13 **1 Abstract**

14 Soil position in the landscape reveals its history of formation and genesis. Therefore, the landscape is the
15 combination of features of the surface of the earth with subsurface components (parent material), while the
16 soil is a three-dimensional, dynamic natural body inserted in the landscape. This research aimed to study the
17 soil-landscape relationship in a sandstone-gneiss topolithosequence in Amazonas, Brazil. The study was
18 carried out along a 9.253-meter transect from the top downwards the softer slope. Soil profiles were selected
19 in five landscape compartments (top, upper third, lower third, transport foothill, and deposition foothill).
20 Morphological, mineralogical, physical, chemical, and ray diffraction characterizations were performed. Soils
21 had different morphological, physical, chemical, and mineralogical attributes due to the variations of the
22 geological substrate and landscape position. The mineralogy of the clay fraction is composed of kaolinite,
23 goethite, hematite, and gibbsite, with goethite being the predominant iron oxide. A sand fraction dominance
24 was observed in relation to the other fractions in all the profiles, being related to the alluvial nature of the
25 parent material, with the highest values occurring in the lower third. The separation of the landscape into
26 geomorphic surfaces and identification of the parent material were effective for understanding the variation of
27 soil attributes along the landscape.

28 **2 Introduction**

29 The soil is the product of the combinations of factors and processes of formation governed by the local
30 conditions of its occurrence. The intensity of these factors and processes promote progressive transformations
31 in the parent material, which over time are expressed by morphological, chemical, physical, and mineralogical
32 soil properties. Thus, considering the Amazonian environments, climate conditions of high temperature and
33 high precipitation prevail in the Brazilian Amazon, favoring an intense mineral weathering and, therefore, the
34 formation of soils with predominant characteristics (Dalamerlinda et al., 2017). For this reason, it is necessary
35 to recognize the interaction among these factors and their role in soil formation (Campos et al., 2012a; Silva,
36 2016).

37 Soil position in the landscape reveals its history of formation and genesis (Campos et al., 2011). Thus, the
38 landscape is the combination of features of the surface of the earth with subsurface components (parent
39 material), while the soil is a three-dimensional, dynamic natural body inserted in the landscape (Minasny and
40 Mcbratney, 2006). In general, soil attributes present the characteristics of the matrix rock, but at a local scale,

41 the occurrence of attributes can be very different due to the existence of more lithologic substrate or even the
42 predominance of a specific formation process (Campos et al., 2012a). Thus, the relief, although considered a
43 supporting factor, acts on the spatial distribution of soil attributes, water dynamics, presence of unconsolidated
44 sediments, pedogenetic development, and processes that translate into the most varied soil types (Bockheim et
45 al., 2005; Vasconcelos et al., 2012; LI et al., 2015).

46 For a better understanding of the soils in the landscape, the preconized concepts of the soil-landscape
47 relationship become necessary as criteria for understanding the spatiotemporal variability of soil attributes and
48 visualization of dynamic processes such as the transport of water, solutes, and sediments (Sommer, 2006;
49 Campos et al., 2011). Despite the great representation of the Middle Madeira River region, the most common
50 physiographic environments are floodplains, native fields, and transition areas, which are dominated by
51 Inceptisols, Ultisols, and Entisols, thus showing the main characteristic of the Amazon region as a function of
52 the exuberant grouping of landscapes associated with different soil classes in a short space of geographical
53 position (Campos et al., 2012a; Campos et al., 2012b).

54 The direct effects of the composition of the parent material have been studied in the literature. Montanari et al.
55 (2010) found the dominance of goethite and kaolinite in a concave landform in relation to linear and convex
56 landforms, while the highest hematite contents occurred in linear landforms. Curi and Franzmeier (1984)
57 studied a toposequence of Oxisols and found higher gibbsite concentration in the highest landscape position
58 and kaolinite in the lowest positions associated with goethites of lower mean crystal diameter. All these
59 investigations reinforce the importance of characterizing soil mineralogy to reinforce the relationship between
60 the landscape and parent material, especially Fe and Al oxides because their formation is influenced by
61 environmental conditions and persist for a long time in the soil (Kämpf and Curi, 2000).

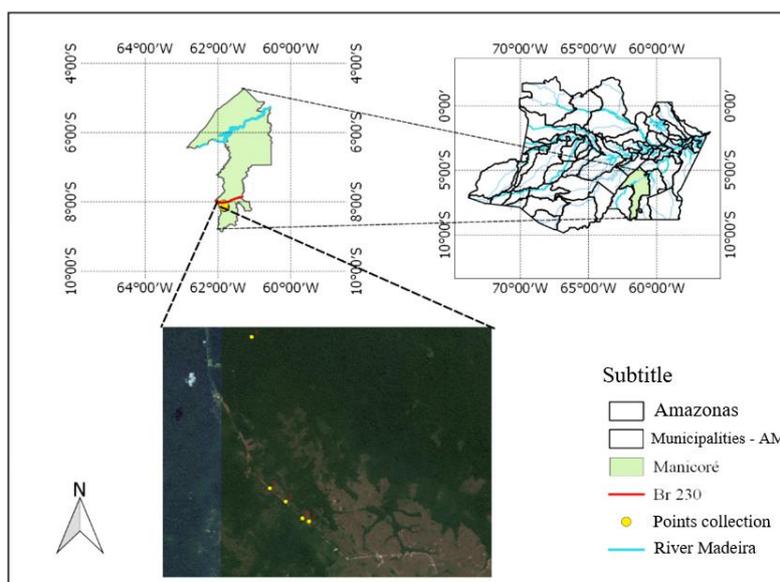

62 Despite the long territorial extension of the Amazon region, studies have been conducted and various
63 characteristics and peculiarities of its landscape have revealed new directions in studies on the soil-landscape
64 relationship. Thus, the properties of the soil-landscape relationship associated with the behavior of parent
65 material transmit records of the intensity of pedogenetic processing conditions that prevailed in the
66 environment that influenced the formation of these soils. Therefore, this research aimed to study the soil-
67 landscape relationship in a sandstone-gneiss topolithosequence in mazonas, Brazil.

