Abstract. In seismotectonic studies, seismic reflection data are a powerful tool to unravel the complex deep architecture of active faults. Such tectonic structures are usually mapped at the surface through traditional geological surveying whilst seismic reflection data may help to trace their continuation from the near-surface down to hypocentral depth. In this study, we propose the application of the seismic attributes technique, commonly used in seismic reflection exploration by oil industry, to seismotectonic research for the first time. The study area is a geologically complex region of Central Italy, struck during the 2016-2017 by a long-lasting seismic sequence, including a Mw 6.5 main-shock. A seismic reflection data-set consisting of three vintage seismic profiles, currently the only ones available at the regional scale across the epicentral zone, represents a singular opportunity to attempt a seismic attribute analysis, by running attributes such as the “Energy” and the “Pseudo Relief”. Our results are critical, because provide information on the relatively deep structural setting, mapping a prominent, high amplitude regional reflector interpreted as the top of basement, which is an important rheological boundary. Complex patterns of high-angle discontinuities crossing the reflectors have also been identified by seismic attributes. These steep fabrics are interpreted as the expression of fault zones, belonging to the active normal fault systems responsible for the seismicity of the region. Such peculiar seismic signatures of faulting generally well-match with the principal geological and tectonic structures exposed at surface. In addition, we also provide convincing evidence of an important primary tectonic structure currently debated in literature (the Norcia antithetic fault) as well as buried secondary fault splays. This work demonstrates that seismic attribute analysis, even if used on low-quality vintage 2D data, may contribute to improve the subsurface geological interpretation of areas characterized by poor subsurface data availability but high seismic potential.

31 **1 Introduction**

32 Studying the connections between the earthquakes and the faults to which they are associated is a primary assignment of
33 seismotectonics (Allen et al., 1965; Schwartz and Coppersmith, 1984). Clearly, to fill the gap between the exposed geology
34 (including the active “geological faults”) and the seismological data (e.g. focal mechanisms, earthquake locations, etc...)
35 which are indicators of the geometry and kinematics of the seismic source at hypocentral depth (“seismological faults”,
36 sensu Barchi & Mirabella, 2008), is not an easy task. The recovery of information on the seismogenic structures at the depth
37 is more challenging, primarily due to the lack of high-resolution geophysical data and/or wells stratigraphy, generating high
38 degree of uncertainty, and bringing to contrasting geological models and interpretation.

39 Different geophysical methods (e.g. Gravimetry, Magnetics, Electric and Electromagnetic such as Magnetotellurics and
40 Ground Penetrating Radar) may contribute to define the stratigraphy and structural setting of the upper crust at different
41 scales. Furthermore, images provided by seismic reflection method are poorly affected by well-known inversion problems
42 typical of the potential methods (Snieder & Trampert, 1999) and are largely the most powerful tool able to produce high-
43 resolution subsurface images. Such type of data, possibly calibrated by deep wells stratigraphy, may provide important
44 constraints to the definition of subsurface geological architecture: these profiles are useful to unveil the deep geometry of
45 active faults from the surface, where they are mapped in the field, down to hypocentral depths. Unfortunately, ex-novo
46 acquisition (possibly 3D) of onshore deep-reflection data for research purposes, is hampered by high costs, environmental
47 problems and complex logistics (e.g. prohibition of dynamite or vibroseis trucks in Natural Parks or urban areas). Significant
48 exceptions are research projects for deep crustal investigations like BIRPS (Brewer et al., 1983), CoCORP (Cook et al.,
49 1979), ECORS (Roure et al., 1989) and CROP (Barchi et al., 1998; Finetti et al., 2001), IBERSEIS (Simancas et al., 2003),
50 ALCUDIA (Ehsan et al., 2014 and 2015). In seismically active regions, old profiles (legacy data) acquired by the industry
51 have been successfully used to connect the active faults mapped at the surface with the earthquakes seismogenic sources
52 depicted by seismological records (Boncio et al., 2000; Bonini et al., 2014; Carvalho et al., 2008; Beidinger et al., 2011;
53 Maesano et al., 2015; Porreca et al., 2018). Legacy seismic lines have in fact some advantages: 1) they are already available
54 from the oil companies 2) they represent a nice source of information in places where new data is difficult to acquire; 3) they
55 can be used to build up and refine geological models. Moreover, such data are often the only available, and are worth to be
56 used in the most appropriate way for constraining the subsurface geological setting and to provide new data on active
57 tectonic structures (see DISS database, Basili et al., 2008). Vintage profiles can therefore significantly contribute to seismo-
58 tectonic researches, even if characterized by intrinsic limitations: i) their location, orientation and acquisition parameters
59 were not specifically designed with this aim; ii) they were collected with seismic technologies and acquisition/processing
60 strategies of some decades ago, producing data with relatively low signal/noise ratio (S/N) and low resolution, especially in
61 comparison to modern data (Manning et al., 2019). In order to improve the data quality and increase the accuracy of the
62 interpretation, two main strategies, ordinarily used by the O&G industry, can be applied on legacy data: 1) reprocessing from

raw data using modern processing strategies and newly performing algorithms and software; 2) use post-stack analysis techniques such as seismic attributes.

An attribute analysis is the easiest, cheapest and fastest strategy to qualitatively emphasize the geophysical features and data properties of reflection seismic data sets, producing benefits particularly in complex geological areas. A seismic attribute is a quantity derived from seismic data (pre-stack and/or post-stack) commonly used to extract additional information that may be unclear in conventional seismic lines. Examples of applications on dense 3D seismic volumes produced impressive results, including identification of ancient river channels or sets of faults at variable scales (Chopra & Marfurt, 2005; Chopra & Marfurt, 2007; Chopra & Marfurt, 2008; Marfurt et al., 2011; Hale, 2013; Barnes, 2016; Iacopini et al., 2016; Marfurt, 2018; Wrona et al., 2018; Di & AlRegib, 2019; Naeini & Prindle, 2019). Different limitations and advantages exist between 2D vs 3D seismic data, extensively discussed by Torvela et al. (2013) and Hutchinson (2016). For these reasons 2D post-stack seismic attribute may not provide the same quality of information than on 3D, being subjected also to possible pitfalls (Marfurt & Alves, 2015; Ha et al., 2019). However, the main point is that in the past, it was common to sample study areas inland by 2D grids of seismic profiles, being the full 3D seismic surveys rare. Hence, it is relevant to extract as much information as possible from such data.

