Abstract. The variation in island arc magma production rates and their influencing mechanisms are of great significance since island arc magma is considered a main source of continental crust growth. The island arc magma directly originates from the molten mantle wedge, and the mantle melting is driven by fluids or melts from the subducted slab. Slab dehydration flux mainly depends on the slab thermal structures, and subducted slab melting requires a sufficiently high temperature. For the Aleutian subduction system, the subducted Pacific Plate has diverse thermal structures due to the existing fracture zones, ridges and slab window, so it is an ideal region for arc magma production rate research. However, the previous estimations are based on seismic profiles that only provide magma production rates at specific regions of the Aleutian arc, and these results are controversial. Here, we design a magma production rate estimation method based on gravity inversion constrained by deep seismic profiles. The first overview map of magma production rates along the Aleutian arc strike demonstrates that the magma production rates have the same trend as the slab dips, and the peaks correspond to the subduction of the fracture zones and ridges. The potential mechanisms for these correlations are as follows: (1) Slab water flux at subarc depths increases with increasing slab dip. More fluid flux would induce more mantle melting, and so the arc magma production rates are increased. (2) Water-rich serpentine is formed by hydrothermal alteration on or near the surface of the subducted slab when there are fracture zones. Serpentine decomposition at a depth of 80–120 km releases fluids in addition to the fluids released during normal slab dehydration. Therefore, more fluids induce more mantle melting and correspond a larger magma production rate. (3) The slab located in the Emperor Seamounts has a relatively high temperature and is also weak, so its melting is easier. Similarly, more slab melt means more mantle melt and a higher island arc magma production rate.

25 1 Introduction

Island arc magmatism is regarded as a main potential source of continental crust growth (Reymer and Schubert, 1984; Taylor, 1967; Rollinson, 2008; Ribeiro et al., 2015), since magmatic rock produced by arc magmatism is the main component of the continental crust (Rudnick and Fountain, 1995; Taylor, 1967; Rollinson, 2008). The formation of island arc magma is influenced by fluids or melts released from subducted slab (Schmidt and Poli, 1998; Grove et al., 2006; Yogodzinski et al., 1995). Under certain temperature and pressure conditions, the hydrous minerals of the subducted slab dehydrate to release fluids (Schmidt and Poli, 1998; Grove et al., 2006; Yogodzinski et al., 1995). The fluids enter the mantle wedge under the island arc and induce the partial melting of the mantle wedge by reducing the minimum decomposition temperature of peridotite (Turner et al., 2000; Tollan and Hermann, 2019). In addition, the subducted slab can also melt at high temperature (Schmidt and Poli, 1998; Grove et al., 2006; Yogodzinski et al., 1995). Si-rich slab melting products rise to the mantle wedge (Yogodzinski et al., 2013; Yogodzinski and Kelemen, 1998; Thorkelson, 1996) and interact with peridotite to form pyroxenite, which melts prior to peridotite due to its lower solidus (Yogodzinski and Kelemen, 1998; Liu et al., 2005; Zhang et al., 2012).

Island arc magma production rate refers to the newly formed magma volume on the island crust within a per unit length (1 km) along the arc strike and a unit time (1 Myr) (Dimalanta et al., 2002; Jicha and Jagoutz, 2015; Crisp, 1984). Because the subducted slab provides fluids and melts, its properties and geological structures, such as slab dips, fracture zones and ridges, play important roles in island arc magma production rate variations. Therefore, mapping island arc magma production rates is helpful for understanding slab dehydration and arc magmatism processes and for understanding magmatism mechanisms (Clift, 2004; Jicha and Jagoutz, 2015). The estimation of island arc magma production rates requires determining magmatic thickness variations in the arc region and constraining the lifespan of magmatic activity (Reymer and Schubert, 1984; Dimalanta et al., 2002; Jicha and Jagoutz, 2015). Arc magmatic thickness used to be estimated based on seismic profiles (Steven Holbrook et al., 1999; Lizarralde, 2002). However, the coverage of seismic surveys is very limited, mainly due to high costs. The limited seismic profiles cannot provide a sufficient overview of the magma production rate along the whole arc strike. With the rapid development of satellite technology, the accuracy of gravity data has been greatly improved (Sandwell et al., 2014). Gravity anomalies can be used to map the large-scale Moho undulations (Bai et al., 2019b; Wang et al., 2011; Tenzer et al., 2015). The crustal thickness can be determined by gravity inversion (Suo et al., 2016), which is an important parameter for estimating the

50 magmatic thickness and further for calculating island arc magma production rates.

There is no back-arc spreading behind the Aleutian island arc, so no residual arcs (Fig. 1), which means that the records of island arc magmatism there are mostly preserved at the present Aleutian arc (Jicha et al., 2011). The subducted Pacific Plate has diverse thermal structures (Levin et al., 2005) and slab dips (Hayes et al., 2018). In addition, there are fracture zones and ridges near the Aleutian Trench (Singer et al., 2007; Scholl, 2007), as well as slab window due to the tearing of the Pacific Plate west of 173°E (Levin et al., 2005; Yogodzinski et al., 2001; Lay et al., 2017). Therefore, the Aleutian island arc is an ideal region for studying the island arc magma production rate and its potential influencing factors, including slab dips, fracture zones and ridges. However, the published magma production rates of the Aleutian island arc based on seismic profiles are controversial. The mean magma production rates of the entire Aleutian arc are (1) 33 km³ km⁻¹ Myr⁻¹ (Reymer and Schubert, 1984), (2) 34 km³ km⁻¹ Myr⁻¹ (Crisp, 1984), (3) 67 km³ km⁻¹ Myr⁻¹ (Lizarralde, 2002), and (4) 89 km³ km⁻¹ Myr⁻¹ (Jicha and Jagoutz, 2015). The mean magma production rates of the intra-oceanic subduction parts of the Aleutian arc are (1) 75 km³ km⁻¹ Myr⁻¹ (Steven Holbrook et al., 1999), (2) 61 km³ km⁻¹ Myr⁻¹ (Dimalanta et al., 2002), and (3) 89 km³ km⁻¹ Myr⁻¹ (Jicha et al., 2006).