68 **3 Material and methods**

69 **3.1 Characterization of the physical environment**

70 The study area is located at BR 230 km 150 – Transamazônica, municipality of Manicoré, AM – direction of
71 Machadinho do Oeste, RO, at Rodovia do Estanho km 14, located between the geographical coordinates
72 08°08'12.6" S and 61°50'06.5" W (Figure 1). According to the Köppen classification, the regional climate is
73 classified as Am, i.e. a rainy tropical climate (monsoon rains), with a dry period of short duration, temperatures
74 varying from 25 to 27 °C, and annual precipitation of 2,500 mm with the rainy season beginning in October
75 and extending until June and relative air humidity between 85 and 90%.

76
77 Figure 1. Location of the profiles studied in the municipality of Manicoré in the state of Amazonas, Brazil.
78 Source: ©Google Maps.

79 Relief configuration is marked by the presence of plateaus in the highest parts, which exhibit flat topographic
80 surfaces, with the border area marked by aligned hills and ridges, while the lower areas constitute a
81 pediplanated surface, locally interrupted by flat top hills (CPRM, 2001).

82 Regarding the geology, the study area is located on Rondonian Granites characterized by the presence of
83 muscovite, biotite, adamelites, and granodiorites of intrusive cratogenic origin, in the form of stocks and
84 batholiths (BRASIL, 1978). According to ZEE (2008), regional soils are Oxisols. The characteristic vegetation
85 of this region is a dense tropical forest consisting of densified and multi-layered trees between 20 and 50 meters
86 in height (figure 2).

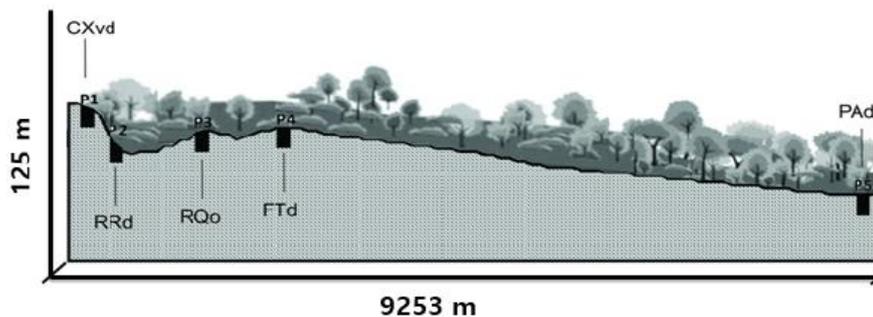

87

88 Figure 2. Images of the collection environment.

89 3.2 Field methodology

90 The study was carried out along a 9.253-meter transect from the top downwards the softer slope to the
91 deposition foothill. Measurements of the altitudes were carried out along this transect to make the altimetric
92 profile. Based on the model of Dalrymple et al. (1968), hillside segments were identified mainly based on the
93 variation of the terrain slope (Figure 3).

94

95 Figure 3. Schematic profile of the terrain topography and trench position in the topolithosequence in
96 Amazonas, Brazil.

97 Five trenches were opened along the hillside topography following the transect illustrated in Figure 3 in order
98 to characterize the soils, as follows: top (08°08'46.0" S and 61°49'25.1" W), upper third (08°08'41.8" S and
99 61°49'33.9" W), lower third (08°08'18.3" S and 61°49'56.3" W), transport foothill (08°07'59.6" S and
100 61°50'17.4" W), and deposition foothill (08°07'59.6" S and 61°50'17.4" W). The identification of horizons
101 and morphological description, followed by the sampling of soil horizons, were performed according to Santos
102 et al. (2013). Soils were classified according to criteria established by the Brazilian Soil Classification System
103 (Santos et al., 2013).

104 Twenty samples were collected at different soil profiles: Top: A – 0.0–0.16 m and AB – 0.16–0.30 m; upper
105 third: A – 0.0–0.12 m and ACr – 0.10–0.20 m; lower third: A – 0.0–0.7 m and C1 – 0.15–0.33 m; transport

106 foothill: A – 0.0–0.18 m and AB – 0.18–0.33 m; and deposition foothill: A – 0.0–0.18 m and AB – 0.18–0.32
107 m. The criterion for choosing the depths was the coincidence with surface and subsurface diagnostic horizons.

108 **3.3 Particle size analysis**

109 Particle size analysis was performed by the pipette method using a 0.1 mol L⁻¹ NaOH solution as a chemical
110 dispersant and mechanical stirring in a low rotation apparatus for 16 h (Donagema et al., 2017). The clay
111 fraction was separated by gravitational sedimentation, the coarse and fine sand fraction by sieving, and the silt
112 fraction was calculated by difference.