In this work, the selected study area is located between the southeastern part of the Umbria-Marche Apennines and the Laga Domain, in the outer Northern Apennines (central Italy) (e.g. Barchi et al., 2001). This area presents ideal characteristics to test the application of seismic attributes as a new approach in seismotectonics. In the past, several seismic profiles were acquired in this region for hydrocarbon exploration, and were later used to constrain subsurface geological interpretation (Bally et al., 1986; Barchi et al, 1991; Barchi et al., 1998; Ciaccio et al., 2005; Pauselli et al., 2006; Mirabella et al. 2008; Barchi et al., 2009; Bigi et al., 2011). After the 2016-2017 seismic sequence, Porreca et al. (2018) provided an updated regional geological model based on the interpretation of vintage seismic lines, but remarked important differences in the seismic data quality across the region, hampering a straightforward seismic interpretation. Therefore, the present work exploits the use of seismic attributes on three low-quality seismic profiles located close to the Mw 6.5 main-shock of the 2016-2017 seismic sequence. The main goal is to squeeze additional information from the 2D data obtaining as much constraints as possible on the geological structures responsible for the seismicity in the area by defining:

- geological/structural setting at depth (e.g. depth of the basement and its involvement)
- trace of potentially seismogenic faults (connection between the active faults mapped at the surface and earthquake's foci).

Any improvements achievable on the data quality and visualization, for example an increase of the resolution and/or an enhancement of the lateral discontinuity of seismic reflectors, would represent a valuable contribution considering the limited data availability in this area. We think that this innovative approach to seismotectonic research can be extended to other on-shore seismically active areas in the world, especially if covered only by sparse vintage low-quality seismic surveys. In such cases, we think the seismotectonic research may benefit of the potential and improvements generated by the seismic attributes.

96 **2 Geological framework and seismotectonics of the study area**

97 The study area is located in the southeastern part of the Northern Apennines fold and thrust belt, including the Umbria-
98 Marche Domain and the Laga Domain, separated by an important regional tectonic structure, known as the M. Sibillini thrust
99 (MSt) (Fig. 1). The Umbria-Marche domain involves the rocks of the sedimentary cover, represented by three main units
100 (top to bottom), characterized by different interval velocities (Bally et al., 1986; Barchi et al., 1998; Porreca et al., 2018):
101 1) on top, the Laga sequence (Late Messinian – Lower Pliocene, up to 3000 m thick, average seismic velocity; $V_{av} = 4000$
102 m/s), consisting of siliciclastic turbidites made by alternating layers of sandstones, marls and evaporites, deposited in marine
103 depositional environment (Milli et al., 2007; Bigi et al., 2011); it is and outcropping in the eastern sector of the study area
104 (i.e. Laga Domain); 2) the carbonate formations (Jurassic-Oligocene, about 2000 m thick, $V_{av} = 5800$ m/s), formed by
105 pelagic limestones (Mirabella et al., 2008) with subordinated marly levels overlying an early Jurassic carbonate platform
106 (Calcare Massiccio Fm.), mainly outcropping in the Umbria-Marche Domain; 3) the Late Triassic evaporites (1500–2500 m
107 thick, $V_{av} = 6400$ m/s), consisting in alternated layers of anhydrites and dolomites (Anidriti di Burano Fm. and and
108 Raethavicula Contorta beds; Martinis & Pieri, 1964), never outcropping and intercepted only by deep wells (Porreca et al.,
109 2018 and references therein). For further details on the stratigraphic characteristics of the area, we remind to the works of
110 Centamore et al. (1992) and Pierantoni et al. (2013).

111 These units rest on a basement with variable lithology (Permian-Late Triassic, $V_{av} = 5100$ m/s) that never crops out in the
112 study area (Vai, 2001), but only intercepted by deep wells (Bally et al., 1986; Minelli & Menichetti, 1990; Anelli et al.,
113 1994; Patacca & Scandone, 2001).

114 This sedimentary sequence is involved in the Late Miocene fold and thrust belt including a set of N-S trending anticlines,
115 formed at the hangingwall of the W-dipping arc-shaped major thrusts. The most important compressional structure is the M.
116 Sibillini thrust (MSt, Koopman, 1983; Lavecchia, 1985), where the Umbria-Marche Domain is overthrust on the Laga
117 Domain.

118 This is a geologically complex region, where in the past the analysis of 2D seismic profiles have produced contrasting
119 interpretations of the upper crust structural setting, i.e. thin- vs. thick-skinned tectonics, fault reactivation/inversion and
120 basement depth (Bally et al., 1986; Barchi, 1991; Barchi et al., 2001; Bigi et al., 2011; Calamita et al., 2012). A review of the
121 geological history of this area has recently been provided by Porreca et al. (2018). These authors propose a tectonic style
122 characterized by coexistence of thick- and thin-skinned tectonics with multiple detachments localized at different structural
123 levels.

124 These compressional structures have been later disrupted by the extensional faults since the Late Pliocene (Fig.1) (Blumetti
125 et al., 1993; Boncio et al., 1998; Brozzetti & Lavecchia, 1994; Calamita & Pizzi, 1994; Pierantoni et al., 2013).