The average rate of island arc magma production cannot reflect the local characteristics, so the variation in arc magma production rates along the island arc strike is estimated in this paper. Marine gravity anomaly data are used to map the arc magmatism thickness; the latest geochemical dating results are used to determine the magmatic activity lifespan; then, the arc magma production rate variations of the whole Aleutian arc are derived. The potential influencing mechanisms will be discussed by analyzing the relationship between the magma production rate and the tectonic features.

2 Geological Setting

The Aleutian subduction zone is located in the northernmost part of the circum Pacific (Fig. 1), and it extends more than 3000 km from the Kamchatka Peninsula on the west to the Alaska on the east (LEWIS et al., 1988; Jicha et al., 2006; Liu et al., 2018; Dimalanta et al., 2002). The convergence rates and incoming plate ages decrease from west to east (Müller et al., 2008; DeMets et al., 2010; Lay et al., 2017). The formation of the Aleutian island arc is related to a series of plate tectonic events in the northern Pacific region (Jicha et al., 2006; Steven Holbrook et al., 1999). At 59 Ma or earlier, the Kula Plate

subducted northward, and a convergent boundary was formed between the Kula Plate and the North American Plate (Jicha et al., 2006; Liu et al., 2018). At 55 Ma, the northward subduction of the Kula Plate was hindered, and the previously formed convergence zone moved southward and formed the original style of the Aleutian subduction zone. The residual Kula Plate evolved into the Bering Sea (Fig. 1) (Jicha et al., 2006; Liu et al., 2018; Scholl, 2007). During the next 8 Myr, the Aleutian Trench was formed by the northward subduction of the Pacific Plate under the Bering Sea (Jicha et al., 2006; Liu et al., 2018). Between 47 Ma and 40 Ma, the movement direction of the Pacific Plate changed from northward to northwestward (Jicha et al., 2006; Liu et al., 2018). And the direction change led toward the transformation of the Emperor Seamounts direction (Scholl, 2007; Torsvik et al., 2017; Sharp and Clague, 2006). Hence, there was a bend between Hawaiian and Emperor Seamounts (Scholl, 2007; Torsvik et al., 2017; Sharp and Clague, 2006).

Geological structures west and east of 173°E of the Aleutian island arc are obviously different. West of 173°E, the structure is more complex. There is a long strike-slip structure named the Bering Fracture Zone (BFZ), which is considered to be the main tectonic plate boundary of the westernmost end of the Aleutian islands (Lay et al., 2017; Kogan et al., 2017). The BFZ separates the Aleutian island arc from the Kamchatka Peninsula (Jonathan M. Lees et al., 2000; Lay et al., 2017; Cross and Freymueller, 2008; Chekhovich et al., 2014) and the Komandorsky Basin (Jonathan M. Lees et al., 2000). The Pacific Plate subducts in northwestward inclines, and the oblique extent increases gradually from east to west along the Aleutian island arc (Davaille and Lees, 2004; Lee and King, 2010; Andrys et al., 2018; Lay et al., 2017). The BFZ is the westernmost end of the Aleutian island arc, and here, the Pacific subduction direction is almost parallel to the strike of the present island arc (Lay et al., 2017; Yogodzinski et al., 1995; Chekhovich et al., 2014).

Another characteristic west of 173°E is that there is a slab window. According to geochemical experiments, adakite is found west of 173°E of the Aleutian island arc (Yogodzinski et al., 2001; Lee and King, 2010; Cai et al., 2014; Levin et al., 2005), which is a special high-Mg rock (Davaille and Lees, 2004; Yogodzinski et al., 2017; Kay, 1978), and its existence is often regarded as evidence of a subducted slab tear (Levin et al., 2005; Cai et al., 2014). The shear wave velocity is low, and there is no deep earthquake in the Aleutian island arc region west of 173°E (Levin et al., 2005; Sdrolias and Müller, 2006; Lee and King, 2010). All of this evidence suggests the existence of a slab tear (Davaille and Lees, 2004; Cai et al., 2014; Lay et al., 2017). Therefore, the slab window is formed due to slab tearing (Yogodzinski et al., 2001; Levin et al., 2005).

In contrast, the structure type is relatively single east of 173°E. There are some fracture zones (Fig. 1), and the subducted slab dip increases from west to east overall. The axis of the Rat Fracture Zone (RFZ) is approximately 178°E (Geist et al., 1988; Singer et al., 2013). From 5 Ma to the modern stage of the Aleutian magmatic activity, the junction of the Amlia Fracture Zone (AFZ) and the Aleutian Trench deflects 300 km westward from below the Yunaska Volcano (Fig. 1) at 171°W and passes under the Segum Island (Fig. 1) at 173°W at less than 1 Ma (Singer et al., 2007).

3 Methodology and Data

The island arc magma production rate (R_{magma}) is estimated via

$$R_{magma} = \frac{\int_{B_s}^{B_n} T_{magma} dl}{L_{magma}}. \quad (1)$$

where, B_n and B_s represent the arc boundaries; T_{magma} represents the magmatic thickness of each sampling point; and L_{magma} represents the magma activity lifespan. Therefore, the arc boundaries, arc magmatic thickness and magmatic activity lifespan are necessary to map the overview of the arc magma production rate along the island arc strike profile (Fig. 2).

3.1 Mapping Magmatism Thickness

The island arc is formed by accretion of magma to the original basement (Turner et al., 2000; Jicha and Jagoutz, 2015). Therefore, arc magmatism is the residual part remaining after removing the original basement from the present arc crust. The original basement thickness is set to 6 km, which is the mean thickness of the residual Kula Plate (Jicha et al., 2006; Garth and Rietbrock, 2018). The expression of crustal thickness (T_c) is

$$T_c = D_m - T_s - T_w. \quad (2)$$

where, D_m is the Moho depth, T_s is the sediment thickness, and T_w is the seawater depth offshore and topography onshore. The remaining unknown quantity is the Moho depth, which is the interface between the crust and mantle since there are open-sourced sediment thickness, bathymetry and topography data (please check our section 3.3).

