day high sea-level (Figure 3).

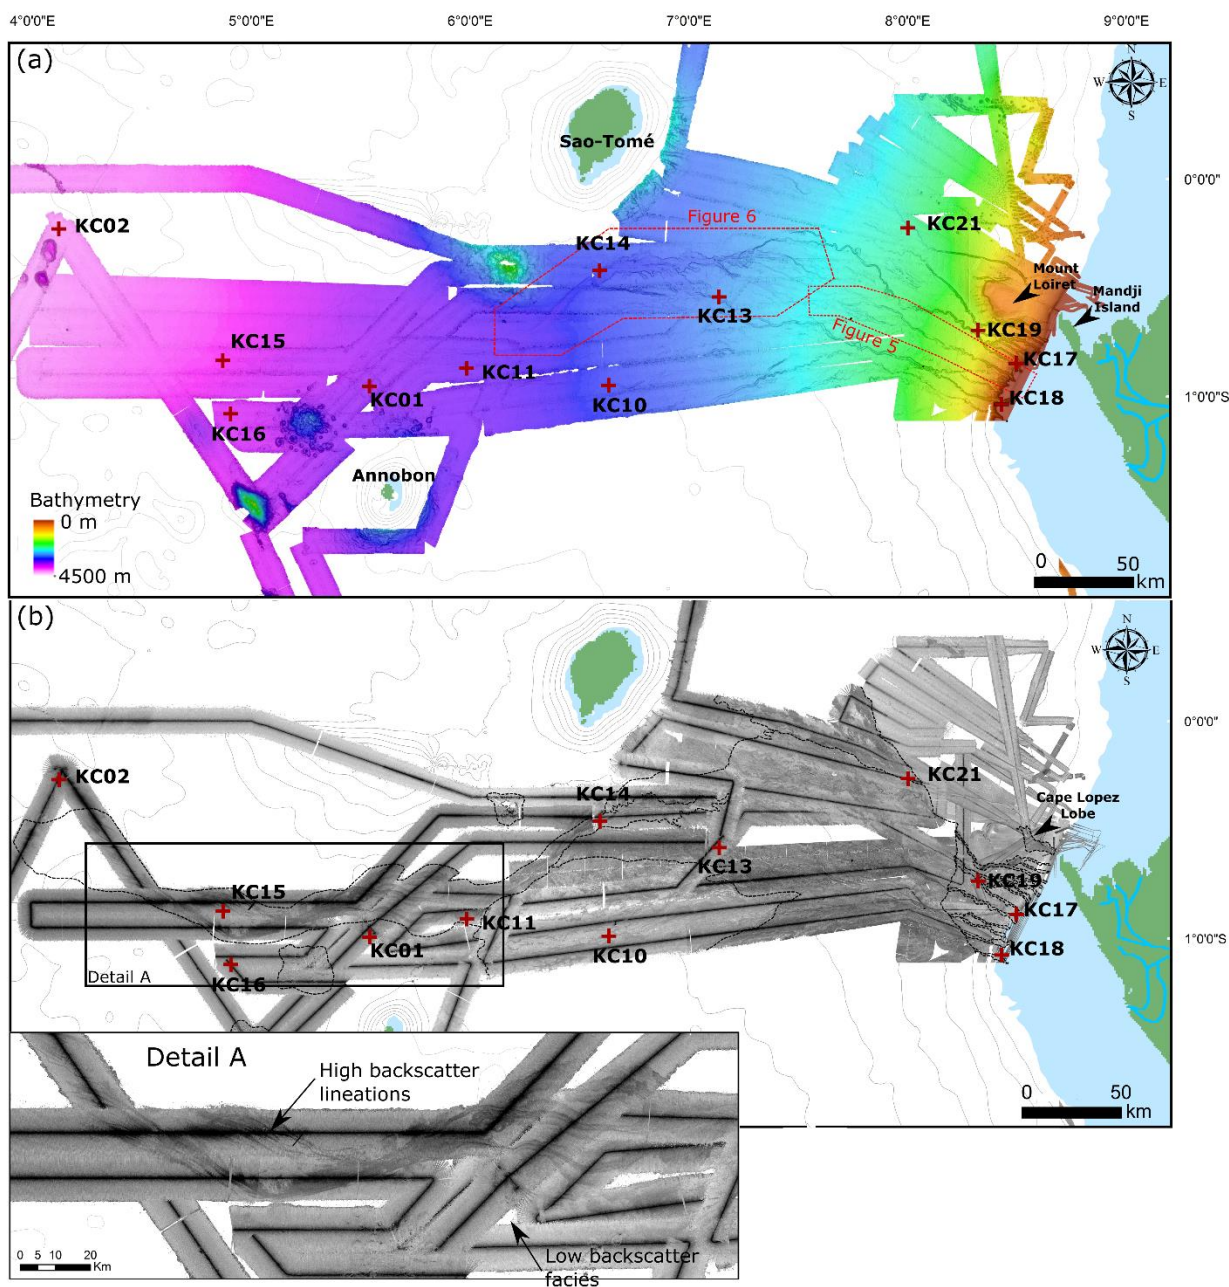

Figure 2: (a) Detailed bathymetric map of the Ogooue Fan, based on the multibeam echosounder data of the Optic Congo2005 and MOCOSSED2010 surveys. (b) Acoustic imagery of the Ogooue Fan (high backscatter: dark tones; low backscatter: light tones). Detail A: close-up of the deepest part of the Ogooue Fan. Red crosses: location of the studied cores.