126 The Late Pliocene-Quaternary extensional tectonic phase, characterized by NNW-SSE striking normal faults, consistent with
127 the present-day active strain field as deduced by geodetic data (e.g. Anderlini et al., 2016). The latter have high dip angles
128 (50-70°) and can be synthetic or antithetic structures (WSW or ENE dipping, respectively) dipping normal faults. These

faults were also responsible of the tectono-sedimentary evolution of intra-mountain continental basins (Calamita et al., 1994; Cavinato and De Celles, 1999). The most evident Quaternary basins of this part of the Apennines are the Castelluccio di Norcia and Norcia basins (Fig.1), located at 1270 and 700 m a.s.l., here named CNb and Nb respectively. A phase of lacustrine and fluvial sedimentation infilled the two basins with hundred meters of deposits, characterized by fine clayey to coarse grained material (Blumetti et al., 1993; Coltorti and Farabollini, 1995). The area is affected by frequent moderate magnitude earthquakes ($5 < M_w < 7$) and has a high seismogenic potential revealed by both historical and instrumental data (e.g. Barchi et al., 2000; Boncio and Lavecchia, 2000; Basili et al., 2008; Rovida et al., 2016; DISS Working Group, 2018). The major seismogenic structures recognized in the area are the Norcia fault (Nf) and the M. Vettore fault (Vf). The Norcia fault (Nf, Fig.1) is associated to several historical events (Galli et al., 2015; Pauselli et al., 2010; Rovida et al., 2016), probably including the 1979 earthquake (Nottoria-Preci fault, Deschamps et al., 1984; Brozzetti & Lavecchia, 1994; Rovida et al., 2016) and the largest event in 1703 ($M_e = 6.8$, Rovida et al., 2016). The Vettore fault (Vf) in part of the easternmost alignment whose historical and pre-historical activity was recognized by paleoseismological and shallow geophysical surveys (Galadini & Galli, 2003; Galli et al., 2008; Ercoli et al., 2013; Ercoli et al., 2014; Galadini et al., 2018; Galli et al., 2018; Cinti et al., 2019; Galli et al., 2019). This system was reactivated during the 2016-2017 sequence characterized by multi-fault ruptures occurred within few months (nine $M > 5$ earthquakes at hypocentral depth < 12 km between August 2016 – January 2017) having characteristics comparable to previous seismic sequences in Central Italy (e.g. L'Aquila 2009 and Colfiorito 1997-1998, Valoroso et al., 2013 and Chiaraluce et al., 2005). The strongest mainshock of ($M_w 6.5$) occurred on 30th October 2016 (Chiaraluce et al., 2017; Chiarabba et al., 2018; Gruppo di Lavoro Sequenza Centro Italia, 2019; Improta et al., 2019; ISIDe working group, 2019), generating up to 2 m (vertical offset) co-seismic ruptures (Civico et al., 2018; Gori et al., 2018; Villani et al., 2018a; Brozzetti et al., 2019), mainly localized along the Mt. Vettore fault (blue thin lines in Fig. 1). Despite of the large amount of surface data collected (Livio et al., 2016; Pucci et al., 2017; Wilkinson et al., 2017; De Guidi et al., 2017; Brozzetti et al., 2019), the deep extension of the Norcia and Castelluccio antithetic and synthetic faults (particularly Nf and Vf), and the overall complex structure of the area are still debated (Lavecchia et al., 2016; Porreca et al., 2018; Bonini et al., 2019, Cheloni et al., 2018, Improta et al. 2019).

3 Data

We have performed seismic attributes analysis on three W-E trending 2D seismic reflection data crossing the epicentral area between the Umbria and Marche regions (Central Italy, Fig.1). These seismic profiles are part of a much larger, unpublished dataset including 97 seismic profiles and few boreholes, drilled for hydrocarbon exploration by ENI in the period 1970-1998. The data quality is extremely variable (medium/poor) with limited fold (generally < 60 traces / Common Mid-Point), mainly due to environmental and logistical factors. Among those, we can list the different acquisition technologies, a limited site access, the complex tectonic setting and especially the different (contrasting) outcropping lithologies (e.g. Mazzotti et al.,

2000, Mirabella et al., 2008). The eastern area, showing higher data quality, consists of siliciclastic units of the Laga foredeep sequence, located at the footwall of the MSt. On the contrary, the lowest S/N recordings coincide with outcropping carbonates formations and Quaternary deposits.

The analysed lines include seismic reflection profiles NOR01 (stack, 14 km long) and NOR02 (time-migrated, 20 km long, partially parallel to NOR01 on the western sector) located west and east to the Nb, respectively; CAS01 (stack, 16 km long), located more to the south crossing the Cascia village (Fig. 1).

NOR01 and CAS01 were acquired using a Vibroseis source, whilst explosives were used for NOR02; all the lines are displayed in Two-Way-Travel-Time (TWTT) limited to 4.5 s. The amplitude/frequency spectra (computed on the entire time window) of the processed lines show a bandwidth in a range 10-50 MHz, with the NOR02 spectrum displaying a slighter high frequency content (Tab.1). Assuming the average peak frequency of 20 Hz, a vertical resolution of ca. 80 m can be estimated (average carbonate velocity = 6 km/s; parameters in Table 1). Some processing artefacts are visible in NOR01 as a straight horizontal signal at ca. 1 s (yellow dashed line and label A in Fig. 2a), and another in CAS01 (Fig. 3a). The data display may benefit of potential improvements by selecting seismic attributes to be tested with different calculation parameters. Therefore, we loaded the lines into the software OpendTect (OdT, <https://www.dgbes.com/index.php/software#free>), setting up a common seismic datum of 500 m. Unfortunately, deep borehole stratigraphy is not available for the study area (all details about surrounding deep wells have been already summarized in Porreca et al., 2018). The OdT seismic project was enriched also by ancillary data, extracted by a complementary GIS project (QGis, <https://www.qgis.org/it/site/>). As visible in Fig. 1, we have included a detailed summary of the main normal faults and surface ruptures of the area (Civico et al., 2018; Villani et al., 2018a; Brozzetti et al., 2019), obtained after carefully checking the most important regional geological maps and fault patterns (Koopman, 1983; Centamore et al., 1993; Pierantoni et al., 2013; Carta Geologica Regionale 1:10'000 – Regione Marche, 2014; Carta Geologica Regionale 1:10'000 – Regione Umbria, 2016; Ithaca database, <http://www.isprambiente.gov.it/it/progetti/suolo-e-territorio-1/ithaca-catalogo-delle-faglie-capaci>); as well as the most recent works published in literature (e.g. Brozzetti et al., 2019; Porreca et al., 2020). The topography was also included using a regional 10 meters resolution DTM (Tarquini et al., 2007; Tarquini et al., 2012). The other important external data-set consists of seismological data, i.e. inferred location and approximated fault geometry as suggested by the focal mechanisms of the mainshocks and by the distribution of the aftershocks (Iside database, <http://iside.rm.ingv.it/iside/> and Chiaraluce et al., 2017). The integration of such information in a pseudo-3D environment offered us a multidisciplinary platform to clearly display the seismic lines and to link surface data and the deep geologic structures at hypocentral depth.