The Moho burial depth variations will be mapped via gravity inversion based on lithospheric density modeling and

120 seismic profile constraints. The free-air gravity anomaly mainly includes gravity effects of the following layers: seawater, sediment, crust and mantle. Therefore, to estimate the gravity anomaly caused by the Moho undulations (g_{moho}), which is the basis for Moho gravity inversion, it is necessary to calculate the gravity anomaly caused by seawater ($g_{seaWater}$), sediment ($g_{sediment}$), crust (g_{crust}) and mantle (g_{mantle}):

$$g_{moho} = g_{freeAir} - (g_{seaWater} + g_{sediment} + g_{crust}) - g_{mantle} \quad (3)$$

125 The gravity effect of each layer is determined by the density variations. Density modeling is a key issue for the Moho inversion. The seawater density is set to be a constant of 1.03 g cm^{-3} (Edgcomb and Bernhard, 2013; Bai et al., 2014; Amos et al., 2003); the sediment density is modeled and estimated based on the porosity and sediment depth (Sawyer, 1985; Bai et al., 2014). The mantle density variations can be converted from the seismic wave structures by the velocity-density relationship (Isaak et al., 1989; Bai et al., 2019a). The island arc crust can be divided into three layers: upper, middle and lower crusts. In
 130 this study, according to seismic-wave velocities and our gravity simulation tests, the crustal density of the upper island arc is set to 2.68 g cm^{-3} (Kay and Kay, 1985; Qian and Wiczorek, 2012), the middle island arc (depth between 7 km and 22 km) is set to 2.93 g cm^{-3} (Kay, 1978; Bai et al., 2013; Calvert, 2011), and the lower island arc is set to 3.18 g cm^{-3} (Kay, 1978; Nirrengarten et al., 2014). The density of normal oceanic crust is set to be a constant of 2.93 g cm^{-3} , which is the same as that of the middle crust (White et al., 1992; Tetreault and Buitier, 2014). The density of the mantle without thermal perturbations
 135 is set to 3.30 g cm^{-3} (Wang, 1970; Ranero and Sallares, 2004). After obtaining the gravity anomalies caused by the Moho undulations, the Moho burial depths are estimated using the gravity inversion method in the frequency domain constrained by the seismic profiles (Oldenburg, 1974; Parker, 2010).

3.2 Defining Arc Boundaries and Magmatism Lifespan

The island arc boundaries distinguish the Aleutian arc from the surrounding plates. The eastern parts of the Aleutian arc
 140 magmas are accreted on continental crust (Reymer and Schubert, 1984; Jicha et al., 2006), and the western and central parts of the Aleutian arc magmas are accreted on oceanic crust. The primitive continental crustal thickness varies greatly, but the oceanic crustal thickness is more uniform (Reymer and Schubert, 1984; Jicha et al., 2006). Therefore, the eastern boundary of

our rate-estimating area is defined as the Unimak Volcano (Fig. 1), since it is a transitional region between the oceanic-oceanic subduction and the oceanic-continental subduction (Calvert, 2011). The southern and western boundaries are the Aleutian Trench and the junction of the Aleutian Trench and the Kuril-Kamchatka Trench, respectively (Fig. 3).

The northern boundary is defined differently at the two sides of 173°E. East of 173°E, arc magmatism driven by dehydration is shallower than 150 km (Ruppert et al., 2007; Jacob et al., 1977; Davies and House, 1979; Ferris et al., 2003; Rasmussen et al., 2018). Therefore, the northern border is set to be the 150 km contour of the slab depth. However, west of 173°E, there is a lack of slab subduction with a depth greater than 100 km due to the slab window here (Levin et al., 2005). The BFZ can be set as the northern border (Jonathan M. Lees et al., 2000; Lay et al., 2017; Davaille and Lees, 2004).

According to the latest 40Ar/39Ar dating and the existing K-Ar age, the Aleutian arc volcanic activity began in the Eocene Epoch, at approximately 46 Ma (Jicha et al., 2006; Jicha and Jagoutz, 2015). The Aleutian island arc is an active area of seismicity today. Therefore, the magmatic activity lifespan is 46 Myr.

3.3 Data Sets

The free-air gravity anomalies, seafloor topography, sediment thickness, initial Moho geometry, oceanic crust age, deep seismic profiles, slab depth and dip are necessary for our magma production rate estimation. The 1 arcmin-resolution global relief model of the Earth's surface (ETOPO1) (Amante and Eakins, 2009), the 5 arcmin-resolution of the Total Sediment Thickness of the World's Oceans and Marginal Seas (Straume et al., 2019), the 1 arcmin-resolution global free-air gravity anomalies (Sandwell et al., 2014), and the 2 arcmin-resolution global oceanic lithospheric age data (Müller et al., 2008) are taken as our input. The three seismic profiles collected in the Aleutian region are the arc strike profile BB' and the two arc crossing profiles AA' and CC' (Lizarralde, 2002; Flidner and Klemperer, 1999; Steven Holbrook et al., 1999) (Fig. 1).

4 Results

Along a series of integral trails perpendicular to the island arc strike, the first overview map of the magma production rate along the Aleutian arc is shown in Fig. 4, which is based on the crustal thickness mapped in Fig. 3. The magma production rates are between 37 km³ km⁻¹ Myr⁻¹ and 89 km³ km⁻¹ Myr⁻¹ for the whole island arc, with an average of 61 km³ km⁻¹ Myr⁻¹

(Fig. 4b). There is a great rate difference between the eastern and western sides of 173°E. West of 173°E, where a slab window is located, the average rate is $41 \text{ km}^3 \text{ km}^{-1} \text{ Myr}^{-1}$. East of 173°E, the average rate is $67 \text{ km}^3 \text{ km}^{-1} \text{ Myr}^{-1}$. There are three peaks on the whole Aleutian island arc (Fig. 4b). Peak A corresponds to the intersection between the Emperor Seamounts and the Aleutian Trench; this position is in the slab window. Between the Rat and Amlia fracture zones, the island arc magma production rate decreases from $70 \text{ km}^3 \text{ km}^{-1} \text{ Myr}^{-1}$ to $53 \text{ km}^3 \text{ km}^{-1} \text{ Myr}^{-1}$ and then increases to $83 \text{ km}^3 \text{ km}^{-1} \text{ Myr}^{-1}$ from west to east. Peak B corresponds to the Rat Fracture Zone, and peak C corresponds to the Amlia Fracture Zone. Overall, the magma production rate coincides with the slab dip, mainly increasing from west to east (Fig. 4b). The correlation coefficient between the rates and dips is 0.83, so the rates are very sensitive to the dip variation. Magma production rates along the Izu-Bonin-Mariana subduction system also show a close correlation between the magma production rates and slab dips (Bai, et al., submitted to EPSL).