113 **3.4 Chemical analysis**

114 Soil pH was determined in water and 1.0 mol L⁻¹ KCl solution in the soil to solution ratio of 1:2.5 (Donagema
115 et al., 2017). The exchangeable cations Ca²⁺, Mg²⁺, and Al³⁺ were extracted with 1.0 mol L⁻¹ KCl and measured
116 by atomic absorption spectroscopy. The hydrogen ion and Al³⁺ were extracted with 0.5 mol L⁻¹ calcium acetate
117 at pH 7.0 and determined by titration (0.025 mol L⁻¹ NaOH) (Donagema et al., 2017). Organic carbon was
118 determined by the wet oxidation method (Walkley and Black, 1934).

119 Bioavailable particulate phosphorus (Pbp) was determined by extraction with anion exchange resin (AER).
120 The principle of phosphorus extraction by AER is its continuous removal from the solution by the exchange
121 with bicarbonate of the resin, creating a concentration gradient that forces the exit of the surface of colloids
122 until an electrochemical equilibrium is reached between the soil and AER (Skogley and Dobermann, 1996).
123 For this, the methodology developed by Kroth (1998) was used as follows: 0.5 g of soil (1 mm) was added in
124 15 mL falcon tubes containing 10 mL distilled water and a sheet of AER saturated with 0.5 mol L⁻¹ NaHCO₃.
125 These tubes were stirred for 16 hours on an end-over-end stirrer (33 rpm). The sheets were removed and
126 washed with distilled water jets and then diluted in 10 mL 0.5 mol L⁻¹ HCl. The tubes remained uncapped for
127 90 minutes and then closed and stirred for 30 minutes in a horizontal stirrer. Subsequently, a 3 mL aliquot was
128 taken from the extract to determine the P content according to Murphy and Riley (1962). The sum of bases
129 (SB), cation exchange capacity (CEC), base saturation (V), and aluminum saturation (m) were calculated based
130 on the results of the chemical analyses.

131 **3.5 Mineralogical analysis**

132 The minerals of the clay fraction hematite (Hm), goethite (Gt), kaolinite (Kt), and gibbsite (Gb) were
133 characterized by X-ray diffractometry using the powder method after the concentration of iron oxides by

134 boiling the clay fraction in NaOH (Norrish and Taylor, 1961) and deferrifying it by the method of Mehra and
135 Jackson (1960). The samples were diffracted with scanning speed of $1^\circ 2\theta \text{ min}^{-1}$ using a Mini-Flex Rigaku II
136 (20 mA, 30 kV) equipped with Cu $K\alpha$ radiation. The Hm/(Gt+ Hm) ratio was estimated by comparing the peak
137 areas from the Hm/(Gt+Hm) with the proportions of relationships obtained from standard Gt–Hm mixtures.
138 The percentages of Hm and Gt were calculated by allocating the difference between Fed and Feo to these
139 oxides. The Kt/(Kt+Gb) ratio was calculated by peak areas of Gb (002) and Kt (001) reflections. The
140 calculation of the content of isomorphous substitution of iron by aluminum in Gt was obtained by the equation
141 $\text{mol mol}^{-1} = 1730 - 572 c$ (Schulze, 1984). For the calculation of the content of isomorphous substitution of iron
142 by aluminum in Hm, the equation $\text{mol mol}^{-1} = 3098.8 - 615.12 a_0$ (Schwertmann et al., 1989) was used. The
143 specific surface area (SSA) of Gt was estimated by the formula $\text{SSA (Gt)} = (1049/\text{MCD gt } 100)^{-5} (\text{m}^2 \text{ g}^{-1})$,
144 according to Schulze and Schwertmann (1984), $\text{MCD}_{100} = \text{MCD (110)} \times 0.42 \text{ nm}$ (Kämpf, 1981), and the
145 SSA of Hm was estimated by the formula $\text{SSA (Hm)} = 2 \times (r + h) \times d (\text{m}^2 \text{ g}^{-1})$, according to (Schwertmann
146 and Kämpf, 1985). The mean crystal diameter (MCD) of Hm and Gt was calculated from the width at half-
147 height (WHH) and the position of mineral reflections using the Scherrer equation (Klug and Alexander, 1974).

148 **4 Results**

149 **4.1 Soil distribution in the landscape**

150 A physiognomy formed by plains was observed in this locality due to the minimal variation of relief. This
151 characteristic is typical in Amazonian environments probably because of the gradual transition action that
152 occurs between fields and the forest in this region. The lowest terrain position is colonized by small shrub
153 species, where there are flood conditions at certain times of the year. Dalrymple et al. (1968) established
154 hypothetical units of hillsides, which may be partially absent or repeated along them. In this study, five hillside
155 segments were identified and mapped in a representative toposequence of the region (Figure 3).

156 The first three hillside segments of the landscape, represented by the top, upper third, and lower third, with
157 elevations from 120 to 125 m, are grouped similarly among each other. This position in the landscape does not
158 confer greater stability to soil attributes, mainly due to the classification of these soils, thus evidencing the
159 total influence of the landscape on its attributes. The third segment is the transport foothill (119 m), with a
160 residual erosional character, starting from the edges of the lower third and showing a slightly sloping
161 conformation to the fifth segment, which may have been formed by relief microvariations of the previous

162 segment. Finally, the fifth segment is the deposition foothill, which presents lower altitudes than the top
163 (between 114 and 116 m), but with different topographic characteristics. In this case, it may be considered a
164 stable geomorphic environment.