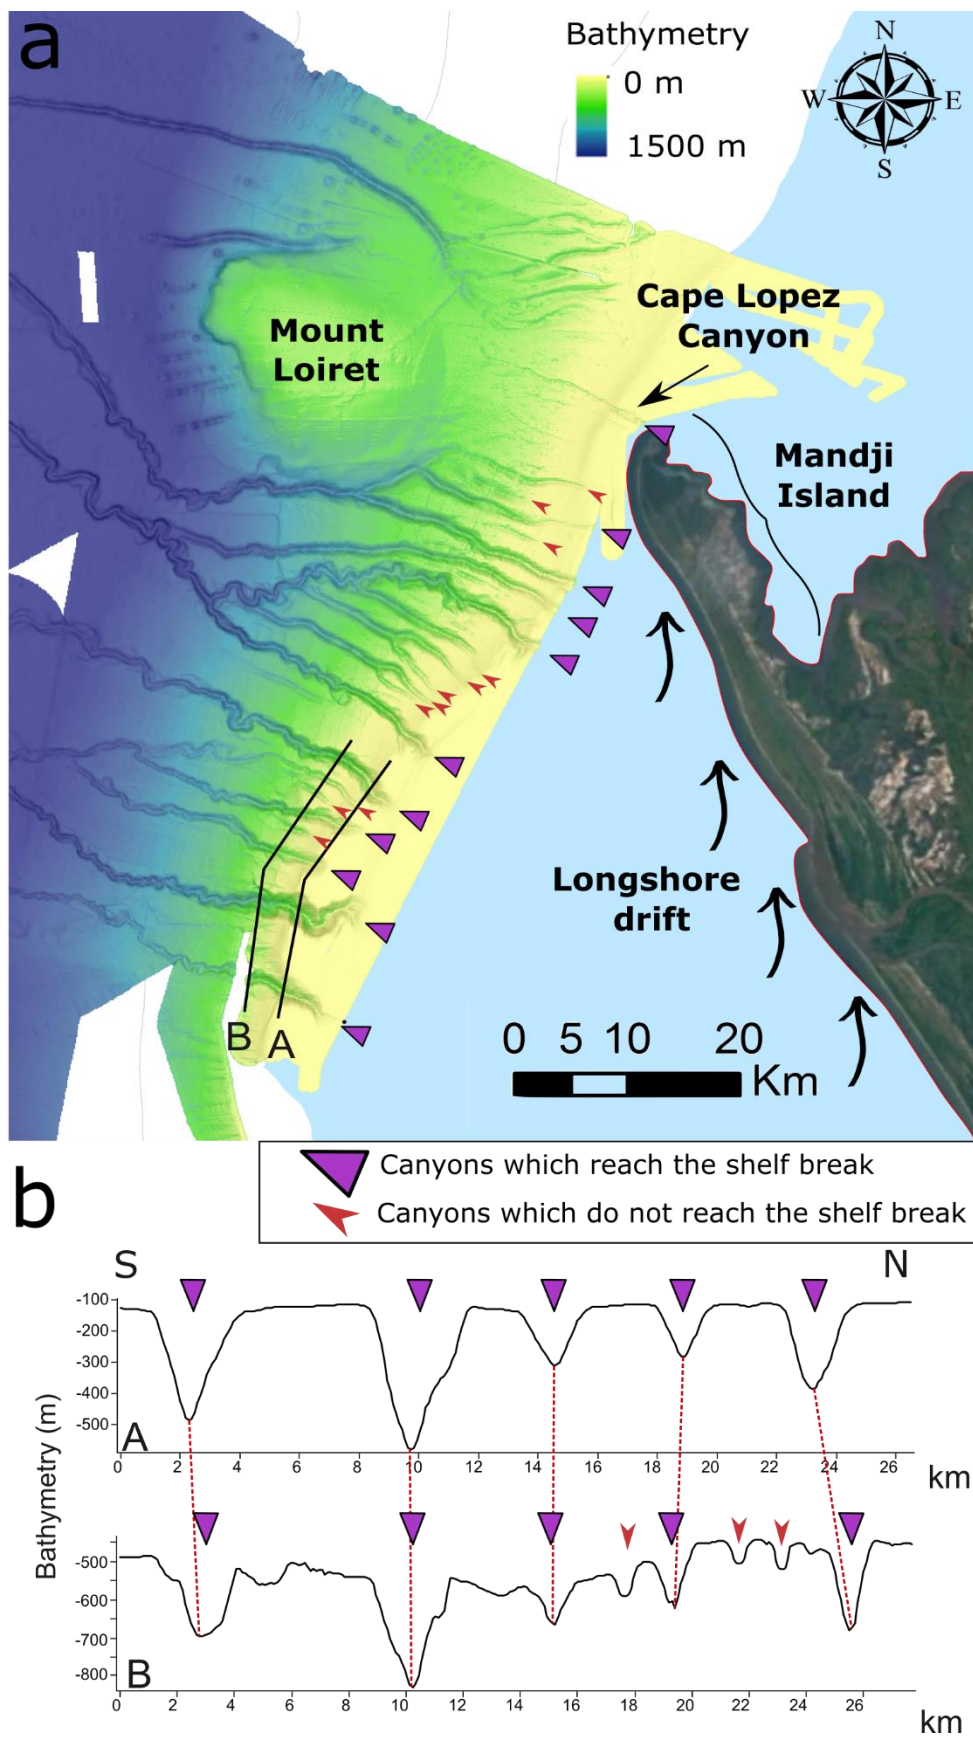

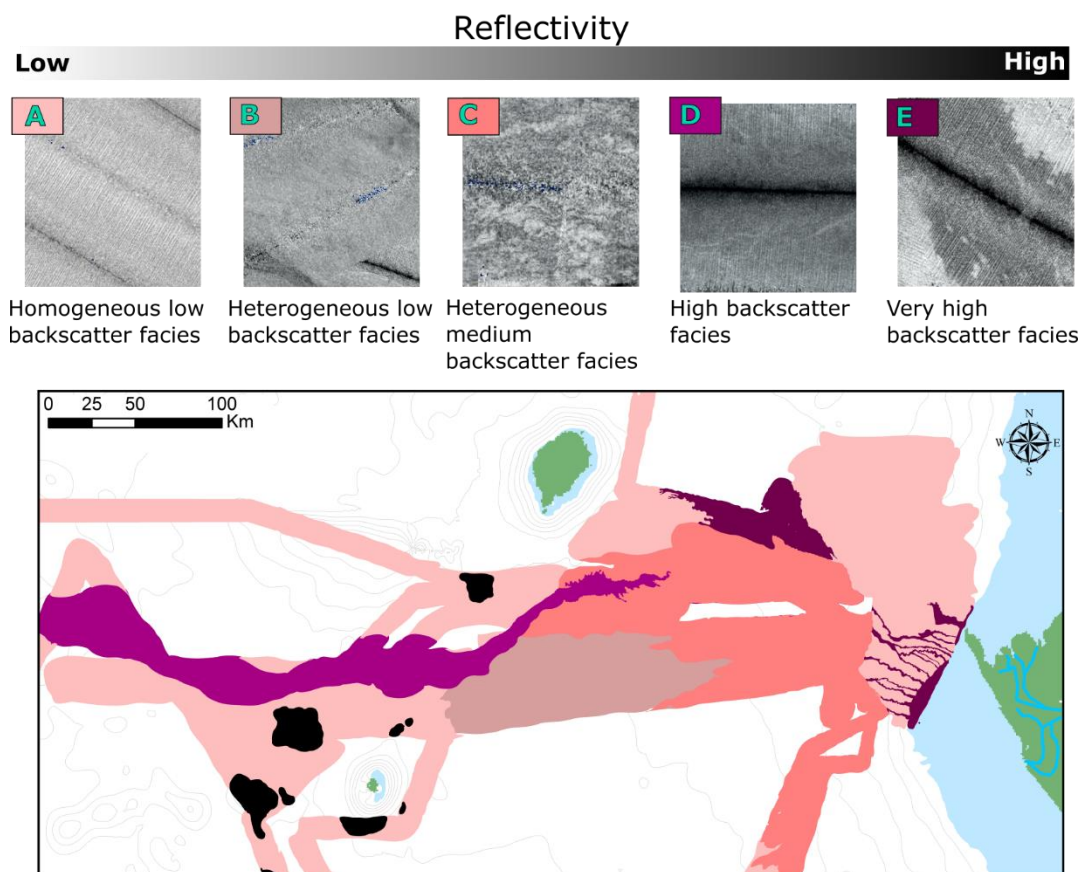

Figure 3: a) Close-up view of the Gabon shelf and canyons ramp. Bathymetry is from the Optic Congo2005 and MOCOSD2010 surveys, satellite view is from Google Earth. b) Two bathymetric profiles across the canyons showing the two types of canyons which are present along the Gabonese slope.

### 169 3 Material and method

170 The bathymetry and acoustic imagery of the studied area result from the multibeam  
171 echosounder (Seabat 7150) surveys conducted onboard the R/V “*Pourquoi Pas?*” and  
172 “*Beautemps-Beaupré*” during the MOCOSSED 2010 and OpticCongo 2005 cruises  
173 (Mouscardes, 2005; Guillou, 2010) (Figure 2). The multibeam backscatter data (Figure  
174 2b) have been used to characterize the distribution of sedimentary facies along the  
175 margin. Changes in the backscatter values correspond to variations in the nature, the  
176 texture and the state of sediments and/or the seafloor morphology (Unterseh, 1999;  
177 Hanquiez et al., 2007). On the multibeam echosounder images, lighter areas indicate  
178 low acoustic backscatter and darker areas indicate high backscatter. Five main  
179 backscatter types are identified on the basis of backscatter values and homogeneity  
180 (Figure 4). Facies A is a homogeneous low backscatter facies, Facies B is a low  
181 backscatter heterogeneous facies, and Facies C is a medium backscatter facies  
182 characterized by the presence of numerous higher backscatter patches. Facies D and E  
183 are high and very high backscatter facies, respectively. High backscatter lineations are  
184 present within Facies D.

**Figure 4:- Reflectivity facies map of the Ogooue Fan showing the five main backscatter facies.**

A total of four thousand five hundred km of 3.5 kHz seismic lines were collected in the area of the Ogooue Fan during the MOCOSSED 2010 cruise and 470 km during the Optic Congo 2005 cruise (iXblue ECHOES 3500 T7). These data were used to analyze the near-surface deposits. The dataset covers the shelf edge, the slope and the abyssal plain. In this study, the 3.5 kHz echofacies has been classified according to Damuth's methodology (Damuth, 1975, 1980a; Damuth and Hayes, 1977) based on acoustic penetration and continuity of bottom and sub-bottom reflection horizons, micro-topography of the seafloor and presence of internal structures.

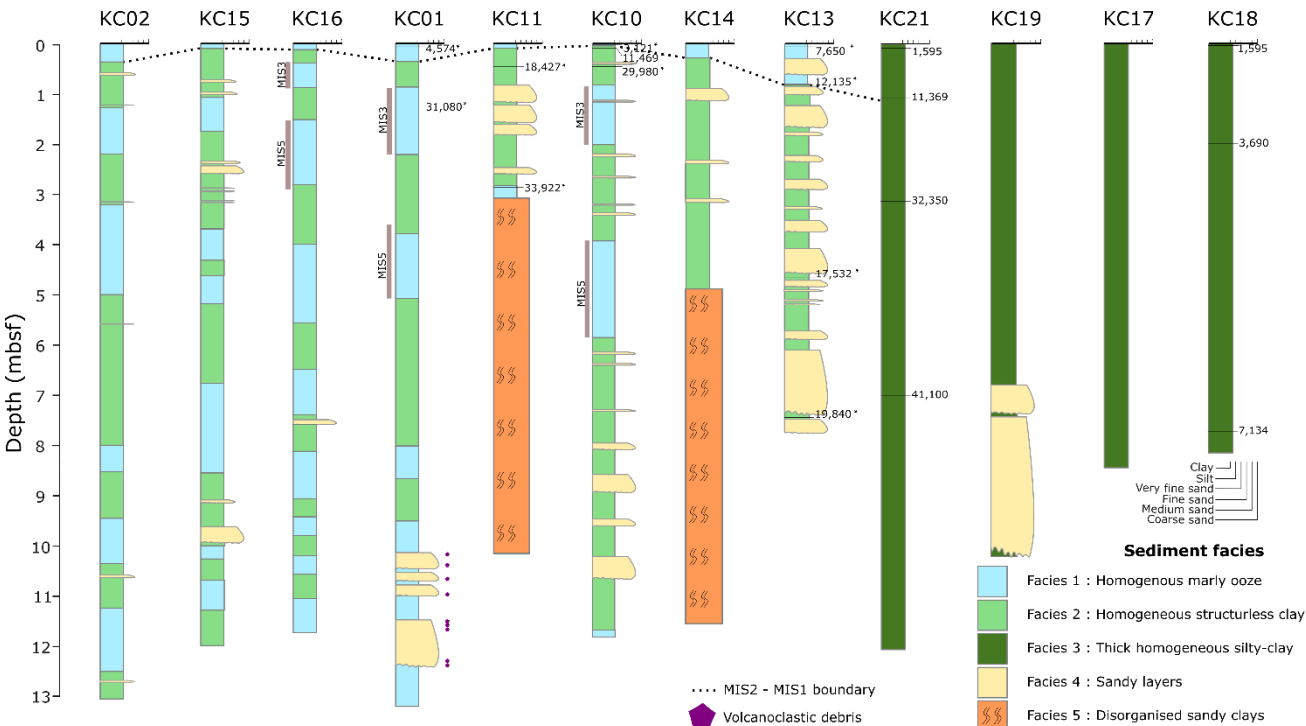

The twelve Küllenberg cores presented here were collected during the cruise MOCOSSED 2010. Five of these cores have already been presented in Mignard et al. (2017) (Table 1). Visual descriptions of the cores distinguished the dominant grain size (clay, silty clay, silt, and fine sand) and vertical successions of sedimentary facies. Thin slabs were collected for each split core section and X-ray radiographed using a SCOPIX

digital X-ray imaging system (Migeon et al., 1998). Subsamples were regularly taken in order to measure carbonate content using a gasometric calcimeter and grain size using a Malvern Mastersizer S. The stratigraphic framework is based on the previous work of Mignard et al., (2017), new AMS  $^{14}\text{C}$  dating (Table 1) done on core KC21 and KC18 and facies correlation to determine the boundary between Marine Isotopic Stage 1 (MIS1) and Marine Isotopic Stage 2 (MIS2). Indeed, the transition from MIS2 to MIS1 in the south-west Atlantic is marked by an abrupt increase in carbonate content (Volat et al., 1980; Jansen et al., 1984; Olausson, 1984; Zachariasse et al., 1984). This feature is recorded in all the cores of this study collected in the medium and distal part of the system (Figure 5). The new AMS  $^{14}\text{C}$  datings were realized on a mixture of different planktonic foraminifer species living in the uppermost water column. Radiocarbon dates have been calibrated using MARINE13 curve (Reimer, 2013) and using a standard reservoir age of 400 years (Table 2; Mignard et al, 2017).

**Table 1: Characteristics of the twelve studied cores (MOCOSSED 2010 cruise).**

Core	Depth (m)	Latitude	Longitude	Length (m)
KC01	3504	00°57,010' S	005°31,806' E	12,96

222 **Table 2: AMS  $^{14}\text{C}$  ages with calendar age correspondences realized for this study (Reimer, 2013).**

Core number	Sample depth	Conventional age (reservoir correction) BP	Calendar age cal. BP
KC18	7	1,523 $\pm$ 30	1,780
KC18	197	3,671 $\pm$ 30	3,690
KC18	787	7056 $\pm$ 40	7,134
KC21	12	1532 $\pm$ 30	1,595
KC21	115	10,654 $\pm$ 80	11,369
KC21	327	30,569 $\pm$ 90	32,350
KC21	700	39,732 $\pm$ 120	41,100

223   **4   Results**

224   **4.1   Sedimentary facies**

225   The classification in five sedimentary facies used here is based on photography and X-  
226   ray imagery, grain size analyses and CaCO<sub>3</sub> content (Figure 5). Interpretation of these  
227   facies is based on the comparison with previous sedimentary facies classifications such  
228   as Stow and Piper, (1984); Pickering et al., (1986) and Normark and Damuth, (1997).

229   *Facies 1: Homogenous, structureless marly ooze.* This facies is composed of  
230   structureless, light beige marly ooze with relatively high concentration of planktonic  
231   foraminifers. The mean grain size is around 15 µm and the CaCO<sub>3</sub> content ranges  
232   between 40 and 60%. This facies is interpreted as a pelagic drape deposit; it forms the  
233   modern seafloor of the deepest part of the Ogooue Fan and is observed in most of the  
234   core tops corresponding to the MIS 1 interval.

235   *Facies 2: Homogenous, structureless clay:* Facies 2 consists of dark brown clay. The  
236   mean grain size is less than 15 µm and the CaCO<sub>3</sub> content is less than 30%. This facies  
237   has been interpreted as hemipelagic drape deposits.