The rate uncertainties are mainly due to the accreted crustal thickness, arc boundaries and magmatic activity lifespan. Figure 5 compares the Moho depths via the seismic interpretation and gravity inversion along the three seismic profiles. The two results have similar long-wavelength trends, and the root mean square (RMS) between them is 2.8 km. The differences are from the uncertainties or error of the gravity modeling and seismic measurements, data processing, interpretations and so on.

To estimate the uncertainties of the rate variations in this paper, a comparison is made with the previous results. However, the previous estimations are based on different magmatic activity lifespans. After setting the magmatic activity lifespan as 46 Myr, the former results were $54 \text{ km}^3 \text{ km}^{-1} \text{ Myr}^{-1}$ (Reymer and Schubert, 1984), $59 \text{ km}^3 \text{ km}^{-1} \text{ Myr}^{-1}$ (Crisp, 1984), $89 \text{ km}^3 \text{ km}^{-1} \text{ Myr}^{-1}$ (Steven Holbrook et al., 1999), $81 \text{ km}^3 \text{ km}^{-1} \text{ Myr}^{-1}$ (Lizarralde, 2002), $72 \text{ km}^3 \text{ km}^{-1} \text{ Myr}^{-1}$ (Dimalanta et al., 2002), and $89 \text{ km}^3 \text{ km}^{-1} \text{ Myr}^{-1}$ (Jicha et al., 2006; Jicha and Jagoutz, 2015). All previous values are in the range of our rate estimations ($37\text{-}89 \text{ km}^3 \text{ km}^{-1} \text{ Myr}^{-1}$). This demonstrates that our estimation results are consistent with those results of our predecessors in general. However, the rates given in this paper are a variety of values.

5 Discussion

The rate estimation results suggest that slab dip, fracture zone, and ridge subduction are potential factors affecting island

190 arc magmatism. Therefore, the specific mechanism influencing the island arc magma production rates are discussed mainly from the former three aspects.

5.1 Influence of Slab Dip Variations on Arc Magma Production Rate

Fluid released from slab dehydration is one of the main driving factors of arc magmatism (Turner et al., 2000; Grove et al., 2012). The dehydration is mainly controlled by the slab thermal structures (Schmidt and Poli, 1998), which vary with the
195 subducted slab depths, so fluid flux also varies with the depth (Zheng et al., 2016). Figure 6 shows the water flux variations according to the burial depths. Approximately 90 % of the water from the slab is released at depths between 60–80 km under the forearc region (Ribeiro et al., 2015; Tatsumi and Kogiso, 1997; Kerrick and Connolly, 1998; Schmidt and Poli, 1998; Gorman et al., 2006). The water released at this depth has no contribution to the formation of the island arc magma that is restricted by temperature here (Tatsumi and Kogiso, 1997; Schmidt and Poli, 1998; Ribeiro et al., 2015). Most of the remaining
200 10 % of the water is released under the island arc with depths from 80–150 km, which can induce melting of the mantle wedge due to the suitable temperature here (Schmidt and Poli, 1998; Ribeiro et al., 2015; Zheng et al., 2016).

Figure 6 also shows the difference in the water flux for the different slab dips: subarc water flux of high dip subduction is slightly greater than that of the low dip subduction (Gorman et al., 2006; van Keken et al., 2011; Zheng et al., 2016). Note that even though the water flux released under the island arc region is limited and the water flux difference is small between
205 the low-dip and high-dip subduction, the mantle wedge melting degree will increase by 10 % by adding a 0.2 % supply of water (Stolper and Newman, 1994; Pearce and Peate, 1995; Stern, 2002). The melting differences at the mantle wedge will result in different arc magma volumes and variable arc magma production rates (Fig. 7).

5.2 Influence of Fracture Zone Subduction on Arc Magma Production Rate

The highly fractured oceanic crust and upper mantle exposes a large amount of peridotite to the fracture surface, and the
210 main elements of peridotite are Fe^{2+} , Mg^{2+} and Si^{4+} (Singer et al., 2013; Manea et al., 2014; Singer et al., 2007; Wehrmann et al., 2014). The subducting Pacific Plate carries a large amount of matter dissolved in seawater such as Na^+ , K^+ , and Cl^- (Parendo et al., 2017). The intense material exchange between peridotite and the soluble matter with different elemental compositions

is called hydrothermal alteration (Stefánsson and Kleine, 2017; Parendo et al., 2017; Kitajima et al., 2010). The intense hydrothermal alteration transforms peridotite into serpentinite on or near the surface of the subducted slab (Singer et al., 2013; Weller and Stern, 2018; Manea et al., 2014; Schlaphorst et al., 2016).

When the water-rich (13 wt %) and light peridotite rises to a depth of 80–120 km, it will decompose due to decompression (Zheng et al., 2016). Therefore, the fluids produced by the fractured slab are more than those released by the normal slab dehydration (Singer et al., 2013; Weller and Stern, 2018; Manea et al., 2014; Wehrmann et al., 2014; Singer et al., 2007; Schlaphorst et al., 2016). More fluids flow into the mantle wedge and promote more mantle wedge melting (Fig. 8) (Ulmer and Trommsdorff, 1995; Scambelluri et al., 2001; Hacker et al., 2003), which increases the island arc magma production rate.