165 The pedogenesis of these soils evidences the action of more than one parent material since the partition is
166 composed of five distinct classes in the different segments. Considering that these classes were developed on
167 different sandstone-gneiss parent materials, they are the main cause of alterations in soil attributes at different
168 magnitudes. As observed by Marques Júnior and Lepsch (2000) and Campos (2012c), understanding the
169 different parent materials in a landscape favor the understanding of the variability of soil attributes, thus
170 indicating that geology provides subsidies to explain the local relief and soil behavior.

171 **4.2 Morphological and textural attributes**

172 The genesis and classification showed that all profiles have a moderate diagnostic surface A horizon (Table
173 1). The topographic position of the top showed an incipient subsurface diagnostic B horizon, with no evidence
174 of predominant pedogenic process, being classified as a leptic Dystraphic Ta Haplic Cambisol.

175 Soils of the upper and lower third are poorly evolved, consisting of mineral material or organic material lower
176 than 20 cm thick, with no type of diagnostic B horizon. In the upper third, the soil was characterized as a
177 Regolithic Neosol because it is in a lytic contact at a depth higher than 50 cm and A horizon overlying C or Cr
178 horizon, presenting altered primary minerals, with gravels from the ACr horizon at a depth of 12–35 cm and
179 presence of fragments of semi-weathered rocks (Santos et al., 2013). On the same surface, there was the
180 presence of Quartzarenic Neosol (lower third), soils with no lytic contact within 50 cm of depth, with sequences
181 of A–C horizons, but showing a sand or loamy sand texture in all horizons up to at least 150 cm, mainly
182 consisting of quartz with coarse and fine sand fractions and whitish colors (Santos et al., 2013).

183 The transport foothill, submitted to a higher influence of seasonal variations of the water table, presented
184 mottles in the subsurface horizons of a reddish color, with a small size and distinct contrast. Associated with
185 the mottled color is the presence of plinthite and petroplinthite in amounts varying from common to abundant,
186 corresponding to values between 15 and 40% of the soil volume. These attributes indicate the occurrence of
187 the plinthization pedogenic process, being a diagnostic character of the plinthic horizon, according to the
188 Brazilian Soil Classification System (SiBCS) (Santos et al., 2013). From the attributes and identified horizons,
189 the profile was classified, at suborder level, as an 3.3 Argiluvic Plinthosol.

190 In this segment, there was the presence of an abruptic Dystrophic Yellow Argisol (deposition foothill),
191 presenting textural B horizon and predominance of colors with hue 10 YR and 7.5 YR in the first 100 cm of
192 the B horizon. In this soil, the slope was determinant for the selective removal of clay, contributing to the
193 formation of a textural gradient. In summary, the mineralogical, physical, and chemical results of the
194 characterized profiles accurately elucidated the characteristics of the sandstone-gneiss rock that originated the
195 soils along the topolithosequence.

196 Soil colors ranged from very dark grayish brown to dark brown in the surface horizons (Table 1). Thus, a clear
197 differentiation was observed for subsurface horizons that have colors from yellowish brown to very pale
198 brown. The grayish tones were observed in most horizons, being this coloration associated with a low
199 concentration of iron oxides and predominance of light-colored minerals such as kaolinite and quartz in the
200 sand fraction (EMBRAPA, 2013). This behavior can be verified in Table 3, which shows the predominance of
201 goethite in all profiles, even in the Plinthosol, which showed higher increases of hematite.

202 Surface horizons had the predominance of a weak, small, medium to large structure in the composition of the
203 top and foothill (Table 1). On the other hand, in transport and deposition foothills predominated a moderate,
204 medium, coarse to large structure. According to Silva et al. (2001), the soil drainage, conditioned by the
205 topographic position, has a strong relationship with the type of structure because moderately to well-drained
206 soils tend to have granular or angular and subangular blocky structures, while poorly to imperfectly drained
207 soils tend to exhibit a standard structure in polygonal prisms. Campos et al. (2012a) observed that the relief
208 conditions influenced several soil attributes, considering that the slope creates a complex pattern of transport
209 of water and solutes, acting mainly on soil profile development.

210 The surface horizon of all profiles presented a sandy loam textural class, except for Neosols, which presented
211 a sandy constitution (Table 1). The dominance of the sand fraction in the profiles is explained by the parent
212 material, composed of sandstones of the Palmeiral Formation and Nova Campo Verde Complex. However, the
213 increase in the clay fraction in the Argisol from the Bt1–Bt2–Btf horizon stood out. As highlighted by Campos
214 et al. (2011) and verified in our study, Argisol and Plinthosol seem to have undergone a process of rejuvenation
215 due to their position in the landscape, with a probable loss of clay from the surface horizons, resulting in an
216 abrupt textural change.

217

TABLE 1. Morphological and granulometric attributes of a topolithosequence in Amazonas, Brazil.

S/C: silt to clay ratio.

220 Soils of the upper and lower third are poorly evolved, consisting of mineral material or organic material lower
221 than 20 cm thick, with no type of diagnostic B horizon. In the upper third, the soil was characterized as a
222 Regolithic Neosol because it is in a lytic contact at a depth higher than 50 cm and A horizon overlying C or
223 Cr horizon, presenting altered primary minerals, with gravels from the ACr horizon at a depth of 12–35 cm
224 and presence of fragments of semi-weathered rocks (Santos et al., 2013). On the same surface, there was the
225 presence of Quartzarenic Neosol (lower third), soils with no lytic contact within 50 cm of depth, with
226 sequences of A–C horizons, but showing a sand or loamy sand texture in all horizons up to at least 150 cm,
227 mainly consisting of quartz with coarse and fine sand fractions and whitish colors (Santos et al., 2013).