4 Methods

The seismic reflection data interpretation is generally accomplished through the definition of specific signal characteristics (seismic signature), supported by the geological knowledge of the study area. A standard seismic interpretation is affected by a certain degree of uncertainty/subjectivity (particularly in case of poor data quality), because is generally based on a

195 qualitative analysis of amplitude, geometry and lateral continuity of reflections. Over the last years, the introduction of
196 seismic attributes and related automated/semi-automated procedures had an important role in reducing the subjectivity of
197 seismic interpretation. A seismic attribute is a descriptive and quantifiable parameter that can be calculated on a single trace,
198 on multiple traces, or 3D volumes and can be displayed at the same scale as the original data. Seismic data can be therefore
199 considered a composition of constituent attributes (Barnes, 1999, Taner et al., 1979, Forte et al., 2012). Their benefits have
200 been first appreciated in 2D/3D seismic reflection data (Barnes 1996; Taner et al., 1979; Barnes, 1999; Chen and Sidney,
201 1997; Taner, 2001; Chopra and Marfurt, 2007; Chopra and Marfurt, 2008; Iacopini and Butler, 2011; Iacopini et al., 2012;
202 McArdle et al., 2014; Botter et al., 2014; Hale, 2013 for a review; Marfurt and Alves, 2015; Forte et al., 2016) and, more
203 recently, also in other reflection techniques like the Ground Penetrating Radar (e.g. McClymont et al., 2008; Forte et al.,
204 2012; Ercoli et al., 2015, Lima et al., 2018). In this work, we have tested several post-stack attributes on three 2D vintage
205 seismic lines (original seismic data in the supplementary material in Fig.1s), and starting our analysis by using first well-
206 known and widely used attributes like the instantaneous amplitude, phase, frequency, and their combinations, also using
207 composite multi-attribute (i.e. simultaneous overlay and display of different attributes e.g. primarily phase, frequency,
208 envelope; Chopra and Marfurt, 2005; Chopra and Marfurt, 2011). Later on, we have also tested attributes (e.g. coherency and
209 similarity, generally more efficient on 3D volumes) but without obtaining positive outcomes, due to limited vertical and
210 spatial resolution of the data. Among tested attributes, we selected three attributes that resulted in the best images (provided
211 in Figs. s2, s3 and s4 of the supplementary material without any line drawing or labels), making possible to detect peculiar
212 seismic signatures of regional seismogenic layers and fault zones. The attributes, computed using OdT software, are:

213
214 **“Energy” (EN):** one of the RMS amplitude-based attributes, it is defined as the ratio between the squared sum of
215 the sample values in a specified time-gate and the number of samples in the gate (Taner, 1979, Gersztenkorn &
216 Marfurt, 1999, Chopra & Marfurt, 2005, Chopra & Marfurt, 2007, for a review of formulas see Appendix A in
217 Forte et al., 2012). The Energy measures the reflectivity in a specified time-gate, so the higher the Energy, the
218 higher is the reflection amplitude. In comparison to the original seismic amplitude, it is independent of the polarity
219 of the seismic data being always positive, and in turn preventing the zero-crossing problems of the seismic
220 amplitude (Forte et al., 2012, Ercoli et al., 2015, Lima et al., 2018, Zhao et al., 2018). This attribute is useful to
221 emphasize the most reflective zones (e.g. characterization of acoustic properties of rocks). It may also enhance
222 sharp lateral variations in seismic reflectors, highlighting discontinuities like fractures and faults. In this work, we
223 set a 20 ms time window (i.e. about the mean wavelet length), obtaining considerable improvements in the
224 visualization of higher acoustic impedance contrasts.

225 **“Energy gradient” (EG):** it is the first derivative of the energy with respect to time (or depth). The algorithm
226 calculates the derivative in moving windows and returns the variation of the calculated energy as a function of time
227 or depth (Chopra & Marfurt, 2007; Forte et al., 2012). It is a simple and robust attribute, also useful for a detailed
228 semi-automatic mapping of horizons with a relative low level of subjectivity. The attribute acts as an edge detection

tool, effective in the mapping of the reflection patterns as well as the continuity of both steep discontinuities like faults and fractures, and channels, particularly in slices of 3D data (Chopra & Marfurt, 2007). In this work, we have used the same time window of the Energy, obtaining considerable improvements in the visualization not only of the strong acoustic impedance reflectors but particularly in the faults imaged in the shallowest part of the seismic sections.

Pseudo-relief (PR): it is obtained in two steps: the energy attribute is first computed in a short time window, then followed by the Hilbert transform (phase rotation of -90 degrees). The Pseudo-relief is considered very useful in 2D seismic interpretation to generate “outcrop-like” images allowing an easier detection of both faults and horizons (Bulhões, 1999; Barnes et al., 2011; Vernengo et al. 2017, Lima et al., 2018). In this work, considerable display improvements have been obtained using the Pseudo-relief computed in a window of 20 ms. In comparison to the standard amplitude, it better highlights the reflection patterns and thus the continuity/discontinuity of reflectors, enhancing steep discontinuities and fault zones.

5 Results

The Figs. 2, 3 and 4 show the comparison between the original seismic lines in amplitude and the images obtained after the attribute analysis, revealing significant improvements in the visualization and interpretability of the geophysical features. In the profiles NOR01, CAS01 and NOR02 we focus our analysis on three types of geophysical features highlighted by the attributes: sub-horizontal deep reflectors, low-angle and high-angle discontinuities. The main faults known at the surface (Fig.1) have been also plotted on top of each seismic line.