5.3 Influence of Ridge Subduction on Arc Magma Production Rate

Geochemical evidence shows that there are obvious elemental differences between adakites west of 173°E and basalts east of 173°E (Defant and Drummond, 1990; Yogodzinski et al., 2001; Levin et al., 2005). The rock difference is due to the two ways of island arc magmatism: the molten mantle wedge is induced by fluids east of 173°E and by slab melts west of 173°E. The slab window west of 173°E exposes the edge of the subducted Pacific Plate to the mantle (Davaille and Lees, 2004; Lay et al., 2017; Lees et al., 2007). As shown in Fig. 8, at the edge of the slab window, the hot asthenosphere mantle upwells and provides a high enough temperature for slab melting. High-Si products emerged after melting of the subducted slab dominated by basalt oceanic crust (Kay, 1978; Cai et al., 2014; Yogodzinski et al., 2013). The melting of the mantle wedge is induced by the melting products of the subducted slab (Yogodzinski et al., 2013; Pineda-Velasco et al., 2018; Rosenbaum et al., 2018), resulting in island arc magma.

At peak A, the subducted slab strength is weak due to the high thermal structure of the seamount located slab (Morell, 2016; Davaille and Lees, 2004; Nishizawa et al., 2017). When the edge of the slab window is at a high temperature, the weak slab will rupture (LisMancilla et al., 2015; De Boorder et al., 1998). Therefore, the lithospheric mantle and lower crust subside into the asthenosphere (Kay and Kay, 1993; LisMancilla et al., 2015; Göğüs et al., 2017). The high temperature and low density materials in the asthenosphere upwell again, which promotes greater melting of the subducted slab (Lee and King, 2010; Levin et al., 2005; Contreras-Reyes et al., 2008). Therefore, due to ridge subduction, more melting products interact with the mantle

wedge and induce more magma upwelling, which finally increases the island arc magma production rate.

6 Conclusions

Estimating island arc magma production rates requires arc magmatic thickness, arc boundaries and magmatism lifespan.

240 Magmatic thickness is mapped via gravity inversion, which is constrained by deep seismic profiles. The boundaries of the intra-oceanic subduction part of the Aleutian arc are delineated according to the tectonic settings. The newest geochemical dating indicates that the subduction initiated at 46 Ma. Finally, the first overview of the island arc magma production rate variations along the Aleutian arc is mapped.

The magma production rate variations along the Aleutian arc indicate that there are mainly three factors affecting the
245 island arc magma production rate: slab dip, fracture zone, and ridge subduction. The formation of island arcs is mainly due to the melting of the mantle wedge, which is driven by the fluids and melts from the subducted slabs at the east and west sides of 173°E of the Aleutian arc.

The fluid-driven mechanisms of magmatism are as follows: (1) The slab water flux at subarc depths increases with increasing slab dip, and the mantle wedge melting degree will increase by 10 % when adding 0.2 % water supply. Therefore,
250 the island arc magma production rates have the same trend as the slab dips. (2) The new water-rich and light serpentine is formed in the fracture zones by the material exchange due to the elemental difference between the soluble matter of the subducted slab and the peridotite exposed on the fracture zones, and it decomposes under the island arc due to decompression. Therefore, both the slab fluid flux and mantle wedge melting degree are increased where the fracture zone is subducting, and subsequently, the fracture zones correspond to peaks in the arc magma production rate.

255 The influence mechanism of the melt-driven factor is as follows: The slab located in the Emperor Seamounts is weak and more easily molten. Therefore, more slab melts are produced, the melting degree of the mantle wedge increases and more island arc magmas are produced. Therefore, the ridge subduction at the slab window also corresponds to the arc magma production rate peak.

Data availability. The datasets used for this research are all recorded in the article, please check section 3.3.

260 *Author contributions.* Bai proposed the idea of this study and wrote the article. Zhang and Dong collated the basic datasets of the research and wrote the code. Everyone participated in the final mechanism discussion, checked and modified the article.

Competing interests. The authors declare that they have no conflict of interest.