228 The transport foothill, submitted to a higher influence of seasonal variations of the water table, presented
229 mottles in the subsurface horizons of a reddish color, with a small size and distinct contrast. Associated with
230 the mottled color is the presence of plinthite and petroplinthite in amounts varying from common to abundant,
231 corresponding to values between 15 and 40% of the soil volume. These attributes indicate the occurrence of
232 the plinthization pedogenic process, being a diagnostic character of the plinthic horizon, according to the
233 Brazilian Soil Classification System (SiBCS) (Santos et al., 2013). From the attributes and identified horizons,
234 the profile was classified, at suborder level, as an 3.3 Argiluvic Plinthosol.

235 In this segment, there was the presence of an abruptic Dystrophic Yellow Argisol (deposition foothill),
236 presenting textural B horizon and predominance of colors with hue 10 YR and 7.5 YR in the first 100 cm of
237 the B horizon. In this soil, the slope was determinant for the selective removal of clay, contributing to the
238 formation of a textural gradient. In summary, the mineralogical, physical, and chemical results of the
239 characterized profiles accurately elucidated the characteristics of the sandstone-gneiss rock that originated the
240 soils along the topolithosequence.

241 Soil colors ranged from very dark grayish brown to dark brown in the surface horizons (Table 1). Thus, a clear
242 differentiation was observed for subsurface horizons that have colors from yellowish brown to very pale
243 brown. The grayish tones were observed in most horizons, being this coloration associated with a low
244 concentration of iron oxides and predominance of light-colored minerals such as kaolinite and quartz in the
245 sand fraction (EMBRAPA, 2013). This behavior can be verified in Table 3, which shows the predominance of
246 goethite in all profiles, even in the Plinthosol, which showed higher increases of hematite.

247 Surface horizons had the predominance of a weak, small, medium to large structure in the composition of the

248 top and foothill (Table 1). On the other hand, in transport and deposition foothills predominated a moderate,
249 medium, coarse to large structure. According to Silva et al. (2001), the soil drainage, conditioned by the
250 topographic position, has a strong relationship with the type of structure because moderately to well-drained
251 soils tend to have granular or angular and subangular blocky structures, while poorly to imperfectly drained
252 soils tend to exhibit a standard structure in polygonal prisms. Campos et al. (2012a) observed that the relief
253 conditions influenced several soil attributes, considering that the slope creates a complex pattern of transport
254 of water and solutes, acting mainly on soil profile development.

255 The surface horizon of all profiles presented a sandy loam textural class, except for Neosols, which presented
256 a sandy constitution (Table 1). The dominance of the sand fraction in the profiles is explained by the parent
257 material, composed of sandstones of the Palmeiral Formation and Nova Campo Verde Complex. However,
258 the increase in the clay fraction in the Argisol from the Bt1–Bt2–Bt_f horizon stood out. As highlighted by
259 Campos et al. (2011) and verified in our study, Argisol and Plinthosol seem to have undergone a process of
260 rejuvenation due to their position in the landscape, with a probable loss of clay from the surface horizons,
261 resulting in an abrupt textural change.

262 In general, the profiles of the soil-landscape relationships presented morphological variations among each
263 other, being the result of a variety of pedogenetic factors and processes. Ribeiro et al. (2012) indicated that the
264 morphological characteristics are due to the soil constitution and conditions under which it was formed,
265 allowing making inferences on pedogenetic processes and environmental conditions, as well as interpreting or
266 predicting the plant behavior and the response of management practices.

267 Particle size composition showed a predominance of the sand fraction over the other fractions, with contents
268 from 207 and 891 g kg⁻¹ (Table 1). These characteristics can be explained by the parent material (sandstone),
269 which presented in their constitution predominance of quartz. These high values of total sand are in accordance
270 with Schiavo et al. (2010), who characterized and classified soils developed from sandstones of the
271 Aquidauana Formation.

272 In the A horizon, silt contents ranged from 53 to 306 g kg⁻¹, with an increment in depth (Table 1). Low values
273 are associated with young soils still in the formation process. In fact, because they are formed from alluvial
274 sediments, a particle selection may have occurred, leaving in the soil lithogenic (more resistant to changes)
275 and pedogenic materials (with a higher degree of crystallinity). Unlike the sand fraction, the clay fraction

276 increased gradually with depth, with values from 48 to 558 g kg⁻¹. However, we cannot say this is a pedogenic
277 process of eluviation and illuviation. The most likely is the selective removal of surface horizons (more sandy),
278 with clay accumulation in the subsurface.

279 Neosols presented higher proportions of coarse fractions (> 2 mm) of consolidated ferruginous material as
280 plinthite and petroplinthite due to a possible lowering of the water table, leading to a better drainage of the
281 environment, which was confirmed by the presence of a more reddish hue (2.5 YR) in relation to the other
282 profiles from 48 cm from the surface (Table 1). This predominance of coarser sand fractions, together with the
283 marked presence of gravels, are indicative characteristics that the weathering processes in this soil were not
284 able to promote a marked fragmentation of these fractions (EMBRAPA, 2013).