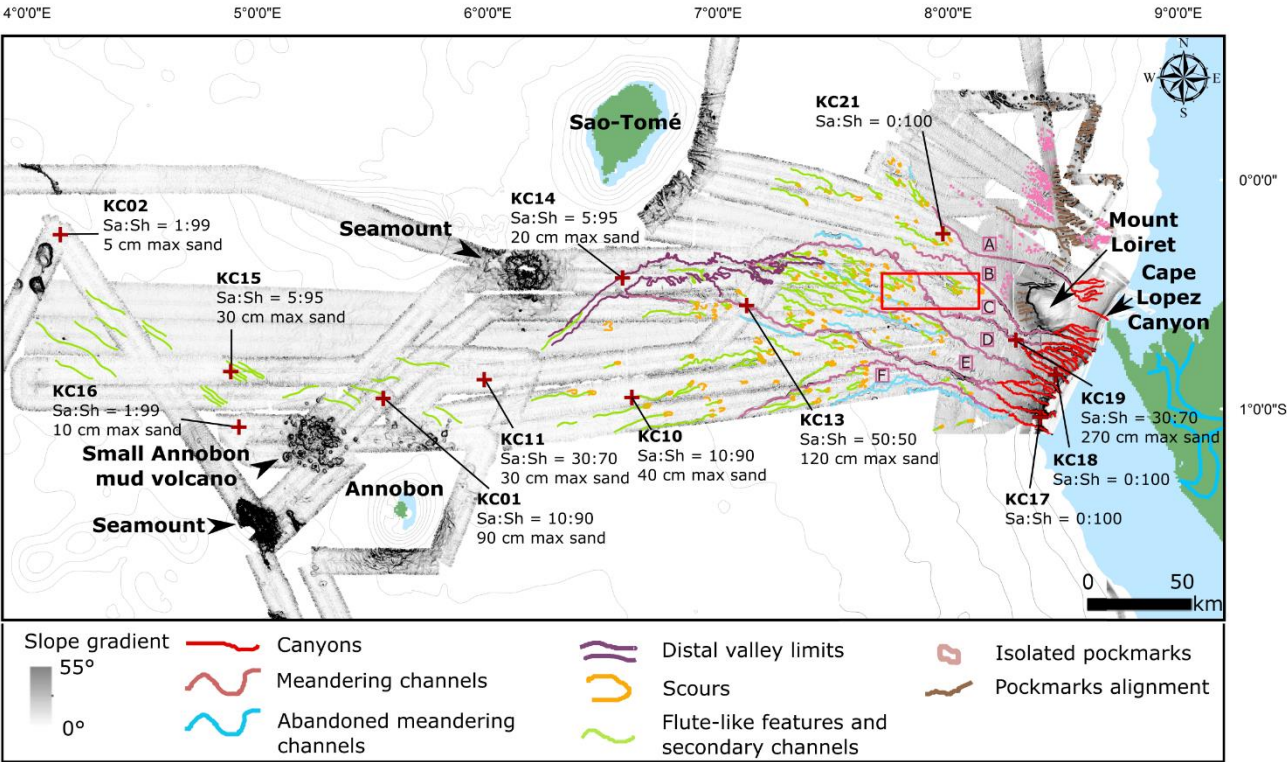

238   *Facies 3: Thick, homogeneous silty-clay:* Facies 3 consists of very thick homogeneous  
239   dark silt-clay layers containing less than 10% of CaCO<sub>3</sub>. This facies contains numerous  
240   quartz and mica grains and plant debris indicating a continental origin of the sediments.  
241   It results from the deposition of the fine-grained suspended load coming from the  
242   Ogooue River and flowing down the slope or belonging to the flow tops of the turbidity  
243   currents.

244   *Facies 4: Silty to sandy layers:* Facies 4 consists of fine- to medium-grained sand beds  
245   with a thickness up to several meters. They are either normally-graded or massive and  
246   display a variety of bedding structures: ripple cross laminations, parallel laminations.  
247   The composition varies from terrigenous (quartz and mica) to biogenic (foraminifers),  
248   some sand beds are highly enriched in organic debris (Mignard et al., 2017). They are  
249   interpreted as being deposited by turbidity currents initiated on the Gabonese  
250   continental shelf. Four beds sampled at the base of core KC01 present a high

concentration of volcanoclastic debris, such particles are completely absent in all the other sandy beds (Figure 5) sandy beds. This specific composition and the particular location of the core both suggest that these sequences originate from the nearby Annobon volcanic island.

*Facies 5: Disorganized sandy clays:* Facies 5 consists of thick intervals of deformed or chaotic clay with deformed or folded silty to sandy layers containing mainly quartz grains and rare plant debris. This facies is interpreted as a slump deposit or debrite.

## 4.2 Fan morphology

**Figure 6: Interpreted gradient-shaded map of the Ogooue Fan showing the main features of the fan. A, B, C, D, E and F are the six main channels discussed in the text. The sand/shale ratio of the cores are shown (Sa:Sh) as well as the maximum sand-bed thickness in each core (max sand). A close-up view of the red rectangle is presented in Figure 8.**

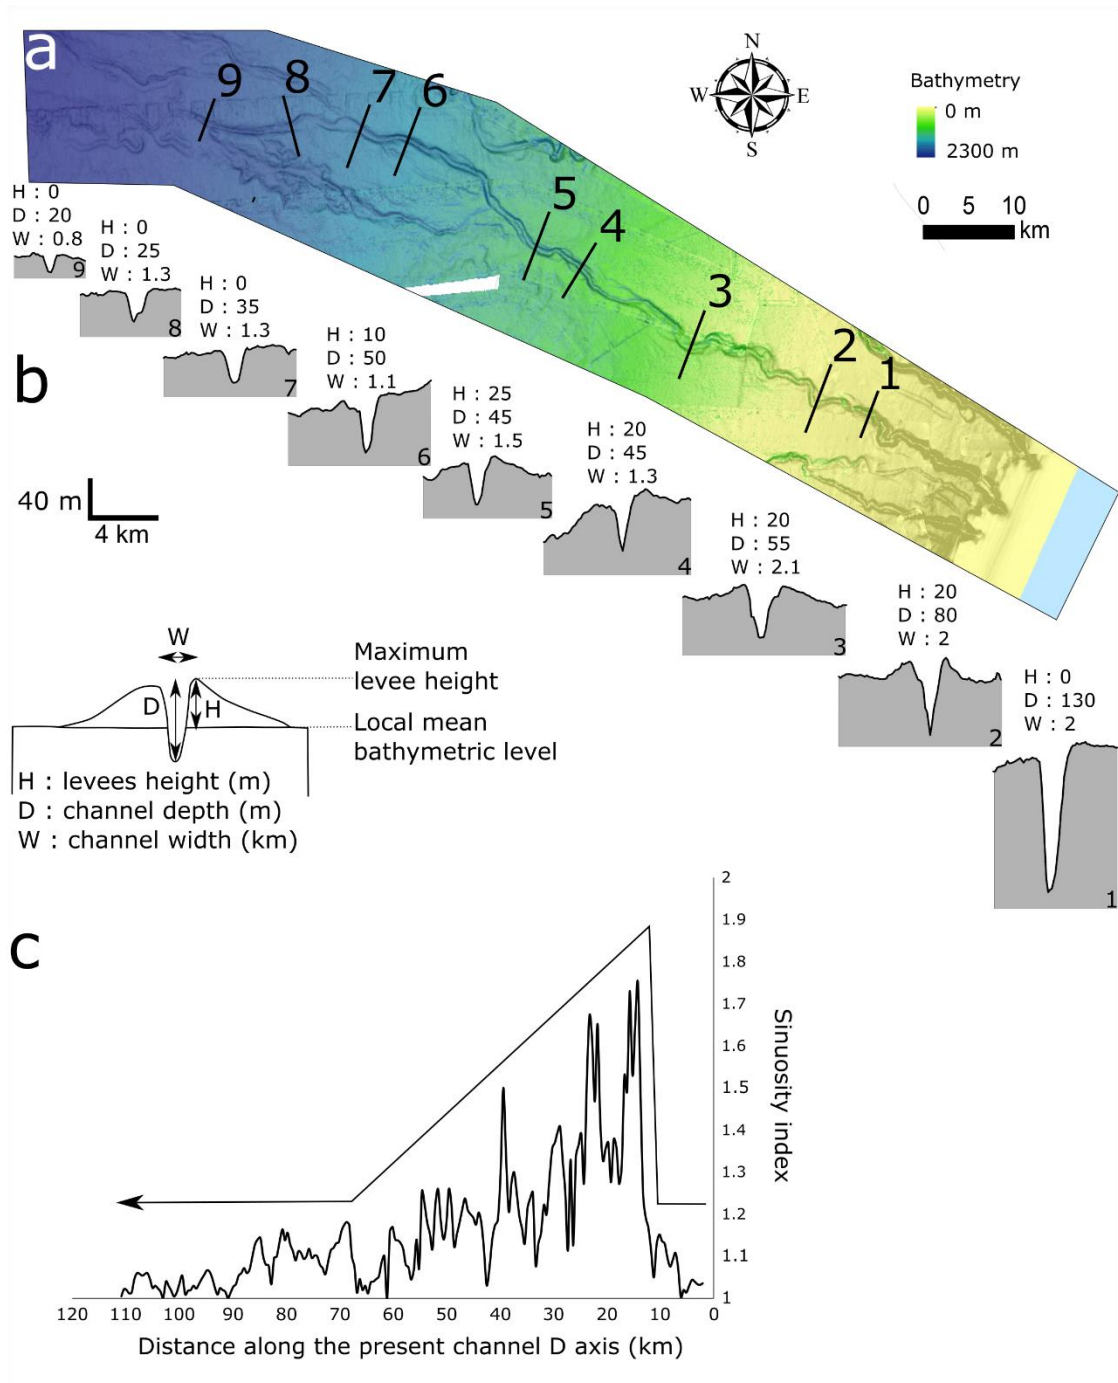

Analysis of the seafloor data (bathymetry and acoustic imagery) reveals the different domains of the Ogooue sedimentary system and the different architectural features of the Ogooue Fan (Figure 6).

The Gabon continental shelf is relatively narrow, decreasing in width from 60 to 5 km toward the Mandji Island (Figure 3). The slope is characterized by two main topographic features: (1) the Mount Loiret, a guyot located just west of the Manji Island, which

270 forms a bathymetric obstacle on the upper slope and (2) a ramp of several tributary  
271 canyons located south of the Mount Loiret (Figure 3). This ramp is composed of several  
272 wide and deep canyons (several hundreds of meters deep and 2-3 km wide near the  
273 canyons head), with a “V-shape” morphology and which heads reach the shelf break.  
274 Several thinner and shallower incisions are located between these deep canyons. They  
275 are less than 100 m deep and 1 km wide and their heads are located between 200 and  
276 400 m water depth (Figure 3). The continental shelf and the slope present low  
277 backscatter values except for the canyons, that correspond to very high backscatter value  
278 (Figure 4).

279 The transition between the continental slope and the continental rise, between 1,200 and  
280 1,500 m water depth, is marked by a decrease in the slope gradient from a mean value  
281 of  $2.3^\circ$  to  $0.9^\circ$ . At this water depth, several canyons merge to form five sinuous channels  
282 (B to F in Figure 6). These channels appear with higher backscatter value than the  
283 surrounding seafloor (Figure 4). These sinuous subparallel channel-levees complexes  
284 extend down to 2,200 m water depth with a general course oriented toward the north-  
285 west (Figure 6 and 7). At 2,200 m water depth, the southernmost channel (channel F in  
286 Figure 6) deviates its path toward the south-west.

287 The sinuosity of these channels decreases Westward. Channel D sinuosity has been  
288 calculated over 2 km long segments (Figure 7C). It is less than 1.1 along the first 13 km  
289 corresponding to the canyon part. From 13 to 40 km ~~d~~ the mean sinuosity is 1.4 and then  
290 decreases to less than 1.2 between 40 to 90 km from the head. Finally, the most distal  
291 part of the channel, from 90 km from the head, is very straight with a sinuosity index  
292 lower than 1.1 (Figure 7C).