Figure

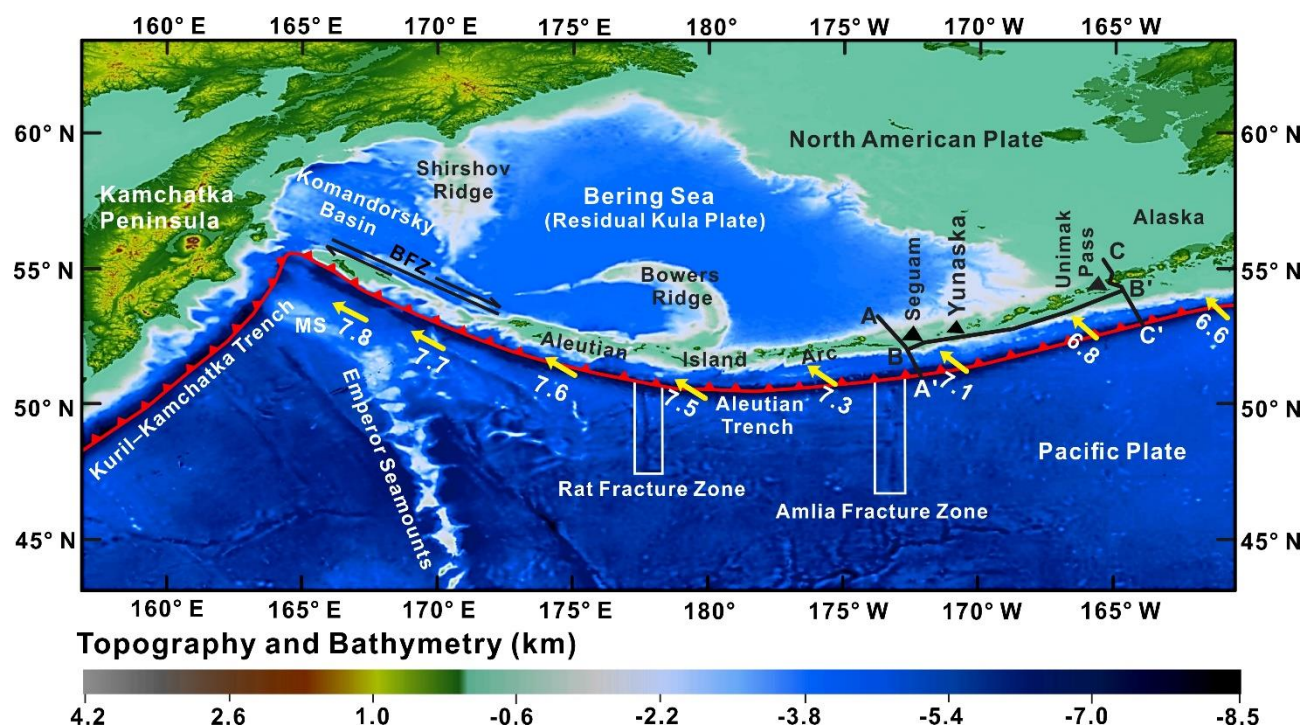

Figure 1. Topography and Bathymetry of the study area, which is released by Amante and Eakins.(2009). The three black solid lines represent the wide-angle seismic lines AA', BB' and CC'. The yellow arrows show the slab convergence directions, and rates (Lay et al., 2017). The white rectangular frames are the fracture zones. BFZ: Bering Fracture Zone; MS: Meiji Seamounts.

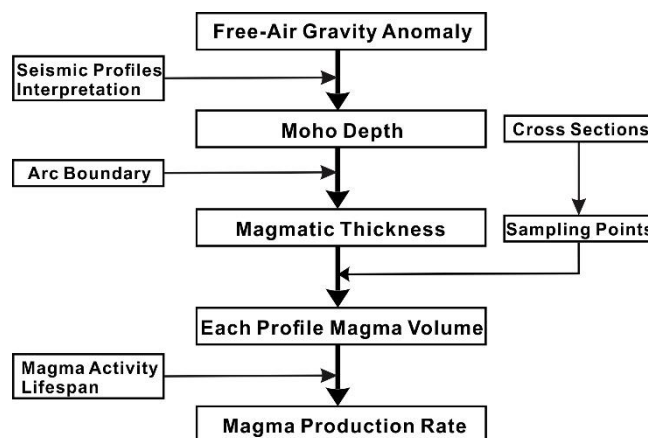

Figure 2. Island arc magma production rate estimation flow. The gravity effect of the different layers of the solid Earth is evaluated by density modeling, and thus, the gravity anomaly caused by the Moho undulations is isolated. The Moho depth can be inverted under the constraints of the seismic profiles. The accreted magma thickness is estimated based on the Moho undulations. Finally, the magma production rate variations along the island arc strike are obtained along different arc crossing sections, under the constraints of the island arc boundary and magmatic activity lifespan.

530

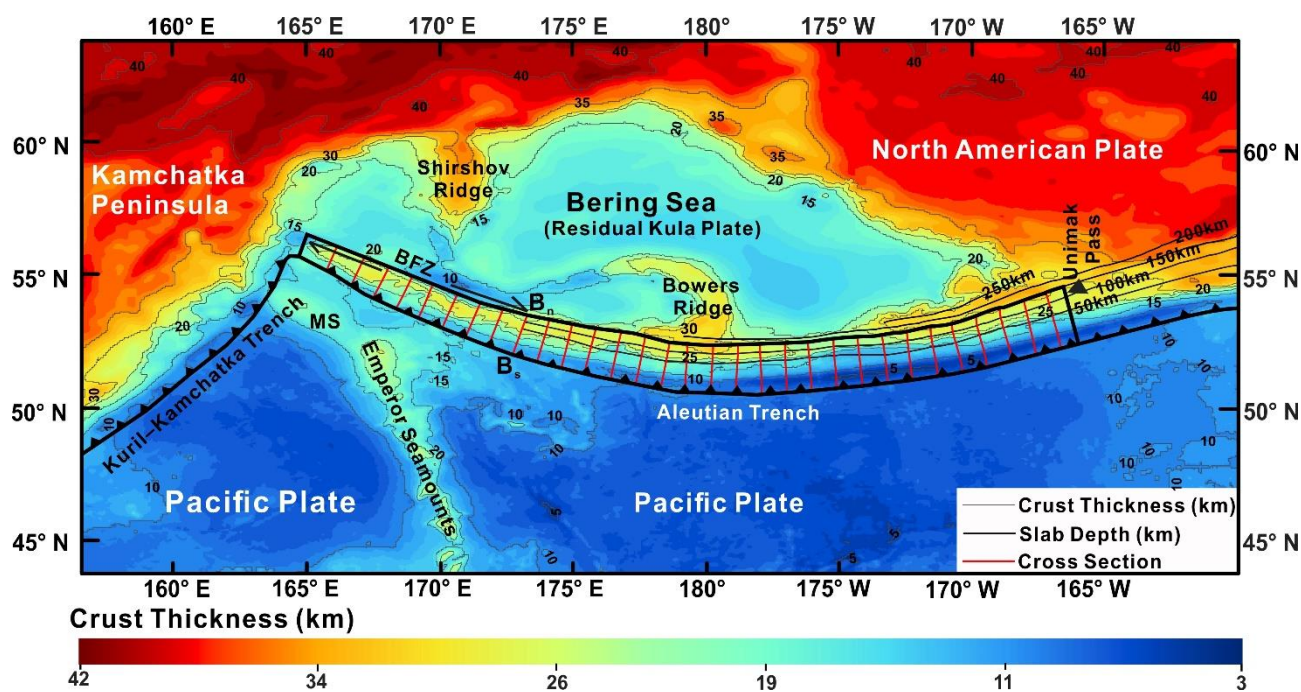

Figure 3. Crustal thickness map, which represents the vertical distance between the sediment bottom and the Moho interface. The Moho depth is obtained by gravity based on lithospheric density modeling. The thick black lines limit the boundary of the intra-oceanic subduction part of the Aleutian island arc. The labeled gray solid lines represent the contour of crust thickness. The labeled black lines represent the subducted slab depths. The labeled red lines are the cross sections along the arc strike. MS: Meiji Seamounts; BFZ: Bering Fracture Zone.