285 In the transport foothill, the clay contents ranged from 95 to 99 g kg⁻¹ in the A, AB, and BA horizons to 548
286 g kg⁻¹ in the Bt1 horizon, 558 g kg⁻¹ in the Bt2 horizon, and 567 g kg⁻¹ in the Btf horizon. The marked textural
287 differentiation between the A and Bt1 horizons characterizes an abrupt textural change with a significant
288 increase of clay in relation to the overlying horizons (Table 1).

289 At the top and upper and lower thirds, the silt to clay ratio (S/C) ranged from 1.43 to 1.50 and 1.19 to 1.43,
290 respectively (Table 1), being associated with less developed soils. The transport foothill showed the lowest
291 S/C ratio, with values between 0.7 and 0.8. On the contrary, the deposition foothill presented the highest values
292 (1.49) in the surface horizons but decreasing to 0.41 with variations in depth. According to Campos et al.
293 (2011), higher values of S/C ratio are due to the low increase in the silt fraction or clay loss, suggesting that
294 small relief variations provide relative losses or gains and, possibly, are not motivated by variations in the
295 parent material.

296 Considering the topographic variations, clay and silt contents tended to increase towards the youngest
297 geomorphic surfaces, i.e. from the top and thirds to the transport and deposition foothills, in an opposite
298 direction to that of the total sand, which reflects their recent sedimentary nature since the soils of these
299 geomorphic environments are closely related to the parent material. Campos et al. (2012b) also evidenced this
300 condition when studying the soil-geomorphic surface relationships in a toposequence floodplain-upland in the
301 region of Humaitá, AM, Brazil.

302 **4.3 Variation of chemical attributes**

303 The values of pH ranged from 4.17 to 5.48 (H₂O) and 3.81 to 5.70 (KCl), especially in the upper and lower

304 thirds and deposition foothill, presenting the highest acidity content in the surface horizon. According to
 305 Campos et al. (2012b), the high regional precipitation contributes significantly to base leaching, increasing
 306 soil pH. The balance of negative net charges, expressed by ΔpH in the B horizon, showed the highest values
 307 at the top and upper and lower thirds, which is in accordance with the trend of occurring soils with a lower
 308 degree of evolution in the youngest surface (Table 2).

309 TABLE 2. Soil chemical attributes in a topolithosequence in Amazonas, Brazil.

310 SB: sum of bases; CEC: cation exchange capacity; V: base saturation; m: aluminum saturation; OC: organic
 311 carbon.

312 The bases Ca²⁺, Mg²⁺, and K⁺ presented values ranging from 0.20 to 1.0 cmol_c kg⁻¹ (Table 2). In general, the
 313 magnitude of this variation is small among the landscape positions, which is mainly due to their reduced
 314 contents in the minerals constituting the sandstone-gneiss and climate conditions that favor the advanced soil
 315 weathering in the region. Moreover, the predominance of oxidic minerals generates positive charges, which,

316 allied with the more sandy texture, provided the loss or movement of these cations to subsurface horizons.
317 This behavior, however, does not apply to K, which remained at higher concentrations near the soil surface.
318 According to Neves et al. (2009), this is a characteristic attributed to the low diffusion power electrostatically
319 adsorbed to negative charges of organic matter or the formation of sphere complexes external to the solid
320 phase.
321 Exchangeable aluminum (Al^{3+}) content had no marked variation along the topolithosequence, with low values
322 recorded in all profiles, mainly in the A horizon and increasing in depth. In addition, the potential acidity (H^+
323 and Al^{3+}) values were high and increase in depth along the topolithosequence (Table 2). Possibly, the intense
324 rainy season of the region associated with unimpeded drainage would be the determining climate factors to
325 acidify the soil in depth (Campos et al., 2012).
326 Along the topolithosequence, organic carbon (OC) contents were very higher in the surface horizons because
327 of the concentration of organic matter from the decomposition of native vegetation (Santos et al., 2012). Cation
328 exchange capacity (CEC) ranged from high to very high, with values between 12 and 28 $\text{cmol}_e \text{dm}^{-3}$. The same
329 trend occurred for the sum of bases (SB), which was higher in the A horizon mainly because of the OM and
330 low clay content, which had low activity.
331 Due to the low activity of the clay fraction, all segments were classified as dystrophic (Table 2). This evidence
332 is a result of the depletion of bases (Ca^{2+} , Mg^{2+} , and K^+), which is in accordance with other investigations
333 developed in the Amazon region (CAMPOS et al., 2012ab; Santos et al., 2012; Martins et al., 2006). This is
334 an interesting aspect since it evidences the Amazon conditions related to the constitution of formation of the
335 parent material associated with weathering conditions of climate, leading the values of base saturation to
336 present a gradient coincident with the geomorphic surfaces, being dystrophic along the topolithosequence.
337 This result is different from those found by Campos et al. (2010), who observed a higher degree of soil
338 development at top positions and dominance of dystrophic soils.
339 Soils were considered alic along the topolithosequence, with values of aluminum saturation (m) ranging from
340 51 to 91%. Martins et al. (2006) studied soils in a transition fields-forest in the region of Humaitá, AM, and
341 also reported the percentage magnitude found here. This is an inherent characteristic of the sandstone-gneiss,
342 which has by nature an acidic character. The richness in Al justifies the formation of gibbsite in the Neosols
343 (upper and lower third), as mentioned.