**Figure 7: a) Detailed bathymetric map of channel D (location in Figure 2) b) serial bathymetric profiles showing the evolution of the channel-levees along the slope and c) sinuosity down the channel D measured along 2 km channel segments.**

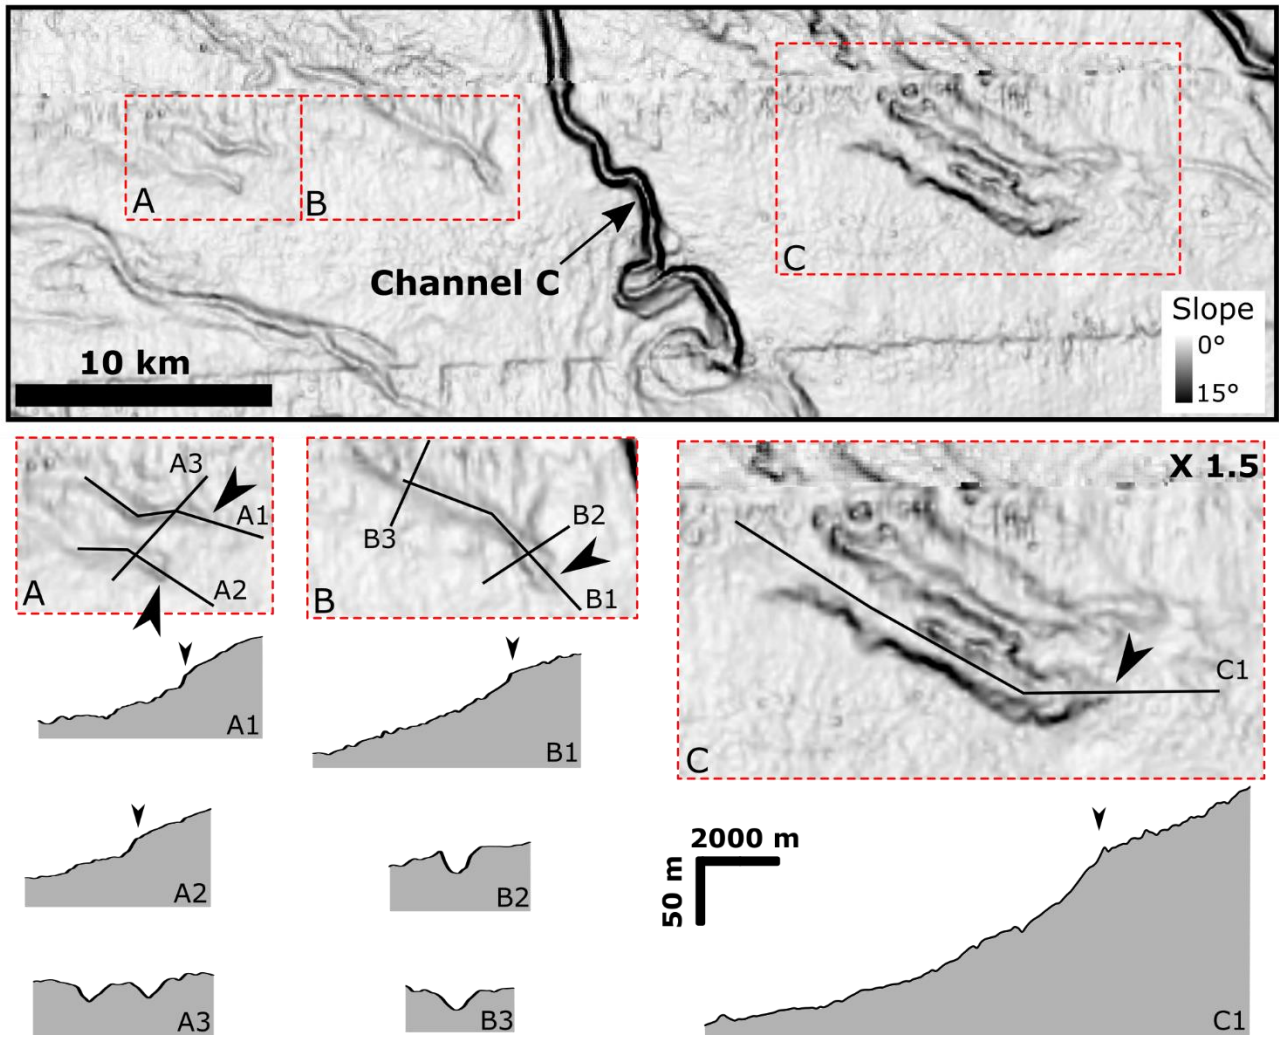

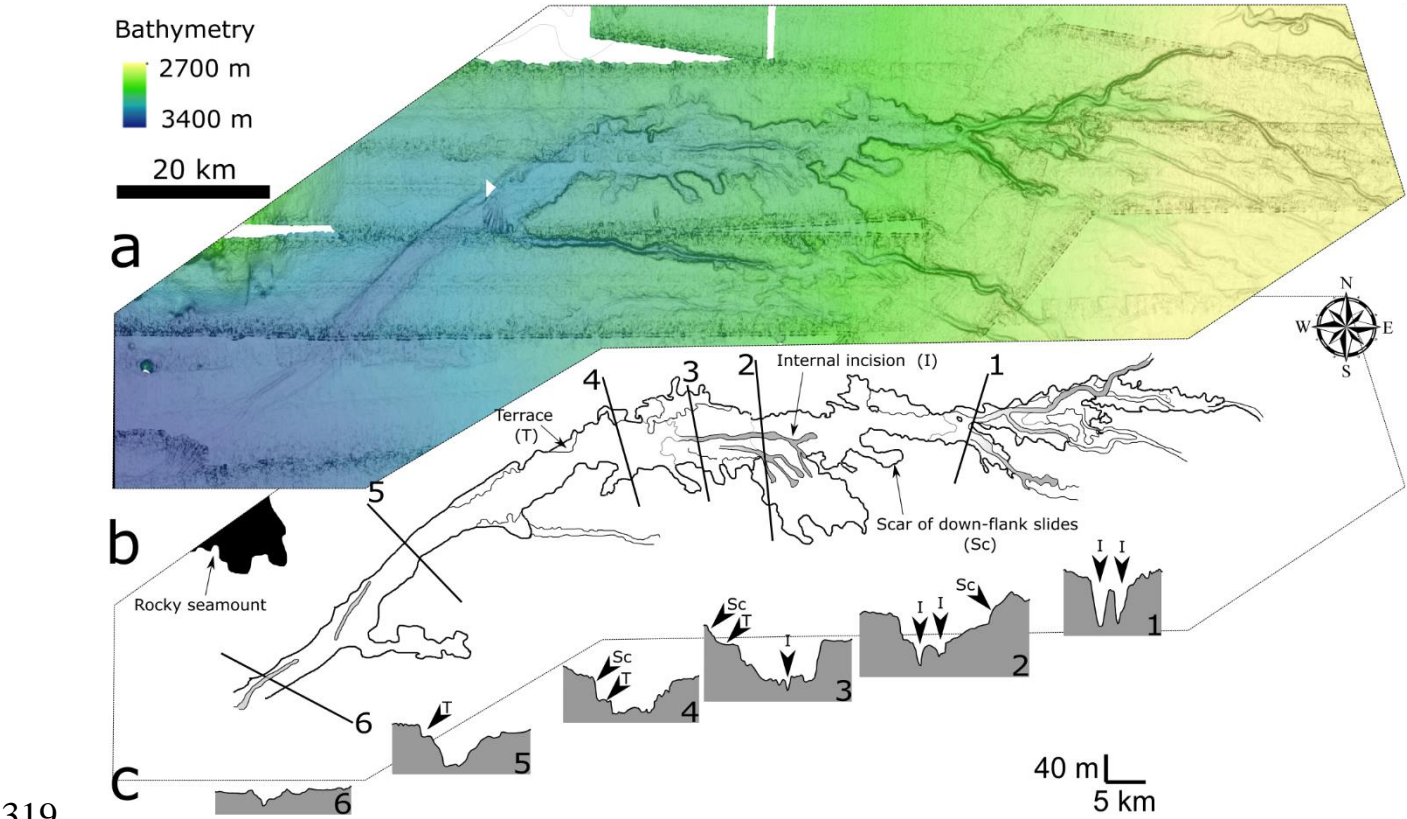

Figure 8: Close-up view of the gradient-shaded map showing erosional lineations (A and B) and amalgamated scours (C) in the central part of the system (location in Figure 6).

Downslope, in the central part of the system, the seafloor located between 2,200 m and 2,500 m water depth, presents numerous erosional features including scours, lineations and smaller, subsidiary channels, corresponding to channels with no headward connection with an obvious feeder system according to Masson et al. (1995) (Figure 8). These erosional features appear on a very gentle slope area ( $0.3^\circ$ ) characterized by a heterogeneous medium backscatter facies (Figure 4). At 2,500 m water depth, just south of the Sao-Tomé Island, the head of a large, 100 km long, mid-system valley appears (Figure 9). This valley can be subdivided in two parts of approximately equal length with two different orientations. The upper part of the valley is oriented E-W, whereas the lower part is oriented NE-SW. This direction change is due to the presence of a rocky seamount located north of the valley and which deflects its course. The upper part

311 of the valley is up to 15 km wide with numerous erosional scars and terraces on its  
 312 flanks. The valley bottom is characterized by very high backscatter value and small  
 313 internal erosion channels. Downstream, the valley becomes narrower with a “U” shape  
 314 (Figure 9, profile 5). Its flanks appear regular with no scar of down-flank mass deposits.  
 315 The depth of the valley decreases from 60 m in its central part to only 10 m near its  
 316 mouth. The area located south of the mid-system valley is characterized by a  
 317 heterogeneous low-backscatter facies. Some erosional features and subsidiary channels  
 318 are present but scarce.

319 **Figure 9: (a) Detailed bathymetric map of the mid-system valley of the Ogooue Fan between 2,700 and 3,400 m**  
 320 **water depth; (b) Interpretation of the main morphological features of the valley; (c) Six transverse profiles of the**  
 321 **mid-system valley extracted from the bathymetry data (Sc: scar of down-flank slides, I: internal incision, T;**  
 322 **Terrace).**  
 323

324 West of the mid-system valley outlet, the seafloor is very flat and shows only subtle  
 325 morphological variations except for local seamounts. Few channel-like, narrow  
 326 elongated depressions (maximum 10 m deep) presenting high backscatter values can be  
 327 identified. These lineations are restricted to a long tongue of high backscatter at the  
 328 mouth of the valley (Figure 2b, Detail A). This tongue is globally oriented E-W at the

329 exit of the mid-system valley and then deflects toward the NW at 3,700 m water depth,  
330 following the steepest slope.

331 North of Mount Loiret, the upper slope presents a lower slope gradient compared to the  
332 south part and is characterized by the presence of numerous linear pockmark trains on  
333 the upper part and pockmarks fields on the lower part. This whole area has a very low  
334 and homogeneous reflectivity. Trace of active sedimentation on this part of the margin  
335 is only visible in association with the Cape Lopez Canyon, which is the only canyon  
336 located north of the Mount Loiret (Figure 3). This canyon is associated with a small  
337 intraslope lobe located just north-east of the Mount Loiret and referred as the Cape  
338 Lopez Lobe (Figure 10) (Biscara et al., 2011). This northern system continues  
339 basinward with Channel A, the head of which is located in the vicinity of the Cape  
340 Lopez Lobe. At 2,200 m water depth, Channel A ends and its mouth is associated on  
341 the backscatter map with a fan-shaped area of very-high reflectivity, which is associated  
342 with some subsidiary channels and erosional marks (Figure 4).