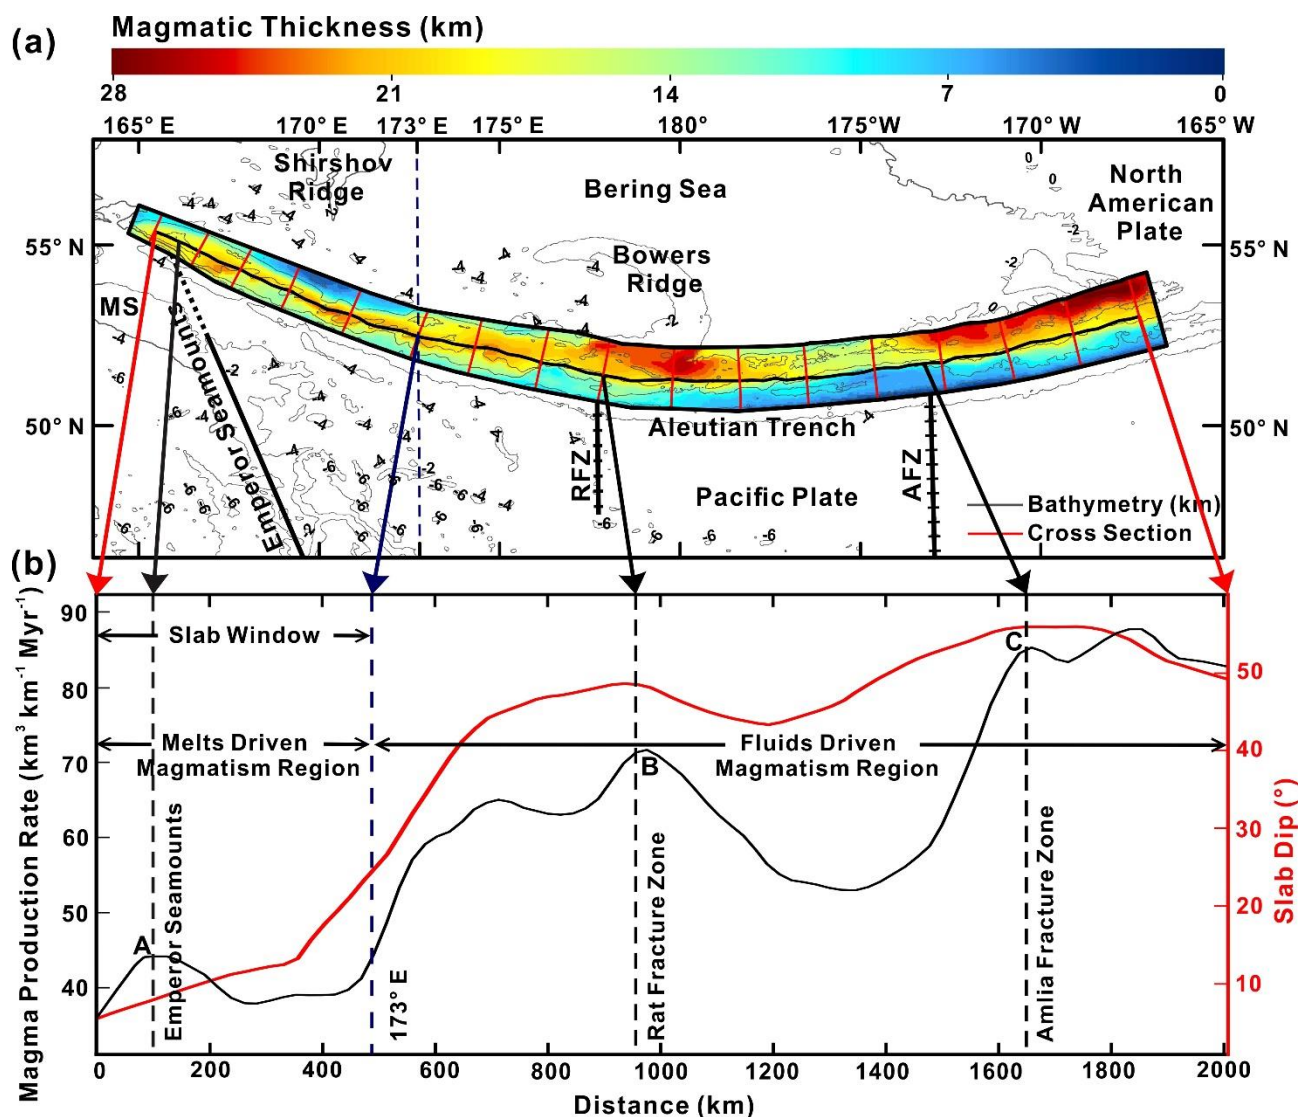

Figure 4. (a) Magmatic thickness is obtained by removing the original oceanic crustal thickness of 6 km from the current arc thickness. The black dotted line represents the extension of the Emperor Seamounts Chain. (b) The island arc magma production rates and slab dips along the Aleutian arc. The black solid curve indicates the island arc magma production rates, and the red solid curve indicates the slab dips (Hayes et al., 2018). A, B and C indicate three rate peaks. RFZ: Rat Fracture Zone; AFZ: Amlia Fracture Zone; MS: Meiji Seamounts. Other symbols are the same with as in Fig. 3.