344 Available phosphorus (P) contents showed a similar behavior along the topolithosequence, with an average of
 345 2.0 mg kg⁻¹ and decreasing in depth. Silva et al. (2006) stated that P remains stable in depth due to its low
 346 mobility. Another point considered is the strong affinity of iron oxides, mainly goethite in phosphorus retention
 347 (Pinto et al., 2013; Rotta et al., 2015). Goethite soils, as is our study, have their P adsorption affinity potentiated
 348 because of the high isomorphic substitution (IS) and SSA of Gt. However, the positions at the top and transport
 349 and deposition foothills presented values of 4.6 and 5.8 mg kg⁻¹, respectively, of available phosphorus in the
 350 A horizon, with the highest values in the topolithosequence. This would be an effect of OM accumulation in
 351 the form of litter on the soil surface horizon. In addition, OM acts as a physical barrier, inhibiting the direct
 352 contact of P to the soil active sites, thus allowing P in the available soil fraction (Fink et al., 2014).

353 4.4 Mineralogical attributes

354 The mineralogy of the clay fraction (Table 3) of diagnostic and transitional B horizons showed the coexistence
 355 of the minerals kaolinite (Kt), gibbsite (Gb), hematite (Hm), and goethite (Gt). In a preferred order, Fe oxides,
 356 Hm, and Gt predominate as follows: transport foothill (9–41g kg⁻¹) > deposition foothill (5–39 g kg⁻¹) > top
 357 (5–24 g kg⁻¹) > upper and lower third (1–5 g kg⁻¹). Among the iron oxides, Gt participated in the clay fraction
 358 of all studied soils, which is due to the iron poverty of sandstone-gneiss sediments (Correa et al., 2008; Santos
 359 et al., 2010). Under this lithological condition, Gt preferably has its formation favored (Barrón and Torrent,
 360 2002; Viscarra Rossel et al., 2010), as shown by the low Hm contents, with a maximum value of 9 g kg⁻¹ in
 361 the topolithosequence.

362 TABLE 3. Crystallographic attributes of soil minerals of a topolithosequence in Amazonas, Brazil.

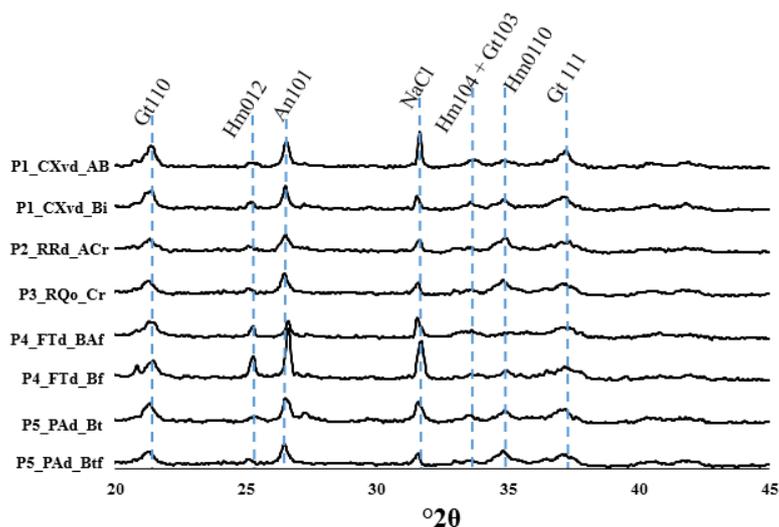

Soil	MCD				WHH		SSA		IS		Ratio	Content	
	°2θ						m ² g ⁻¹		mol mol ⁻¹		Kt/(Kt+Gb)	Gt	Hm

363 MCD: mean crystal diameter; WHH: width at half-height, SSA: specific surface area, IS: isomorphic

364 substitution; Gt:goethite; Hm: hematite; Kt: kaolinite; Gb: gibbsite; ni: not identified.

365 In general, the crystallographic parameters (MCD, WHH, SSA, and IS) were sensitive to the peculiarities of
366 the topolithosequence (Table 3). The mean crystal diameter (MCD) values for Gt110 (10–28 nm) and Gt111
367 (9–21 nm) peaks lower than Hm111 (12–25 nm) and Hm012 (30–89 nm) peaks revealed the persistence of the
368 crystalline Hm in relation to Gt, a common characteristic in tropical soils (Inda Júnior and Kämpf, 2005;
369 Barbieri *et al.*, 2014) clearly observed in the transport foothill, where peaks referring to the face of Hm012 are
370 well-defined and narrow (Figure 4). The climatic conditions of the Amazon, especially precipitation and
371 temperature, combined with the natural increase of OM, acid pH (Table 2), and intense microbial activity,
372 contribute to a higher presence of Al in the goethite structure, which decreases its crystallinity.

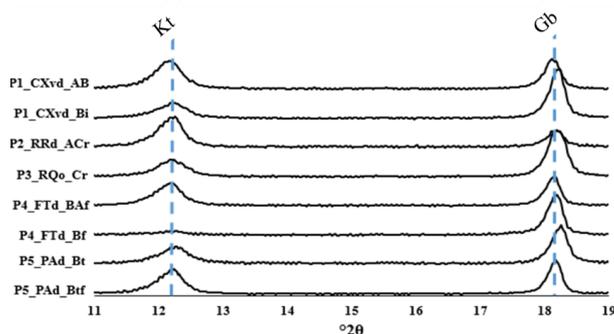

373
374 Figure 4. X-ray diffractograms of the clay fraction for hematite (Hm) and goethite (Gt) in the profiles of Haplic
375 Cambisol (CXvd_AB), Regolithic Neosol (RRd_ACr), Quartzarenic Neosol (RQod_Cr), Argiluvic Plinthosol
376 (FTd_Bf; P4_FTd_BAf), and Yellow Argisol (PAd_Bt; P5_PAd_Btf) in Amazonas, Brazil.