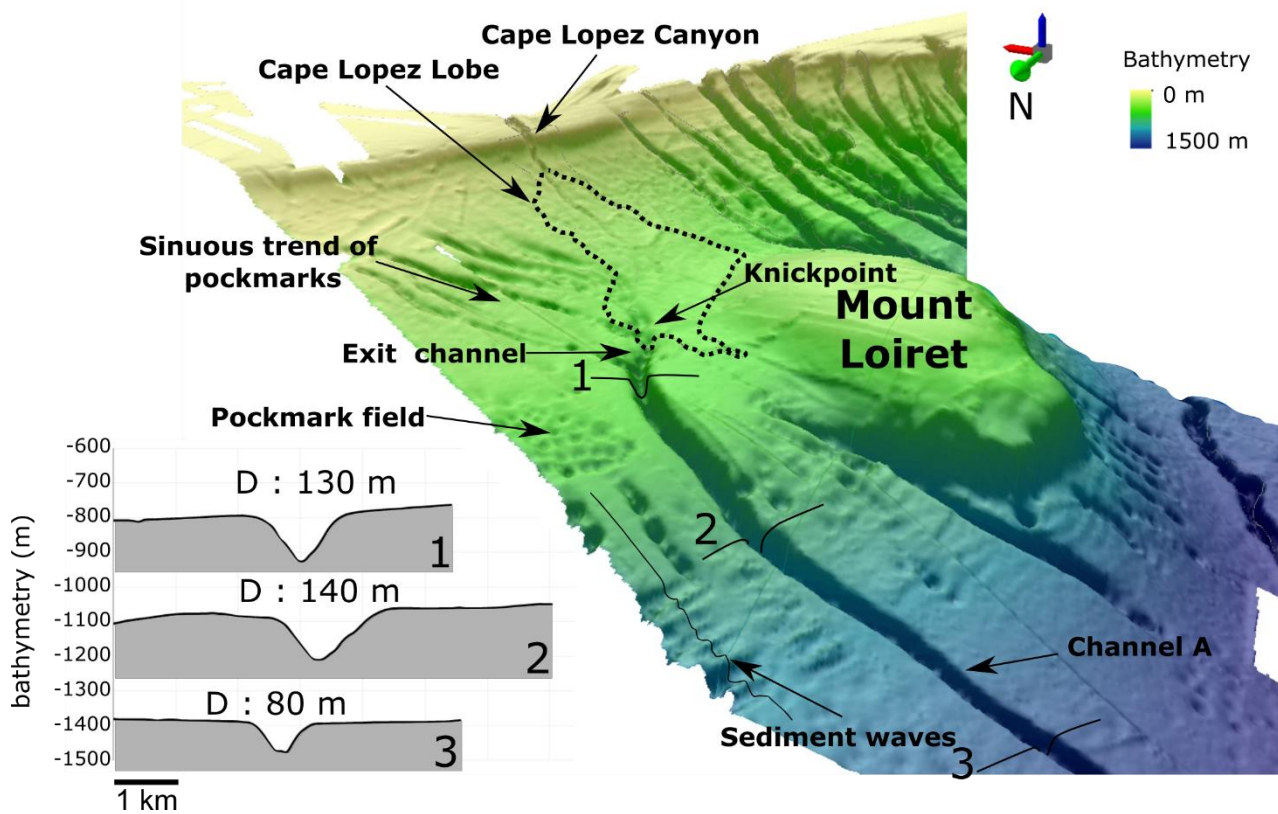

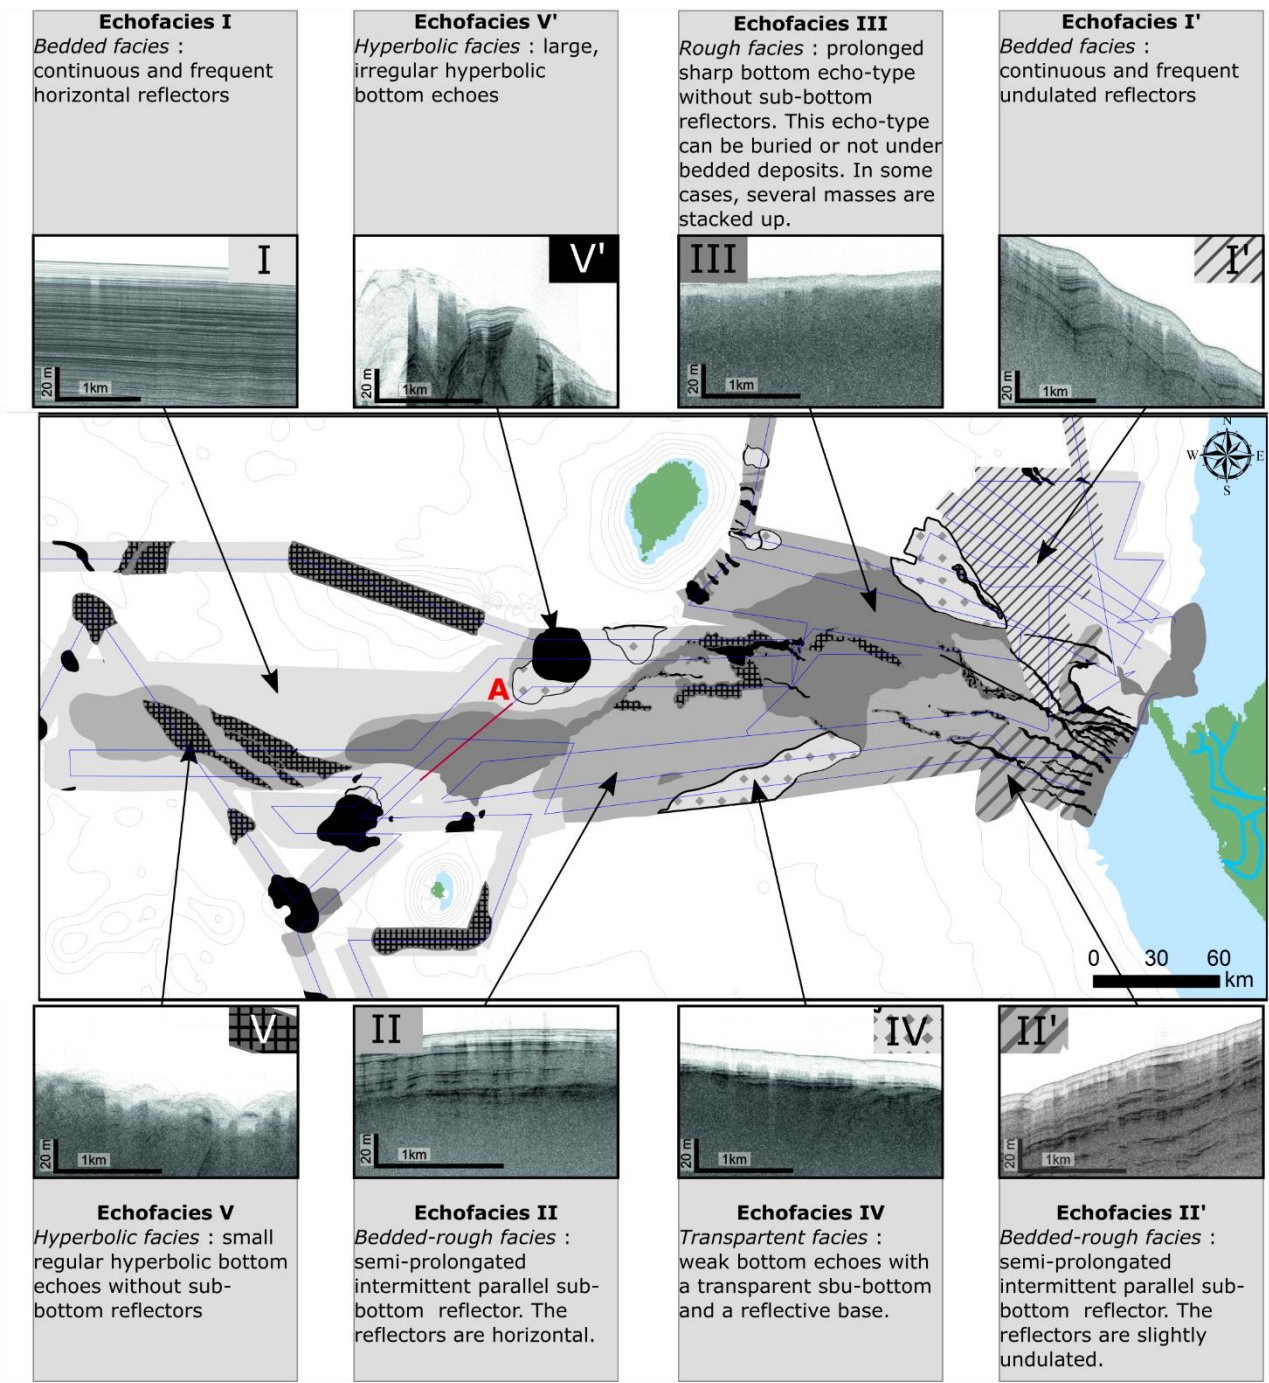

Figure 10: a) Three-dimensional representation of the Cape Lopez, Canyon, Cape Lopez Lobe and Channel A, b) three transverse profiles of Channel A.

346 **4.3 Echofacies analysis and distribution**

347  
348 **Figure 11: Echofacies map of the Ogooue Fan. Eight shades of grey represent the specific echofacies.**

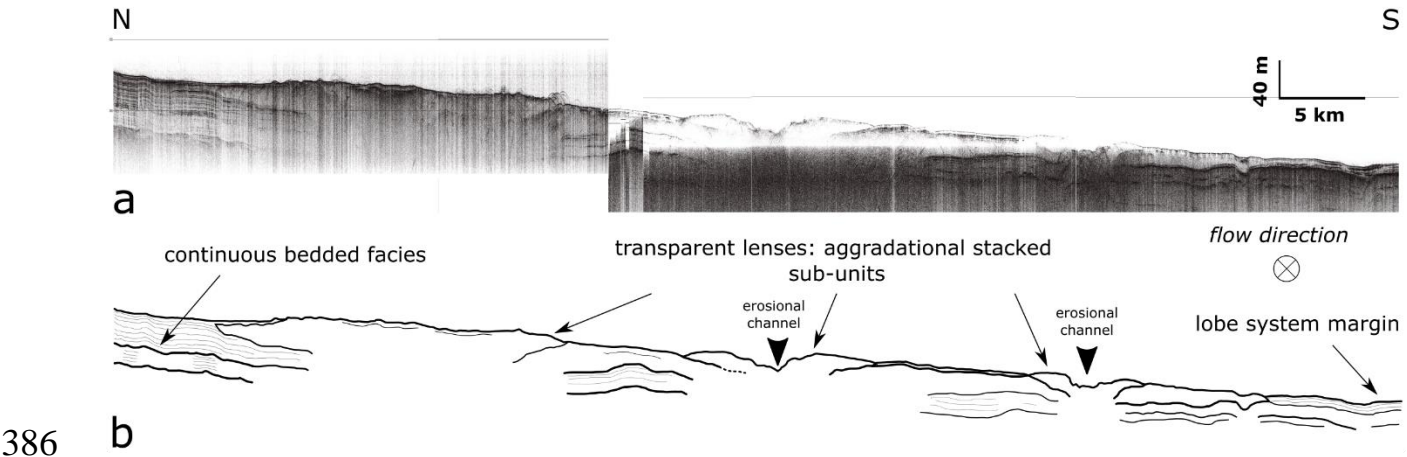

349  
350 The main echofacies have been discriminated on the profiles based on amplitude,  
351 frequency and geometry of the reflections (Figure 11). They have been grouped into  
352 five main classes: (I) bedded, (II) bedded-rough, (III) rough, (IV) transparent and (V)  
353 hyperbolic. Most transitions between echofacies are gradual.

354 The echofacies of the edge of the Gabonese shelf consists of rough echofacies III (Figure  
355 11). Core KC18 indicates that this area is dominated by fine-grained, structureless,  
356 terrigenous sedimentation.