In the original seismic line NOR01 (Fig. 2a), the overall low S/N ratio hampers the detection of clear and continuous reflectors. At ca. 1 s a horizontal processing artefact is visible (label A, yellow dots), possibly related to a windowed filter. The most prominent sub-horizontal reflections (labelled H) are located in the central portion between 2-3 s (TWT) (strong reflectors in the black box i). Shallower and less continuous reflectors are also visible in the eastern side of the profile, beneath the Nb (black box ii). The EN attribute (Fig. 2b) enhances the reflectivity contrast, better focusing the high-amplitude, gently W-dipping reflector H (blue arrows) and also outlining its lateral extension. In this image most of the reflected energy is concentrated on its top at ca. 2.5 s, so that it is readily apparent that H separates two seismic facies, with higher (top) and lower (bottom) amplitude response, respectively. The EG and PR attributes of NOR01 (Figs. 2c, 2d) better show the geometry of horizon H, characterized by a continuous, ca. 8 km long, package of reflectors (ca. 200 ms thick) having common characteristics in terms of reflection strength and period. In the eastern part of the profile, below the Nb, the EG and PR attributes also enhance two major opposite-dipping high-angle geophysical features (red arrows in fig. 2c and 2d), crossing and disrupting the shallower reflectors. The W-dipping lineament propagates down to ca. 2.5 s, intercepting the eastern termination of the reflector H. The two discontinuities border a relatively transparent, shallow seismic facies, corresponding to the area where the Nb crops out. In the same area, the reflectors are pervasively disrupted by other, minor discontinuities.

262 The original seismic reflection line CAS01 (Fig. 3a) displays a generalized high-frequency noise content. As in NOR01, a
 263 shallow processing artefact (A, yellow dots) is visible and possibly related to a filter. Fragmented packages of high-
 264 amplitude reflectors (H) are visible at the same time interval observed in NOR01 (ca. 2.5 s), in both the western (black box i,
 265 in Fig. 3a) and, more discontinuous, in eastern part of the line (black box ii, in Fig. 3a). The EN attribute (Fig. 3b)
 266 emphasizes the presence of the H reflector better focusing the reflectivity (blue arrows). Both the EG and PR attributes (Figs.
 267 3c and 3d) further help to delineate the reflector H. The steeper discontinuities have been analysed mainly in the western part
 268 of the profile, closer to the 2016-2017 seismically active area. A major high-angle, east-dipping discontinuity has been traced
 269 at about 13 km (alignment of red arrows in Fig. 3c and 3d).

270 The original seismic line NOR02 (Fig. 4a), displays geophysical features similar to the ones detected in NOR01 and CAS01.
 271 This seismic profile shows a generalized poor continuity of the reflectors, with the exception of the eastern side, where a set
 272 of west-dipping, coherent reflections can be recognized: the higher S/N ratio of this part of the section is due to the
 273 outcropping turbidites of Laga sequence, which are known to favour the energy penetration, respect to the carbonates (e.g.
 274 Bally et al., 1986; Barchi et al., 1998). The prominent reflection H, gently east-dipping and relatively continuous for more
 275 than 8 km (black box in Fig 4a), is located in the centre of the line, at greater depth (3.2–3.5 s TWT), respect to the
 276 previously described NOR01 and CAS01 profiles. As in the previous cases, the EN attribute (Fig. 4b) effectively focuses the
 277 horizons reflectivity, emphasising the strong amplitude of the reflector H (blue arrows). The EG and PR attributes (Figs. 4c
 278 and 4d) improve the overall visualization of the reflection patterns, aiding the detection of the low-angle and high-angle
 279 discontinuities. A major westward low-angle discontinuity T (green dots in Figs.4c and 4d) crosses the entire profile,
 280 descending from ca. 2 s (East) to ca. 4 s (West), where it interrupts marks the continuity of the reflector H. Several high-
 281 angle discontinuities have been traced along the section, marked by alignments of red arrows in Figs. 4c and 4d. The most
 282 important alignments have been recognised beneath the two major Quaternary basins (i.e. Nb and CNb) crossed by the
 283 profile: in both cases, major W-dipping alignments can be traced from the near surface, where they correspond to the eastern
 284 border of the above mentioned basins, down to a depth of ca. 4 s TWT. Other discontinuities, W and E dipping, have been
 285 traced in the hanging-wall of these two major alignments. In the seismic volume bounded by these features, many secondary
 286 (minor) discontinuities pervasively cross-cut the set of reflectors, producing a densely fragmented pattern. Unfortunately,
 287 limited resolution and data quality in the deeper part of the section hampers a univocal interpretation of the cross-cutting
 288 relationships between the low-angle discontinuity T and the major W-dipping high-angle discontinuity: two alternative
 289 interpretations are here possible, that will be discussed in detail in the next paragraph 6.

290 The global improvement in the dataset interpretability can be better appreciated in a 3D visualization of the seismic
 291 attributes, also using multi-attribute displays (Fig. 5). Such images better clarify the deep geometry of the main reflectors
 292 and the location of the geophysical discontinuities, later interpreted on the light of known and debated tectonic structures on
 293 the study area. In Fig. 5a we report a 3D perspective of the seismic line NOR02, after combining in transparency the EN
 294 attribute with the PR attribute (EN+PR). The reflectors characteristics and a pattern of discontinuities are clearly visible at
 295 different levels of detail, and the link with the faults at surface is again proposed (red segments on the top). The two boxes

(blue and black colours in Fig.5a, respectively) point out the two most representative seismic facies described above. The Fig. 5b and 5c display a comparison of the signature of reflector H in the standard amplitude line (SA) (Fig. 5b) and in a version including PR attribute in transparency with SA itself. Again, in the inserts Figs. 5d and 5e, an analogous data comparison shows the scarce detectability of the dense pattern of steep discontinuities in the original seismic profile. The Fig.5e displays the enhancement obtained plotting the PR attribute plus SA in transparency, greatly improving the visualization of the dense reflectors' fragmentation.