377 Except for the top position, values of isomorphous substitution (IS) higher than 0.33 mol mol⁻¹, regardless of
378 the soil position in the topolithosequence, indicate soils with a markedly weathering, non-hydromorphic, and
379 acid pH (high Al activity) (Table 2). These conditions justify the persistence of Gt with a high Fe substitution
380 ($r=0.065$) by Al ($r=0.053$), which promoted the contraction of the unit cell and, consequently, increased the
381 specific surface area (SSA), ranging from 82 to 234 m² g⁻¹ in Gt and 41 to 89 m² g⁻¹ in Hm. These results are
382 consistent with those found by other authors in Brazilian soils (Melo *et al.*, 2001; Correa *et al.*, 2008; Carvalho

383 Filho et al., 2015) since the highest values of IS and SSA in Gt are attributed to its higher structural capacity
384 to accommodate Al in relation to Hm (Schwertmann and Taylor, 1989; Rolim Neto et al., 2004).
385 The contents of Fe oxides are concentrated in the soils in the following order: transport foothill > deposition
386 foothill > top > upper and lower third (Table 3 and Figure 4). In turn, the highest contents of Fe oxide,
387 especially Hm in the Plinthosol (P4), are due to an increase of iron in the BAf and Bf horizons, characterized
388 by the presence of ferruginous concretions, which is peculiar to Plinthosols in the study region (Campos et al.,
389 2012). Well-formed peaks of Gt were observed even in poorly developed profiles, as in the case of RQo_Cr,
390 in which the presence of lytic contact (weak rock or outcropping saprolite) is noticeable (Figure 4). This fact
391 was already expected since goethite is the first Fe oxide formed in the early stages of pedogenesis in the initial
392 horizons close to the rock (Curi and Franzmeier, 1984; Silva, 2016).
393 The Kt/(Kt+Gb) ratio showed that Gb is an important constituent of the mineralogical assembly of the studied
394 soils, except for upper and lower thirds and deposition foothill (Table 1 and Figure 5). The lower Kt contents,
395 as well as its absence in the transport foothill, are probably due to the higher iron oxides contents, which may
396 have disrupted Kt nucleation, a behavior also observed in the studies of Gidhin et al. (2006). This resulted in
397 the highest values of width at half-height (WHH), which ranged from 0.483 to 0.703 nm when compared to
398 Gb crystals, which in turn ranged from 0.273 to 0.307 nm. This result indicates that Gb crystals are much more
399 crystalline than Kt, which is soil characteristic with a higher degree of weathering (Gidhin et al., 2006;
400 Camargo et al., 2008), in which the growth of Gb crystals are favored by the low Si concentration in the soil
401 (HSU, 1989).

402
403 Figure 5. X-ray diffractograms of the clay fraction for kaolinite (Kt) and gibbsite (Gb) in the profiles of Haplic
404 Cambisol (CXvd_AB), Regolithic Neosol (RRd_ACr), Quartzarenic Neosol (RQod_Cr), Argiluvic Plinthosol

405 (FTd_Bf; P4_FTd_BAf), and Yellow Argisol (PAd_Bt; P5_PAd_Btf) in Amazonas, Brazil.
406 The proportions of $Kt[Kt/Kt+Gb > 75]$, associated with the low iron oxide contents found in Neosol profiles,
407 confirm the lower intensity of pedogenesis or that morphogenesis predominated over the pedogenesis
408 (Scarciglia et al., 2005). Thus, the geomorphological characteristics such as a more rugged and dissected
409 topography of Neosol environments (Figure 3) favored the partial removal of basic cations and silicon, which
410 are combined in the soil to form Kt (Kämpf et al., 2009). In addition, part of this Si and Al removed from the
411 weathering of soils located at the landscape top could have been transported and accumulated in the lower
412 landscape positions, which increased the values of the $Kt[Kt/Kt+Gb > 60]$ ratio in Argisols (P5). These
413 evidences are in accordance with several studies (Curi and Franzmeier, 1984; Ghidin et al., 2006; Campos et
414 al., 2007; Silva, 2016), which considered the landscape a passive factor of formation and retribution of
415 pedogenic minerals.

416 **5 Conclusions**

417 Landscape separation into compartments and parent material identification were efficient for understanding
418 the variation of soil attributes along the transect.

419 Variations in soil classes are related to topography surfaces and parent material, thus showing variations related
420 to physical, chemical, morphological, and mineralogical attributes.

421 The mineralogy of the clay fraction is composed of kaolinite, goethite, hematite, and gibbsite, with goethite
422 being the predominant iron oxide. In addition, mineralogy confirmed that the chemical properties, especially
423 the cations of exchangeable bases, from sediments originating from these soils were naturally poor in bases
424 and, therefore, not related to the removal process of the system, as it is widely recognized in the Amazon
425 region.

426 A sand fraction dominance was observed in relation to the other fractions in all the surfaces, which is related
427 to the alluvial nature of the parent material, with the highest values occurring in the Quartzarenic Neosol and
428 increasing values as soil profile deepens.