357 North of the Mount Loiret, the continental slope presents bedded echofacies I, which  
358 evolves into echofacies I' down isobath 1,500 m which corresponds to an increase in  
359 the slope gradient. Previous studies have shown that bedded echofacies are commonly  
360 associated with alternating sandy and silty beds (Damuth, 1975, 1980a; Pratson and  
361 Laine, 1989; Pratson and Coakley, 1996; Loncke et al., 2009) or with hemipelagic  
362 sedimentation (Gauillier and Bellaiche, 1998). The very low reflectivity of the area and  
363 the absence of any channel suggest that only hemipelagic sedimentation occurs in this  
364 area. The wavy aspect of echofacies I' is certainly due to the post-deposition  
365 deformation of the hemipelagic sediments (Bouma and Treadwell, 1975; Jacobi, 1976;  
366 Damuth and Embley, 1979; Damuth, 1980b).

367 South of Mount Loiret, echofacies II and II' dominate on the continental slope. Despite  
368 the lack of sampling, the presence of discontinuous seismic reflectors can indicate the  
369 presence of coarse-grained sediment interpreted as turbidites (Damuth, 1975; Damuth  
370 and Hayes, 1977). The echo-mapping of the continental rise reveals the presence of  
371 different facies. The central part, just upstream of the mid-system valley, is  
372 characterized by rough echofacies III that suggests the presence of a high proportion of  
373 coarse-grained sediments. Some large channels are marked by hyperbolic facies  
374 certainly due to the irregular and steep seafloor. South of the mid-system valley, facies  
375 II dominates. Core KC10, collected in this area, indicates the alternation of clayey and  
376 sandy layers but with a predominance of fine-grained sediments (Figure 5). Echofacies  
377 IV is present in two main areas on the continental rise where they respectively form two  
378 lobe-shaped zones: one on the northern part, following the limits of the high-reflectivity  
379 area located at the mouth of channel A; the second in the southern part of the system in  
380 association with channel F. This echo-facies commonly corresponds to structureless  
381 deposits without internal organization due to mass-flow processes (Embley, 1976;  
382 Jacobi, 1976; Damuth, 1980a, 1980b, 1994) but it can also characterize basinal fine-

383 grained turbidites (Cita et al., 1984; Tripsanas et al., 2002). Core KC21, collected in the  
384 northern area indicates homogeneous silty-clay sediments with numerous detrital debris  
385 similar to those collected near the continental shelf.

386 b  
387  
388 **Figure 12: a) Transverse 3.5 kHz very-high resolution seismic line and b) line drawing in the upper distal lobe area,**  
389 **see Figure 11 for location of the line.**

390 In the abyssal plain, the area of the elongated tongue noticeable on the backscatter data  
391 presents different echofacies. Based on the 3.5 kHz profiles, it can be subdivided into  
392 two main domains. The upstream part, at the outlet of the mid-system valley, is  
393 characterized by rough echo character but with a specific organization: multiple  
394 aggradational stacked transparent sub-units from 10 to 30 meters thick are visible on the  
395 seismic lines (Figure 12). This organization is characteristic of sandy lobes deposits  
396 (Kenyon et al., 1995; Piper and Normark, 2001). Core KC11, collected in this  
397 environment, presents several decimeters-thick sandy layers and a several meter-thick  
398 disorganized sandy-clay units interpreted as a slump. The downstream part presents  
399 bedded-rough echofacies (II) associated with hyperbolic echofacies (V). Core KC15  
400 intersected fine-grained sediments and several silty layers corresponding to the  
401 distalmost turbidites.

402 On the edge of this tongue, high-penetration bedded facies (I) is dominant. The highly  
403 continuous parallel bedding indicates hemipelagic sedimentation with no coarse-  
404 grained fraction, which is confirmed by core KC16 and core KC02 both composed of  
405 alternating carbonate-rich and carbonate-poor clay sediments. Facies V' forms some

406 patches on the seafloor and correspond to seafloor mounts. The hyperbolic facies is due  
407 to the steep slopes and the irregular topography.  
408 Facies V and IV are also present and form lenses around the island of Sao-Tomé and  
409 Annobon. These features indicate some downslope sedimentary transfer from these  
410 islands. The limited area covered by these facies suggests short transport by sliding.

411 **5 Interpretation and discussion**

412 **5.1 Sedimentary processes along the fan**

413 The Ogooue Fan is a delta-fed passive margin deep-sea mud/sand-rich submarine fan  
414 according to the classification of Reading and Richards (1994). However, analysis of  
415 sub-surface data (bathymetry, acoustic imagery and 3.5 kHz echo-characters) reveals a  
416 great variability of sediment processes in the different domains of the margin, controlled  
417 by variations in slope gradient and the presence of seamounts (Figure 13a).

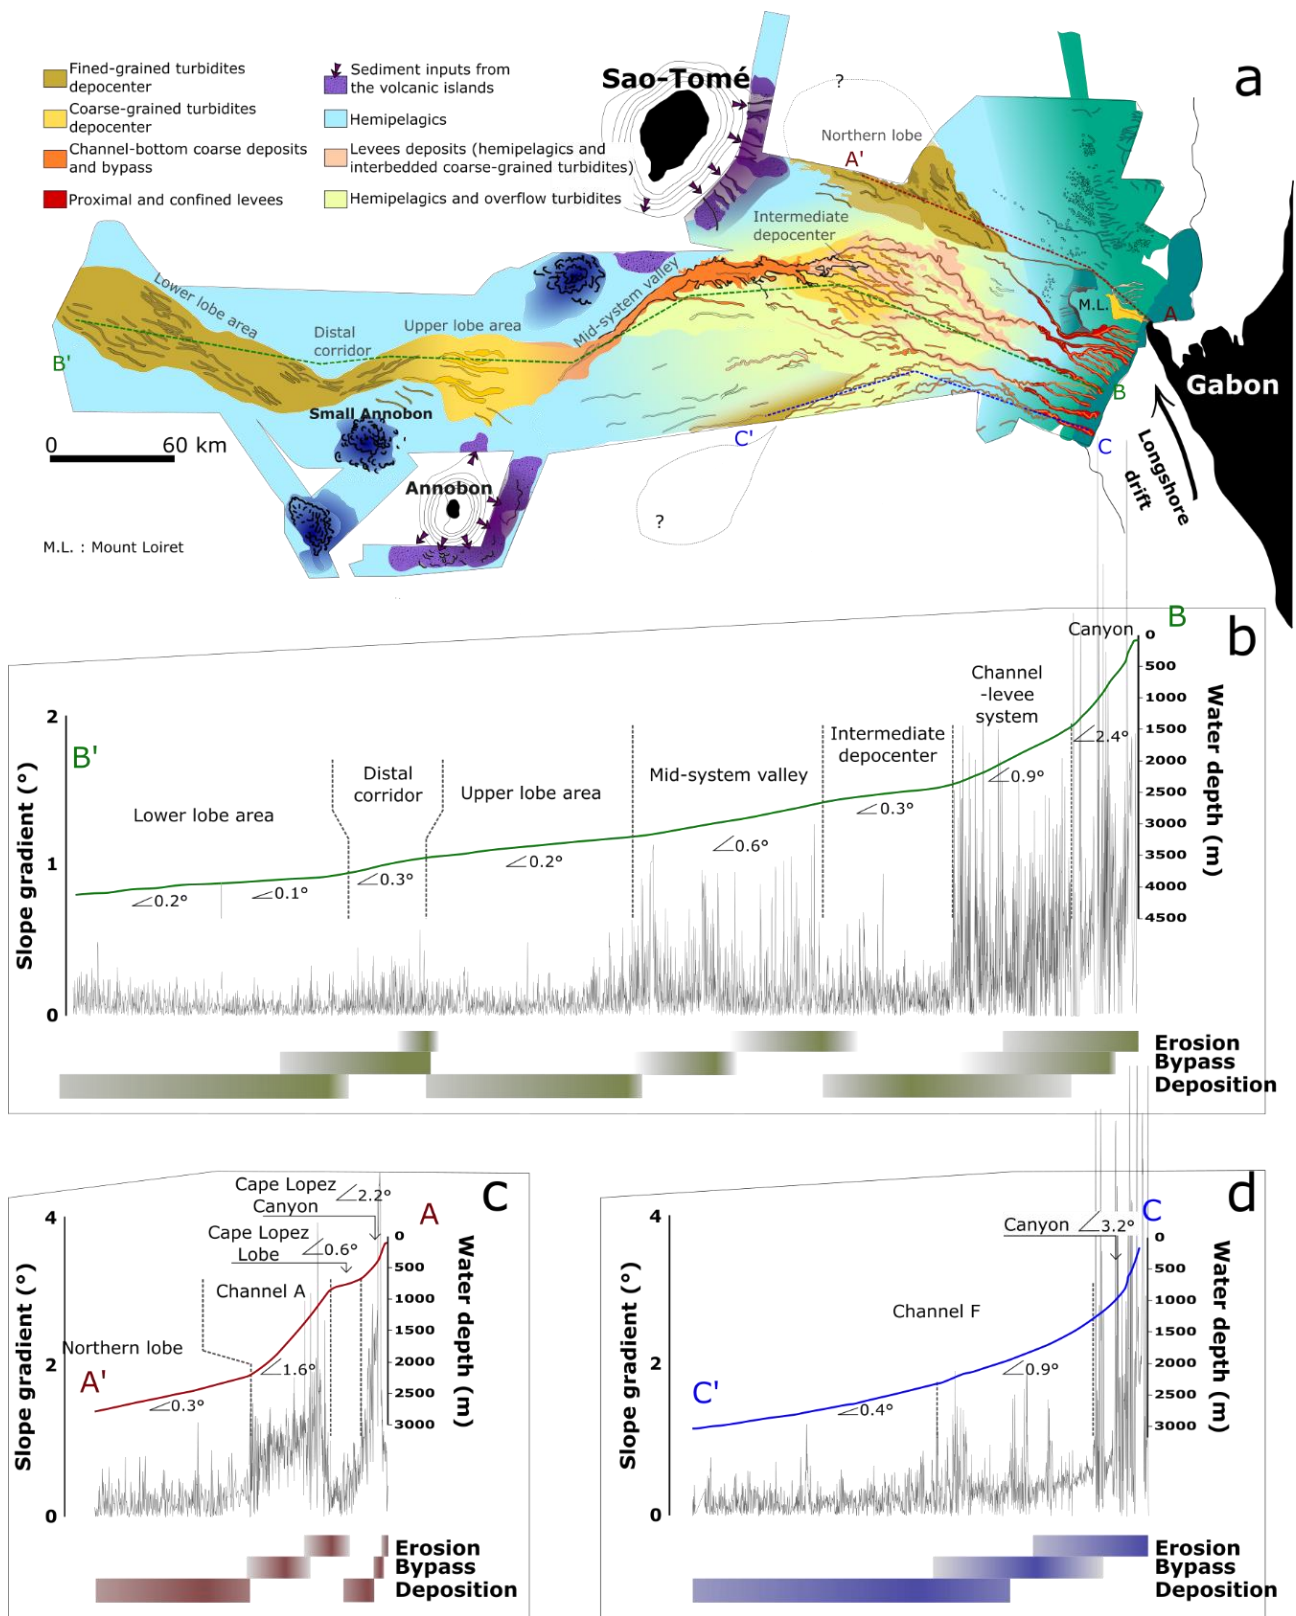

Figure 13: a) Synthetic map showing the architecture and the recent sedimentary processes of the Ogooue Fan determined by imagery and echofacies mapping; b) c) and d) Longitudinal profiles from the bathymetric data along the central, northern and southern part of the Ogooue Fan and slope gradient (in degree, measured every 100m). The differences in slope gradient along the transects are associated with the main sedimentary processes encountered along the slope.