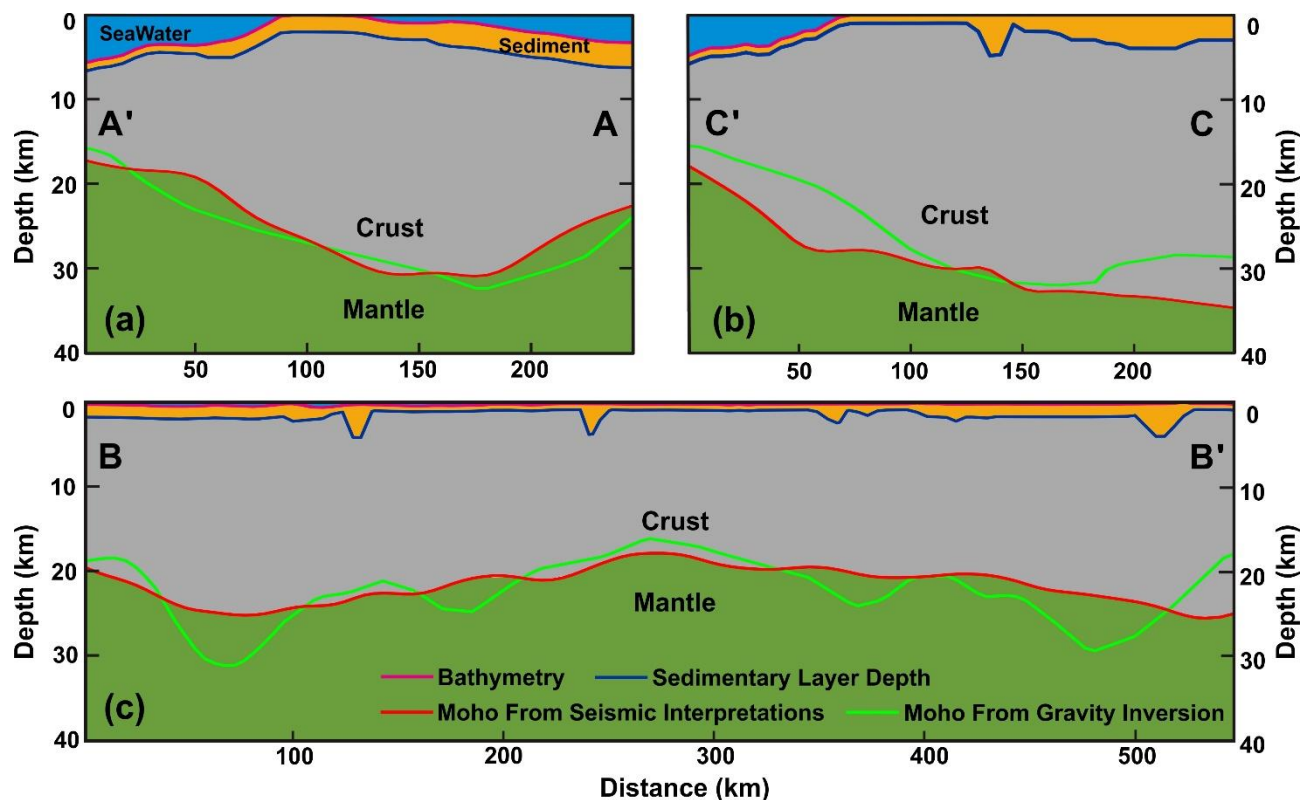

Figure 5. Contrast between the Moho geometries from the seismic interpretations and gravity inversion along the three seismic lines whose locations are shown in Fig. 1 (Calvert, 2011). Bathymetry is from ETOPO1 (Amante and Eakins, 2009) and sediment thickness is by Straume et al. (2019).

Figure 6. Water flux variations at different depths for low-dip (a) and high-dip (b) subduction after Gorman et al. (2006). The Water flux increase with the increase of slab dip. Approximately 90 % of the water is released under the forearc region (depth less than 80 km), and approximately 10 % are released under the island arc (depth between 80 and 150 km), very limited parts are lost under the back arc basin (depth greater than 150 km).

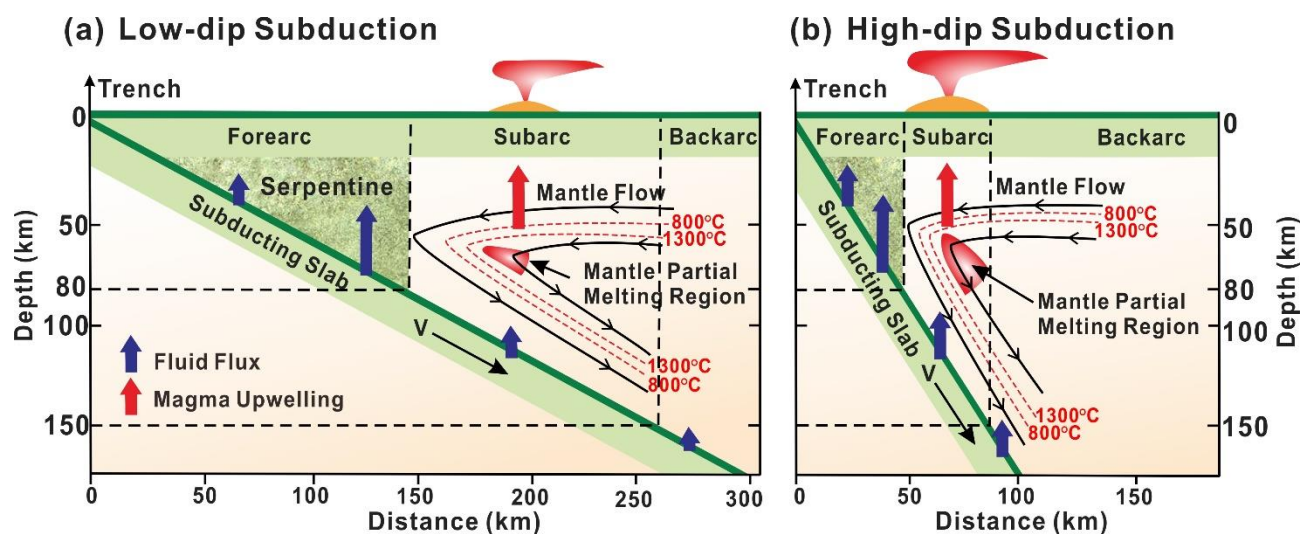

Figure 7. The island arc magma formation for low-dip (a) and high-dip (b) subduction after Schmidt and Poli. (1998). The black arrow indicates the mantle flow direction. The water flux at the subarc depths of high-dip subduction is greater than that of at the low-dip subduction. More water flux at the subarc depths means more mantle partial melting and more island arc magmatism to island arc.

Figure 8. The 3D cartoon of island arc magmatism when there are a fracture zone subduction and a slab window. The fluids and melts represent the parts which can contribute to the island arc magmatism. The fracture zone would supply more fluids because of the formation of serpentine by hydrothermal alteration near or on the slab surface. At the location of the slab window, the asthenosphere mantle upwells, resulting in melting of the exposed slab edge. Fluids and melts from the subducted slab upwell to the mantle wedge and induce mantle partial melting of the mantle. The molten mantle then would then contribute to island arc magmatism.