An analogous 3D multi-display of attributes EN and PR is proposed in Fig. 6a for the seismic line NOR01. The comparison between the original line (blue box in Fig. 6b) and the EN+PR (Fig. 6c) shows the improved and peculiar signature of the strong reflector H. The black box again reports the original plot vs. the PR+SA, which clearly boost the visualization of the high-angle discontinuities.

6 Data Interpretation: new elements and insights on the deep geological structure of the study area.

The comparison between the original seismic data and the images obtained by the attribute analysis ensures an easier and accurate interpretation of the geophysical features, allowing to extend the surface geological data in depth. The geological interpretation of these features requires a thoughtful comparison and calibration with the other data available for the area, e.g. geological and structural maps, co-seismic ruptures, high-resolution topography and mainshocks hypocentres. The seismic attributes provide a multiple view of the original data through the enhancement of different physical quantities. Therefore, peculiar geophysical signatures have been detected delineating interpretative criteria (e.g. high amplitude reflectors, phase discontinuities, fragmented reflectors patterns etc...). Such geophysical features, after a first order interpretation, fit well with the main outcropping geologic structures. Using the same interpretation criteria, other surface-uncorrelated discontinuities, poorly visible in the original amplitude lines, are apparent at a more detailed scale after the attributes analysis. In addition, deep reflectors showing a common signature have been also recognized, revealing a regional character. The geological meaning and the relation of such geophysical features with the surface geology and with the hypocentre location of the main earthquakes are hereafter discussed.

Fig. 7 reports a global pseudo-3D view of the study region summarizing all the data analysed across the area, together with all the faults mapped at surface (Fig. 7a) and the location of Mw 6.5 mainshock (30th October 2016). The two seismic images in Figs. 7b and 7c have been obtained using again a multi-attributes visualization, overlapping the PR and EN attributes in transparency with the original seismic lines NOR01 and NOR02, following the same procedure used for the images in Figs. 5 and 6. The Figs. 7d and 7e propose an interpretation of the geophysical features being associated to the faults highlighted after an accurate analysis of the discontinuities of attributes signatures, as shown in fig. s5. Regarding the deeper parts of the sections, the reflector H (blue arrows and dashed line) highlighted in NOR01 (and in CAS01), presents a seismic character and an attribute signature compatible with the deeper reflector of NOR02 beneath CNb. This set of reflectors is interpreted as a high acoustic impedance contrast, possibly related to an important velocity inversion occurring between the Triassic Evaporites (anhydrites and dolostones, $V_p \approx 6$ km/s, e.g. Trippetta et al., 2010) and the underlying

acoustic Basement (metasedimentary rocks, $V_p \approx 5$ km/s, sensu Bally et al., 1986). Comparable deep and prominent reflectors were detected also in other legacy data across adjacent regions of the Umbria-Marche Apennines (e.g. Barchi et al., 1998; Mirabella et al., 2008). This fact confirms its regional importance, particularly because it represents a lithological control marking a seismicity cutoff (Chiaraluce et al., 2017; Mirabella et al., 2008; Porreca et al., 2018; Mancinelli et al., 2019).

As already pointed out in the previous figures, the continuity of the deep reflector H is interrupted in the western edge by the low-angle west-dipping discontinuity T crossing NOR02 (Fig. 7e), and not identified in the interpretation by Porreca et al. (2018). This deep discontinuity can be interpreted as a regional thrust emerging at the footwall of the MSt, in an easternmost sector of the region, and corresponding to the Acquasanta thrust (Centamore et al., 1993).

In NOR01, the most visible high-angle seismic discontinuity is marked by an E-dipping fault, bordering the western area of Nb (Fig. 7d). The location and geometry of this fault, whose presence is still debated in literature, perfectly match its supposed position at surface (Blumetti et al., 1993; Pizzi et al., 2002; Galadini et al., 2018; Galli et al., 2018). Therefore, it may represent the first clear geophysical evidence at depth of the antithetic normal fault of Norcia (aNf), suggested by morphological studies (Blumetti et al., 1990) and paleoseismological records (Borre et al., 2003) and belonging to a conjugate tectonic system (Brozzetti & Lavecchia, 1994; Lavecchia et al., 1994).

The other principal structure is a synthetic (W-dipping) high-angle, normal fault bordering the eastern flank of Nb (“Nottoria-Preci fault” – Nf, Calamita et al., 1982; Blumetti et al., 1993; Calamita & Pizzi, 1994). The Nf in NOR02 is marked by a downward propagation of a steep alignment (continuous red line in Fig. 7d). This area is also fragmented by several minor strands parallel to the main faults (dashed lines in Fig. 7d). In particular, several west-dipping minor faults are observed in Fig. s5a, where the shallower high-amplitude reflectors of the PR attribute are clearly disrupted.

Another discontinuity interpretable as a deep fault is visible slightly eastward, close to the mainshock hypocentral location (Fig. 7e). This E-dipping discontinuity, emphasized by the attribute analysis, does not reach the surface. The presence of this blind fault has been suggested by several authors in relation to the occurrence of an aftershock (Mw 5.4), which “ruptured a buried antithetic normal fault on eastern side of Nb, parallel to the western bounding fault of CNb” (Chiaraluce et al., 2017, Porreca et al., 2018 and Improta et al., 2019).

The central portion of NOR02, corresponding to CNb, shows a peculiar reflection fabric, dominated by high-angle discontinuities, interpreted as two opposite-dipping normal faults bordering the basin, well matching their positions mapped at surface (cfr. Pierantoni et al., 2013). The main fault is here represented by the W-dipping Vf, reactivated during the 2016 earthquake (e.g. Villani et al., 2018a) which can be traced from its surface expression downward to hypocentre location. Parallel to the Vf, several high-angle seismic discontinuities representing minor normal faults cross-cut the gently W-dipping reflectors (Fig. 7e, further details in Fig. s5).