### 5.1.1 Canyons system

Erosional processes predominate on the upper part of the slope as indicated by the presence of numerous tributary canyons (Figure 3). Based on the comparison of the canyon depths, widths and head positions, we observe the existence of two types of canyons as described in Jobe et al. (2011) along the Equatorial Guinea margin. The canyons presenting a deep (> hundreds of meters deep) “V” shape and which indent the shelf edge are type I canyons (*sensu* Jobe et al., 2011), whereas the shallower canyons (<100 m deep) with a “U” shape and which do not indent the shelf are type II canyons (*sensu* Jobe et al., 2011). The difference between these two types of canyons indicates different initiation and depositional processes. Type I are commonly associated with high sediment supply and the canyons initiation and morphology are controlled by sand-rich erosive turbidity currents and mass-wasting processes (Field and Gardner, 1990; Pratson et al., 1994; Pratson and Coakley, 1996; Weaver et al., 2000; Bertoni and Cartwright, 2005; Jobe et al., 2011). In contrast, Type II canyons are found in areas of low sediment supply. Their initiation is attributed to retrogressive sediment failures and subsequent headward erosion (Shepard, 1981; Twichell and Roberts, 1982; Stanley and Moore, 1983). Their evolution is controlled by depositional processes involving fine-grained sediments - hemipelagic deposition and dilute turbidity currents - that can be carried over the shelf and upper slope into the canyon heads but without significant erosion (Thornton, 1984). North of the Mount Loiret, the fine-grained sedimentation has completely infilled several type II canyons creating sinuous trains of pockmarks. These pockmarks have been previously described in Pilcher and Argent (2007). Variations in the localisation of coarse-grained sediment supplies play a key role on the development of the two types of canyons. Along the central Gabonese shelf, the very recent development of the Mandji Island 3,000 years BP (Giresse and Odin, 1973; Lebigre, 1983) favoured the construction of the Cape Lopez Type I canyon, which is presently active (Biscara et al., 2013).

### 5.1.2 Channels system

The transition from canyons to sinuous channels with external levees (*sensu* Kane and Hodgson, 2011) is related to a decrease in slope gradient from the continental slope ( $> 2^\circ$ ) to the continental rise ( $< 1^\circ$ ). The sinuous channel-levees systems develop on a relatively gentle slope ( $0.9^\circ$ ) from 1,500 to 2,200 m water depth. These channels are mainly erosive in their axial part (Normark et al., 1993) while deposition occurs on low-developed external levees (25 m maximum levees height for channel D; Figure 7). The external levees of the four central channels (B, C, D and E in Figure 2) show high reflectivity that suggests frequent turbidity currents overspill. These channels are deeply incised in the seafloor (average 70 m deep for channel D and 90 m deep for channel A; Figure 7 and Figure 10) below the associated levees, when present. This feature is similar to the modern Congo Channel (Babonneau et al., 2002) and is opposed to the morphology of aggrading channels (such as the Amazon Channel) where the thalweg is perched above the base of the levees system (Damuth, 1995). This entrenched morphology prevents extensive overflow of turbidity currents and is the probable cause of low development of external levees and inhibits channel bifurcation by avulsion. It has been proposed for the Congo Channel that the entrenched morphology of the channel confines the flow and keeps the energy high enough to allow a transport of sediment to very distant areas (Babonneau et al., 2002).

Several studies have documented that sinuosity of submarine channels increases with time (Peakall et al., 2000; Babonneau et al., 2002; Deptuck et al., 2003, 2007; Kolla, 2007). The sinuous upper parts of the channels ( $1.3 < \text{sinuosity} < 1.75$  for channel D; Figure 7C) have consequently undergone a long history whereas the distal straighter parts of the channels are in a more immature stage. Moreover, the height of the external levees and the depth of the channels both decrease in the lower parts of the channels system (Figure 7). These morphological changes are due to a slope gradient decrease ( $< 0.5^\circ$  from transect 6 along channel D; Figure 7) that progressively slows down the flow velocity and reduces its erosional power. Simultaneously, deposition of fine particles by spilling of the upper part of the flow on the external levees leads to a

progressive decrease of the fine-grained fraction transported by the channelized flows (Normark et al., 1993; Peakall et al., 2000).

At 2,200 m water depth, the appearance of numerous erosional features such as isolated and amalgamated spoon-shaped scours (Figure 8 C1), erosional lineations and subsidiary channels with limited surface expression (10-20 m deep, Figure 8 B2, B3) are characteristic of the channel lobe transition zone (Figure 8) (Kenyon et al., 1995; Wynn et al., 2007; Jegou et al., 2008; Mulder and Etienne, 2010). The appearance of these features correlates with a second abrupt decrease in slope gradient (from 0.9° to 0.3°) and with the transition from bedded-rough to rough echo-facies indicating a change in the sedimentary process. This area corresponds to deposition by spreading flows in an unchanneled area referred as the intermediate depocenter in Figure 13 and covering area surface of ca. 4,250 km<sup>2</sup>. However, the low penetration of the 3.5 kHz echosounder and the limited number of seismic lines in this area did not allow a more detailed interpretation of the sedimentary processes in this part of the system.

### **5.1.3 Mid-system valley and distal lobe complexes**

The presence of a steeper slope downslope of the intermediate depocenter (0.6°) led to the incision of the mid-system valley, which acts as an outlet channel for turbidity currents that are energetic enough to travel through the flatter depositional area (Figure 13b). The upstream part of the valley is multi-sourced and has migrated upstream by retrogressive erosion, whereas the downstream part appears more stable with a straighter pathway and steeper flanks, these features being similar to the Tanzania Channel described by Bourget et al. (2008). The pathway of the valley seems to be controlled by the seafloor topography as the valley deviates near the rocky seamount located west of Sao-Tomé. This large mid-system valley corresponds to a single feeding “source” for the lower fan and, consequently, the final depositional area is located downstream of the valley.

At the outlet of the mid-system valley, the echofacies shows an area mainly characterized by rough echofacies (III) forming stacked lenses. This area, referred as

the upper lobe area in Figure 13, constitutes the main lobe complex (*sensu* Pr  lat and Hodgson, 2013) of the Ogooue Fan. According to the seismic data, the depositional area of the lobe complex is ~ 100 km long, reaches ~ 40 km in width, spreads over 2,860 km<sup>2</sup> and reaches up to 40 m in thickness. The transparent lenses are interpreted as lobe elements and seem to be bounded by erosive bases (Mulder and Etienne, 2010). Some incisions (< 15 m deep) are imaged on the top surface of the lobes; two of them are visible in Figure 12. The area where incisions are present is interpreted as the channelized part of the lobe. This lobe area presents a gentle slope (0.3  ) oriented north-south, suggesting that topographic compensation would shift future lobe element deposition southward. However, the few numbers of seismic lines do not allow the precise internal geometry and the timing of the construction of the different lobe units. This depositional area is not the distalmost part of the Ogooue Fan. West of this lobe, evidences of active sedimentation are visible on the reflectivity map (Figure 2, Figure 4). The reflectivity map shows high-backscatter finger-shape structures suggesting pathways of gravity flows (Figure 2b, detail A). These lineations (< 10 m deep) are concentrated in a 20 km wide corridor just west of the lobe area and then form a wider area extending up to 550 km offshore the Ogooue Delta. This part of the system follows the same scheme as the one previously described between the intermediate depocenter and the upper lobe area (Figure 13b). The corridor appears on a segment of steeper slope (0.3  ) just at the downslope end of the upper lobe area (0.2  ). This corridor, which disappears when the slope becomes gentler (0.1  ), was certainly formed by the repeated spill-over of the fine-grained top of turbidity currents over the upper lobe area. This architecture suggests that this corridor is dominated by sediment bypass (*sensu* Stevenson et al., 2015). On the most distal segment with a very low slope gradient (0.1-0.2  ) sediment deposition dominates.

#### **5.1.4 Isolated systems**

On the northern part of the slope, the isolated system composed of the Cape Lopez Canyon, Cape Lopez intraslope lobe, channel A and northern lobe follows the same

scheme (Figure 13c). Cape Lopez Canyon terminates at 650 m water depth at an abrupt decrease in slope gradient (from more than  $1.7^{\circ}$  to  $0.6^{\circ}$ ) caused by the presence of the Mount Loiret (Figure 10). The Cape Lopez intraslope lobe occupies a small confined basin, 6 km wide and 16 km long and covers an area of 106 km<sup>2</sup>. This lobe appears very similar with the “X fan” described in Jobe et al. (2017) on the Niger Delta slope (8 km x 8 km, 76 km<sup>2</sup>) and is in the same size range as the intraslope complexes studied in the Karoo Basin by Spychala et al. (2015) (6-10 km wide and 15-25 km). The two successive depositional areas, composed by the Cape Lopez lobe and the northern lobe, are located on areas with a low slope gradient ( $0.6$ - $0.3^{\circ}$ ) whereas erosion and sediment bypass dominate on segments of steeper slope gradient ( $1.6^{\circ}$ ). The high slope gradient between the two depositional areas favored the construction of a straight deeply entrenched channel (>100 m deep near the knickpoints) without levee (Figure 7b) instead of a large valley similar to the central mid-system valley.

In the southern part of the fan, channel F transports sediments southward (Figure 13d). At 2,200 m water depth, a transparent echofacies appears associated with the pathway of this channel. This echofacies suggests that sediment transported by this channel might be partly deposited in this area by turbidity current overflow. This channel might also be associated with a depositional lobe; however, the area covered by the MOCOSSED survey does not allow us to image it.

**5.2 The Ogooue Fan among other complex slope fans**

The Ogooue Fan develops on a stepped-slope (Prather, 2003) which creates a succession of depositional areas on segments with gentle slope (referred as ‘steps’ in Smith, (2004)) and segments of steeper slope (“ramps” in Smith, 2004) associated with erosion or sediment bypass (Figure 13) (Demyttenaere et al., 2000; O’Byrne et al., 2004; Smith, 2004). The depositional behavior in these systems is guided by an equilibrium profile of the system that forms preferential areas of sedimentation or erosion (Komar, 1971; Ferry et al., 2005). As described in the conceptual model of O’Byrne et al. (2004), erosion is favored where local gradient increases, the eroded sediments being delivered

564 downstream resulting in a local increase in sediment load (O’Byrne et al., 2004; Gee  
565 and Gawthorpe, 2006; Deptuck et al, 2012). This kind of fan geometry is common along  
566 the West African margin where abrupt changes in slope gradient and complex seafloor  
567 morphology are inherited from salt tectonic movement (Pirmez et al., 2000; Ferry et al.,  
568 2005; Gee and Gawthorpe, 2006; Gee et al., 2007). Deptuck (2012) has described the  
569 influence of stepped-slope on sedimentary processes along the western Niger Delta. He  
570 showed that differences of slope gradient between ramps ( $0.8^{\circ}$  to  $2.1^{\circ}$ ) and steps ( $0.3^{\circ}$   
571 to  $1.1^{\circ}$ ) induce the transition from vertical incision and sediments removal to  
572 preferential sediments accumulation (Deptuck et al., 2007; Deptuck, 2012). Gradient  
573 changes along the Gabonese margin are however lower than the ones reported in  
574 Deptuck, (2012) and variation in slope gradient of  $0.2^{\circ}$  appears to be enough to modify  
575 sedimentary processes. The impact of subtle changes of slope gradients has already been  
576 highlighted by studies of the Karoo basin (Van der Merwe et al., 2014; Spsychala et al.,  
577 2015; Brooks et al., 2018) and Moroccan margin where sedimentary processes are  
578 controlled by very subtle gradient changes ( $<0.1^{\circ}$ ) (Wynn et al., 2012   
579 Moreover, in the case of the modern Ogooue Fan, and conversely to what is observed  
580 in the Congo and Niger systems, the presence of several bathymetric highs including  
581 the volcanic islands of the CVL and the Mount Loiret constitutes additional stresses for  
582 the flows and creates a more complex slope profile. These bathymetric highs induce a  
583 lateral shift of the pathways of different channels as well as the pathway of the mid-  
584 system valley and form several downslope depositional lobes such as the Cape Lopez  
585 lobe that is constrained by the presence of the Mount Loiret. Several complex-slope  
586 systems have already been described in the literature with slope complexity due to salt-  
587 related deformations (e.g. Gulf of Mexico (Prather et al., 1998; Beaubouef and  
588 Friedmann, 2000), offshore Angola (Hay, 2012) or basin thrusting (offshore Brunei;  
589 McGilvery and Cook, 2003, Markan margin; Bourget et al., 2010). For these systems,  
590 the slope evolves rapidly, and sedimentation and erosion are unlikely to establish an  
591 equilibrium profile. In contrast, the Gabonese margin reached a mature evolutionary  
592 stage with only weak and slow salt tectonic activity (Chen et al., 2007), and

593 sedimentation and erosion certainly dominate the short-term evolution of the slope. The  
594 Ogooue Fan appears to be much more similar to the morphology of the Northwest  
595 African margin where the Madeira, the Canary and the Cape Verde islands create a  
596 complex slope morphology along the Moroccan and Mauritanian margin (Masson,  
597 1994; Wynn et al., 2000, 2002, 2012).