Analogous considerations can be extended to a multitude of E-dipping steep discontinuities at the westward side of CNb. These may represent the evidence of an antithetic fault (aVf), and several minor fault strands characterized by high-angle dip at shallow depths (Villani et al., 2018b). Such a fault appears connected at about 2-3 s to the W-dipping master Vf,

363 producing a conjugate system geometry like observed at Nb (Fig. 8e). At depth of 3.2 s, Vf fault clearly interrupt the
364 continuity of the top basement reflector H, whilst the relationships with the Acquasanta thrust (low-angle discontinuity T) is
365 more ambiguous. Two alternative interpretations can be proposed, schematically represented in Fig. 8. In Fig. 8a, we
366 propose a model in which Vf merges into the deep Acquasanta thrust, suggesting a negative inversion, as a mechanism
367 proposed by other authors (e.g. Calamita and Pizzi, 1994; Pizzi et al., 2017; Scognamiglio et al., 2018). In Fig. 8b, Vf cuts
368 and displaces the Acquasanta thrust, following a steeper trajectory (ramp) (Lavecchia et al., 1994 and Porreca et al., 2018).
369 For both Norcia and Castelluccio di Norcia basins, the interpreted data suggest two slightly asymmetric fault systems, due to
370 conjugate sets of seismogenic master faults (Ramsay & Huber, 1987) producing a “basin-and-range” morphology (Serva et
371 al., 2002), progressively lowering the topography from east to west, and forming two major topographic steps, corresponding
372 to the CNb and Nb, respectively. Such fault systems control the evolution of the continental basins, and are associated with
373 several complex sets of secondary strands building up complex fault zones. Such fault strands are able to produce surface
374 ruptures in future earthquakes, as occurred in the 2016-2017 seismic swarm, and would require further studies through high-
375 resolution geophysical investigations (e.g. Bohm et al., 2011 and Villani et al. 2019).
376 The results of the seismic interpretation proposed in this work, supported by the attribute analysis, suggests that such
377 synthetic and antithetic tectonic structures at the Norcia and Castelluccio di Norcia basins cannot be actually simplified as a
378 unique fault plane, but they could be imaged as complex and fractured fault zones, like also conceived also by Ferrario &
379 Livio (2018) as “distributed faulting and rupture zones”.

380 **Conclusions**

381 Taking into account the important role that seismic attributes play in the O&G industry, their usage might be of high interest
382 also for improving the geological interpretation of vintage seismic data, aimed to scientific purposes. When applied to
383 seismically active areas, this analysis may contribute to constrain the buried geological setting and, combined with
384 seismological data (i.e. focal mechanisms and accurate earthquake locations), may have high potential impact for the
385 identification and characterization of the seismogenic sources and eventually on earthquakes hazard assessment.

386 This contribution presents one of the first case studies where the seismic attribute analysis is used for seismotectonic
387 purposes. The analysis is applied to seismic reflection data collected more than 30 years ago in Central Italy. Such industrial
388 data, nowadays irreproducible in regions where the seismic exploration is forbidden, represent, despite the limited quality, a
389 unique source of information on the geological setting at depth.

390 This contribution reveals that the use of seismic attributes can improve the interpretation for the subsurface assessment and
391 structural characterization. Certainly, the overall low quality of the data sets did neither allow to extract rock petrophysical
392 parameters, nor more quantitative information. However, the attributes aid the seismic interpretation to better display the
393 reflection patterns of interest and provided new and original details on complex tectonic region in Central Italy. Our attribute
394 analysis considerably improved the overall interpretability of the vintage seismic lines crossing the epicentral area of the
395 2016-2017 Norcia-Amatrice seismic sequence. In particular, we detected peculiar seismic signatures of a deep horizon of

396 regional importance, corresponding, most probably, to the base of the seismogenic layer, and to the location and geometry of
397 the complex active fault zones. Those consists of several secondary synthetic and antithetic splays in both the Quaternary
398 basins, generally consistent with its surface location, but also reinforcing the existence of several faults with no clear surface
399 outcrop, issue currently much debated in the literature.

400 The analysis and integration of the seismic attributes allowed the determination of the deep continuation of the (known and
401 supposed) faults and, the recently mapped co-seismic ruptures at surface, providing a pseudo-3D picture of the buried
402 structural setting of the area. The seismic attributes may help to reduce the gap between the surface geology and deep
403 seismological data, also revealing a high structural complexity at different scales, which cannot generally be detected only
404 by using traditional interpretation techniques. This approach has shown the potential of the attribute analysis, that even when
405 applied on 2D vintage seismic lines, may significantly extend the data value. For all these reasons, we strongly encourage its
406 application for seismotectonic research, aimed to provide new information and additional constraints across other seismically
407 active regions around the world.

408 **Acknowledgments**

409 We are grateful to Eni S.p.A. for providing an inedited set of seismic reflection lines after the 2016-2017 seismic crisis in
410 Central Italy (raw data available in Fig.2 of supporting information). The original seismic reflection lines used in this study
411 are available in the supplementary material, well as the high-resolution Figures 2,3,4,7. The authors are very grateful to dgB
412 Earth Sciences and to QGIS teams for providing the academic software used in this work. We thank Dr. Christian Berndt and
413 Dr. David Iacopini for their valuable comments provided for this paper. We also thank the two anonymous reviewers for
414 their patience in providing useful suggestions and detailed corrections that considerably improved this work.

754 **Table 1**

Parameters	NOR01	NOR02	CAS01
Source	Vibroseis	Explosive	Vibroseis
Length (km)	14	20	16
Number of traces	938	825	1069
Samples/trace	1600	1750	1600
Time window (ms)	6400	7000	6400
Sampling interval (ms)	4	4	4
Trace interval (m)	15	25	15
Mean Spectral amplitude (dB)			

755

756 **Figures and Tables captions:**

757 **Figure 1:** Simplified geological map of the study area (modified after Porreca et al., 2018), showing the 2D seismic
758 data tracks, the 2016-2017 mainshock locations, beachballs with earthquakes magnitude, the surface ruptures and
759 the known master faults. Norcia basin (Nb), Castelluccio di Norcia basin (CNb), Monti Sibillini Thrust (MSt), Mt.
760 Vettore fault (Vf), antithetic (aVf), Norcia fault (Nf), antithetic Norcia fault (aNf).

761 **Figure 2:** Stack version of NOR01; a) standard reflection amplitude line, in the insert on the top the main faults
762 mapped at surface. The label A underlines a processing artefact whilst the boxes i) and ii) indicate the clearest
763 reflectors; b) Energy attribute enhancing a strong reflectivity contrasts (H); c) Energy Gradient, improving the
764 detection of dipping alignments and continuity of reflectors; d) Pseudo-Relief enhancing the reflection patterns cross-
765 cut by steep discontinuities. Nf Norcia fault, aNf antithetic Norcia fault at surface, yellow dots = A, blue arrows = H,
766 red arrows = indication of the main lineaments and areas with major discontinuities highlighted by the attributes.

767 **Figure 3:** Stack version of CAS01: a) standard reflection amplitude line, on the top insert the main faults mapped at
768 surface. The label A underlines a processing artefact, whilst the boxes i) and ii) indicate the main visible reflectors; b)
769 Energy attribute c) Energy Gradient attribute; d) Pseudo-Relief, showing the strong regional reflector H. A high-
770 angle discontinuity on the western margin corresponds with the southern prosecution of aNf inferred at surface. aNf
771 antithetic Norcia fault at surface, yellow dots = A, blue arrows = H, red arrows = indication of the main lineaments
772 and main signal discontinuities enhanced by the attribute's analysis.

773 **Figure 4: Time migrated version of NOR02; a) standard reflection amplitude line, on the top insert the main faults**
774 **mapped at surface; the box i) points out the most visible reflector b) Energy attribute displaying the reflector H and a**
775 **possible low angle discontinuity (T); c) Energy Gradient attribute, showing the main lineaments detected; d) Pseudo-**
776 **Relief, improving the reflectors continuity/discontinuity and the display of the areas with main signal discontinuities**
777 **(red polygon) after the attribute computation. Nf Norcia fault, aNf antithetic Norcia fault; Vf Mt. Vettore fault, aVf**
778 **antithetic Mt. Vettore fault at surface, yellow dots = A, blue arrows = H, green dots = T, red arrows = indication of**
779 **the main lineaments**

780 **Figure 5: Multi-attribute display of NOR02, displaying the position of the main faults at surface in relation to their**
781 **deep seismic attribute signature; a) Energy+Pseudo-Relief attributes, the seismic facie in the blue box is compared**
782 **with the original seismic line (b) and Energy+Pseudo-Relief (c) for comparison; the same plot for the black box is**
783 **reported in figures d) and e) (original line and Pseudo-Relief+Standard Amplitude, respectively).**

784 **Figure 6: Multi-attribute rendering of NOR01, displaying the position of the main faults at surface in relation to their**
785 **deep seismic attribute signature.; a) Energy+Pseudo-Relief attributes, the seismic facie in the blue box showing a**
786 **strong set of deep reflectors is compared with the original seismic line in b) and Energy+Pseudo-Relief c). An**
787 **analogous plot of the black box reports in figures d) and e) the original line and the combination Pseudo-**
788 **Relief+Standard Amplitude.**

789 **Figure 7: Integration of surface and subsurface data; a) 3D-view (DTM by Tarquini et al., 2012) of a W-E section**
790 **crossing the Norcia and Castelluccio di Norcia basins (Nb and CNb), and the mainshock locations (ISIDE working**
791 **group, 2016). Surface and deep data allow to correlate the master faults and coseismic ruptures mapped at the**
792 **surface. The multi-attribute display of NOR01 (b) and NOR02 (c), is obtained overlapping the reflection amplitude in**
793 **transparency with the Pseudo-Relief and Energy attributes (red palette). The black boxes centred on Nb and CNb**
794 **have been magnified for . An important improvement of the subsurface images provides additional details on the**
795 **seismogenic fault zones: the sketches d) and e) show an interpretation reporting two conjugate basins, showing**
796 **master faults along the borders and several minor synthetic and antithetic splays.**

797 **Figure 8: The figure proposes two alternative interpretations of the relation between the normal Vf, the deep**
798 **Acquasanta thrust (T) and the Top- Basement reflector (H). Fig. 8a reports a model in which Vf merges into the deep**
799 **Acquasanta thrust, suggesting a negative inversion, as a mechanism proposed by some authors (e.g. Calamita and**
800 **Pizzi, 1994; Pizzi et al., 2017 Scognamiglio et al., 2018). In Fig. 8b, Vf cuts and displaces the Acquasanta thrust,**
801 **following a steeper trajectory (ramp) as proposed by other authors (Lavecchia et al., 1994 and Porreca et al., 2018;**
802 **2020).**

803

804 **Table 1: List of some parameters extracted from SEG-Y headers and three mean frequency spectra of the three**
805 **seismic lines. An approximate vertical resolution equal to 75 m was derived ($v=6$ km/s).**

806

807 **Fig.s1: Figure summarizing the three original seismic reflection profiles in amplitude used in this work.**

808 **Fig.s2: Figure 2 reporting the computed seismic attributes without any line drawing and labels.**

809 **Fig.s3: Figure 3 reporting the computed seismic attributes without any line drawing and labels.**

810 **Fig.s4: Figure 4 reporting the computed seismic attributes without any line drawing and labels.**

811 **Fig.s5: The image is a magnification of two portions of NOR01 and NOR02, focused on the two basins of Norcia and**
812 **Castelluccio di Norcia, aiming to better display the discontinuities enhanced by the Pseudo Relief; a) PR on the Nb**
813 **and interpretation of the primary (continuous lines) and secondary faults (dashed lines); b) PR on the CNb and**
814 **interpretation of the primary (continuous lines) and secondary (dashed lines) faults bordering the basin.**

815 **The continuous red lines are the primary normal faults bounding Nb, whilst the dashed red segments compose a**
816 **pattern of possible secondary splays within the basin.**