### 598 **5.3 Sedimentary facies distribution**

599 The main processes involved in the deposition of the Upper Quaternary sediments of  
600 the Ogooue Fan are pelagic and hemipelagic suspension fall-out together with turbidity  
601 currents. Fine-grained pelagic/hemipelagic 'background' sedimentation is dominant  
602 across a large area of the margin, particularly on the lower rise and the adjacent basin  
603 plains. These sediments are then overprinted by downslope gravity flows such as  
604 turbidity currents. However, the previously described fan organization implies a specific  
605 distribution of the sedimentary facies and grain-size distribution within the system  
606 (Figure 6).

607 Cores collected in the upslope area (KC18 and KC17) show mostly hemipelagic  
608 sediments with a very low carbonate content. This reflects significant detrital flux  
609 associated with proximity to the Ogooue platform and the influence of the Ogooue river  
610 plume. Core KC19 collected down the slope just at the transition from canyon to  
611 channel-levee complexes show two several meters-thick sandy successions  
612 corresponding to top-cut-out Bouma sequences (Ta) interbedded with the upper slope  
613 hemipelagites. These sandy turbidites, which are the thickest sand beds recorded in all  
614 the cores (Figure 6), indicate the occurrence of high-density turbidity currents flowing  
615 down the canyons. The lack of the upper parts of the turbidite is consistent with  
616 deposition in the canyons of coarse-grains located at the base of the turbidity currents,  
617 whilst the finer upper part of the current is transported downstream and/or spills over  
618 the external levees. External levee deposits have been sampled by core KC13, which  
619 shows numerous turbidites made up of centimeter-thick, ~~fining upward~~ parallel or  
620 ripple cross-laminated of silt and fine sands (Figure 5). Unfortunately, no core has been

621 collected directly in the intermediate depocenter. However, the rough echofacies III  
622 found in this area associated with various erosional features both suggest a high  
623 sand/mud ratio.

624 The mid-system valley acts as a conduit for the sediments coming from the upper part  
625 of the system, transporting them further downstream. However, the sediments resulting  
626 from the erosion of this valley constitute certainly a part of the sediments deposited in  
627 the lobe complex area. According to the available bathymetric data, the volume of  
628 sediment removed from the mid-system valley is between 8 and 10 km<sup>3</sup>. We assume  
629 that these sediments are mainly fine-grained due to the deep location of the valley. Core  
630 KC14, collected on an internal terrace of the valley, shows that this valley is also an  
631 area of active sedimentation notably due to down-flank sliding. The bottom of the valley  
632 comprises slump deposits and coarse-grained sediments deposited by gravity flows  
633 coming from the upper part of the system.

634 Downstream of the mid-system valley, core KC11 show that coarse-grained turbidity  
635 currents are deposited in the proximal part of the lobe complex. The abrupt transitions  
636 between erosional/bypass and depositional behavior observed notably at the mouth of  
637 the mid-system valley is the result of hydraulic jumps affecting flows when they become  
638 unconfined between channel sides and spread laterally (Komar, 1971; Garcia and  
639 Parker, 1989). Core KC15, located in the lower lobe area, is composed of very thin silty  
640 turbidites corresponding to the upper parts of the Bouma sequence interbedded with  
641 hemipelagic deposits. The upper lobe acts as a trap for the basal sand-rich parts of  
642 gravity flows. Consequently, only the upper part of the flows, which is composed of  
643 fine-grained sediments, travels beyond this area. The spatial distribution of facies  
644 suggests a filling of successive depocenters with a downslope decrease of the coarse-  
645 grained sediment proportion (Figure 6). The same facies distribution can be observed in  
646 the northern system. No sandy turbidites are recorded in KC21 located in the Northern  
647 lobe, only fine-grained sedimentation, whereas the study of cores taken in the Cape  
648 Lopez lobe shows the presence of numerous sandy turbidites (Biscara et al., 2011). The  
649 Northern lobe is thus fed by the downslope flow stripped suspended fines transported at

the top of turbidity currents flowing through the Cape Lopez Canyon, similarly to intraslope lobes observed in other locations (e.g. Spychala et al., 2015; Jobe et al., 2017). Whatever the current pathways are, the deposited material has a continental origin as suggested by the abundance of quartz, micas and plant debris in the coarse-grained fraction. The important proportion of planktic foraminifers in the coarse-grained fraction of turbidites located in the distal part of the system (core KC10- KC11- KC15) suggests that turbidity currents previously entrained pelagic and hemipelagic deposited upslope where such deposits cover large areas (Viana and Faugères, 1998). The presence of volcanoclastic debris in a sandy layer found at the base of core KC01 suggests that sedimentary input may also come from the volcanic islands of Sao Tomé or Annobon. However, acoustic data indicate that these inputs are limited to the close vicinity of the Sao-Tomé and Annobon islands. In contrast to the model proposed by Wynn et al., (2000) for the Northwest African slope, the volcanic islands and other seamounts present on the Ogooue Fan act mainly as obstacles for the flow pathway but are not important sediment sources for the fan.

#### **5.4 Palaeoceanographic control on the fan activity**

The results of Mignard et al. (2017) concerning the study of five cores located along the central part of the Ogooue Fan showed that the fluvial system fed the fan with sediments almost only during times of relative low sea-level. This relative sea-level control on turbidite activity (switch on/off behavior) is classical for mid and low latitude passive margin fans where canyon heads are detached from terrestrial sediment sources (e.g. Mississippi Fan (Bouma et al., 1989), Amazon Fan (Flood and Piper, 1997), Rhone Fan (Lombo Tombo et al., 2015), Indus Fan (Kolla and Coumes, 1987). Conversely, sedimentation during periods of relative high sea-level such as the Holocene, is dominated by hemipelagic to pelagic fall-out with a low part of fine terrigenous particles. Therefore, all cores collected in the central part of the system are capped by 8 to 20 cm of light-brown nannofossil ooze corresponding to Holocene hemipelagites (Figure 5).

678 However, the northern part of the system appears to have a different behavior. Biscara  
679 et al., (2011) showed that the Cape Lopez lobe is currently recording both hemipelagic  
680 and turbidity current sedimentation despite the present-day high sea-level. This lobe is  
681 fed with sediment from the Cape Lopez Canyon, which incises the shelf to the edge of  
682 the Mandji Island (Biscara et al., 2013). The deep incision of the continental shelf up to  
683 the coast combined with the longshore sediment transport along the Mandji Island and  
684 the narrow shelf in this area (4 km wide) favor the capture of sediment by this canyon  
685 during time of high sea-level (Reyre, 1984; Biscara et al., 2013). The northern lobe,  
686 which is directly connected to the Cape Lopez lobe by Channel A, appears to be also  
687 fed by terrigenous sediments during the Holocene. Core KC21, located at the entrance  
688 of the northern lobe, is entirely composed of *facies 3*, even for sediments deposited  
689 during MIS1 (Figure 5).

690 In the Ogooue Fan, the shelf width between the littoral area and the canyon heads is the  
691 main control factor on the fan activity. During periods of ~~relative~~ low sea-level,  the  
692 canyons of the central part of the system receive sediment from the river system that  
693 extended across the subaerially exposed continental shelf. During periods of ~~relative~~  
694 high sea-level, river sediments are unable to reach the canyon heads south of the Manji  
695 Island and accumulate on the continental shelf close to the Ogooue Delta. However, part  
696 of these sediments mixed with sediments coming from the south Gabon margin are drift-  
697 transported and contribute to supply the Cape Lopez Canyon and consequently the Cape  
698 Lopez and Northern Lobe. Due to their specific location and favorable hydrodynamic  
699 conditions on the shelf, sedimentation on the Cape Lopez and the Northern lobes is  
700 active during relative sea-level highstands, in contrast to the rest of the Ogooue Fan.  
701 Examples of this type of supply have already been described along the California margin  
702 where the La Jolla canyon is fed by drift-transported sediments during highstand  
703 (Covault et al., 2007, 2011) but also on the southeast Australian coast near the Fraser  
704 Island (Boyd et al., 2008), which appears very similar to the Mandji Island.

## 705 6 Conclusions

706 This study provides the first data on the morphology of the recent Ogooue Deep-sea fan  
707 and interpretations on sedimentary processes occurring in this environment. The  
708 Gabonese margin presents a pelagic/hemipelagic background sedimentation overprinted  
709 by downslope gravity flows. The fan is made up of various architectural elements and  
710 consists of both constructional and erosional sections. The pattern of sedimentation on  
711 the margin is controlled by subtle slope gradient changes ( $< 0.3^\circ$ ). The long-term  
712 interaction between gravity flows and the seafloor topography has induced the  
713 construction of successive depocenters and sediment bypass areas. The gravity flows  
714 have modified the topography according to a theoretical equilibrium profile, eroding the  
715 seafloor where slopes are steeper than the theoretical equilibrium profiles and depositing  
716 sediments when slopes are gentler than the theoretical equilibrium profile. Three  
717 successive main sediment depocenters have been identified along a longitudinal profile.  
718 They are associated with three areas of low slope gradient ( $0.3^\circ$ - $0.2^\circ$ ). The two updip  
719 deposition areas – the intermediate depocenter and the upper lobe area – have recorded  
720 coarse-grained sedimentation and are connected by a well-developed large mid-system  
721 valley measuring 100 km long and located on a steeper slope segment ( $0.6^\circ$ ). The  
722 distalmost depocenter – the lower lobe area - receive only the fine-grained portion of  
723 the sediment load that has bypassed the more proximal deposit areas. Sedimentation on  
724 this margin is made more complex by the presence of several volcanic islands and  
725 seamounts that constrain the gravity flows. The presence on the slope of the Mount  
726 Loiret has caused the formation of an isolated system composed of the Cape Lopez  
727 Canyon and lobe, which continues downstream by the Northern Lobe area. The Ogooue  
728 Fan is currently in a low activity period since the recent Holocene rise of sea-level.  
729 Nowadays, the sedimentation is mostly located on the shelf, in the Ogooue Delta and  
730 on the upper slope. The fan was more active during the last glacial lowstand.  
731 Nonetheless, the northern part of the system appears to have an asynchronous activity  
732 with the rest of the fan as this part is fed by the drift-transported sediments during time  
733 of relative high sea-level when the activity in the rest of the system is shut-down.

## 7 Acknowledgments

We thank the SHOM (hydrological and oceanographic marine service) for the data, the ‘ARTEMIS’ technical platform for radiocarbon age dating. We are also grateful to EPOC technicians and engineers: I. Billy, P. Lebleu, O. Ther and L. Rossignol for the data acquisition. P. Haugton and D.M. Hodgson are thanked for their constructive and helpful reviews.
