## Abstract

Six hydraulic shearing experiments have been conducted in the framework of the In-situ Stimulation and Circulation experiment within a decameter-scale crystalline rock volume at the Grimsel Test Site, Switzerland. During each experiment  
15 fractures associated with one out of two shear zone types were hydraulically reactivated. The two shear zone types differ in terms of tectonic genesis and architecture. An extensive monitoring system of sensors recording seismicity, pressure and strain was spatially distributed in eleven boreholes around the injection locations. As a result of the stimulation, the near-wellbore transmissivity increased up to three orders in magnitude. With one exception, jacking pressures were unchanged by the stimulations. Transmissivity change, jacking pressure and seismic activity were different for the two shear zone types,  
20 suggesting that the shear zone architectures govern the seismo-hydro-mechanical response. The elevated fracture-fluid-pressures associated with the stimulations propagated mostly along the stimulated shear zones. The absence of high-pressure signals away from the injection point for most experiments (except two out of six experiments) is interpreted as channelized flow within the shear zones. The observed deformation field within 15 m – 20 m from the injection point is characterized by variable extensional and compressive strain, produced by fracture normal opening and/or slip dislocation, as well as stress  
25 redistribution related to these processes. At greater distance from the injection location, strain measurements indicate a volumetric compressive zone, in which strain magnitudes decreasing with increasing distance. These compressive strain signals are interpreted as a poro-elastic far-field response to the emplacement of fluid volume around the injection interval. Our hydro-mechanical data reveal that the overall stimulation effected volume is significantly larger than implied by the seismicity cloud, and can be subdivided into a primary stimulated and secondary effected zone.

## 30 1 Introduction

The need for CO<sub>2</sub>-neutral and nuclear-free energy production has led to global interest in the extraction of deep geothermal energy. It has been stated, that only a small portion of the worldwide geothermal resources are exploited (Tester et al., 2006). Unfortunately, at the depths where temperatures are high enough for industrial scale electricity production (>150 °C), the  
35 natural transmissivities of interconnected fractures are too small to establish sufficient fluid circulation for effective heat extraction (Manning and Ingebritsen, 1999) in many regions of the world. Thus, in these regions, the geothermal reservoirs need to be engineered by high-pressure hydraulic stimulation treatments that aim to increase the reservoirs transmissivity (Brown et al., 2012).

These engineered heat exchangers are mostly located within the crystalline crust and are referred to as engineered/enhanced geothermal systems (EGS). Hydraulic stimulations include two possible endmember mechanisms: hydraulic shearing (HS),  
40 i.e., the hydraulic reactivation of pre-existing fractures by irreversible shear dilation, and hydraulic fracturing (HF), i.e. the

initiation and propagation of new tensile fractures. Both mechanisms can occur concomitantly under certain conditions that depend upon the in-situ stress field, injection pressure and/or flow rate, initial fracture transmissivity, and fracture network connectivity (McClure and Horne, 2014; Rutledge et al., 2004).

Examples of hydraulic stimulation injections in crystalline rocks have shown that they give rise to induced seismicity (Evans et al., 2005a; Häring et al., 2008; Parker, 1999; Pearson, 1981; Sasaki, 1998), which can exceed magnitudes that are recognized at the surface (Davies et al., 2013; Zoback and Harjes, 1997). Thus, one of the main challenges for EGS is keeping the seismic hazard at an acceptable level while strongly increasing the reservoirs transmissivity and connectivity. A deeper understanding of the seismo-hydro-mechanical (SHM) responses of rock masses and its fractures to elevated fluid pressure is needed to meet these challenges.

10 Quantitative seismological, hydraulic and/or mechanical observations pertaining to reservoir stimulation have been made in a number of laboratory experiments (Bandis et al., 1983; Olsson and Barton, 2001; Vogler et al., 2018), and in field projects on the kilometer-scale (i.e. reservoir-scale) (Evans, 2005; Evans et al., 2005b; Häring et al., 2008). Experiments on the scale of tens to hundreds of meters are relatively few in number, but are key to bridge the gap in process understanding between the laboratory- and reservoir-scale. Experiments on the intermediate scale are less controlled compared to laboratory-sized  
15 experiments, but still allow monitoring of seismicity, and the pore-pressure and deformation response at a high spatial resolution. However, in multiple projects at this scale (e.g. Cornet & Morin, 1997; MacDonald et al., 1992; Niitsuma, 1989; Rummel & Kappelmayer, 1983; Wallroth et al., 1999) the reservoirs were accessed from boreholes drilled from the surface, giving little possibility of installing dense instrumentation in the near-field. Experiments performed at similar scale within underground rock laboratories, where holes are drilled from galleries, can overcome this limitation.

20 So far direct observations of fracture fluid pressure during the stimulation of full- and intermediate-scale reservoirs are rare, owing to the practical difficulties of sensor emplacement. Thus, information about pressure propagation and induced deformations usually stems from micro-seismic recordings (e.g. Duboeuf et al., 2017; Evans, Moriya, et al., 2005; Rutledge et al., 2004) and active seismic velocity tomography (Doetsch et al., 2018b; Rivet et al., 2016). In addition, seismicity clouds are often used to infer size, shape and growth of the rock mass volume affected by the stimulation treatments (Cipolla and Wallace,  
25 2014; Mayerhofer et al., 2010; Shapiro et al., 1997). However, Duboeuf et al. (2017) argued that induced seismicity is not necessarily directly associated with fluid pressure diffusion, but rather with induced stress perturbations. This is consistent with evidence from some field sites that a significant fraction of the induced slip and deformation was aseismic (Cornet et al., 1998; Duboeuf et al., 2017; Evans et al., 2005a; Guglielmi et al., 2015, Villiger et al., 2020). Thus, there is some doubt as to the degree to which induced seismicity and the seismic cloud illuminate the volume affected by stimulation treatments.

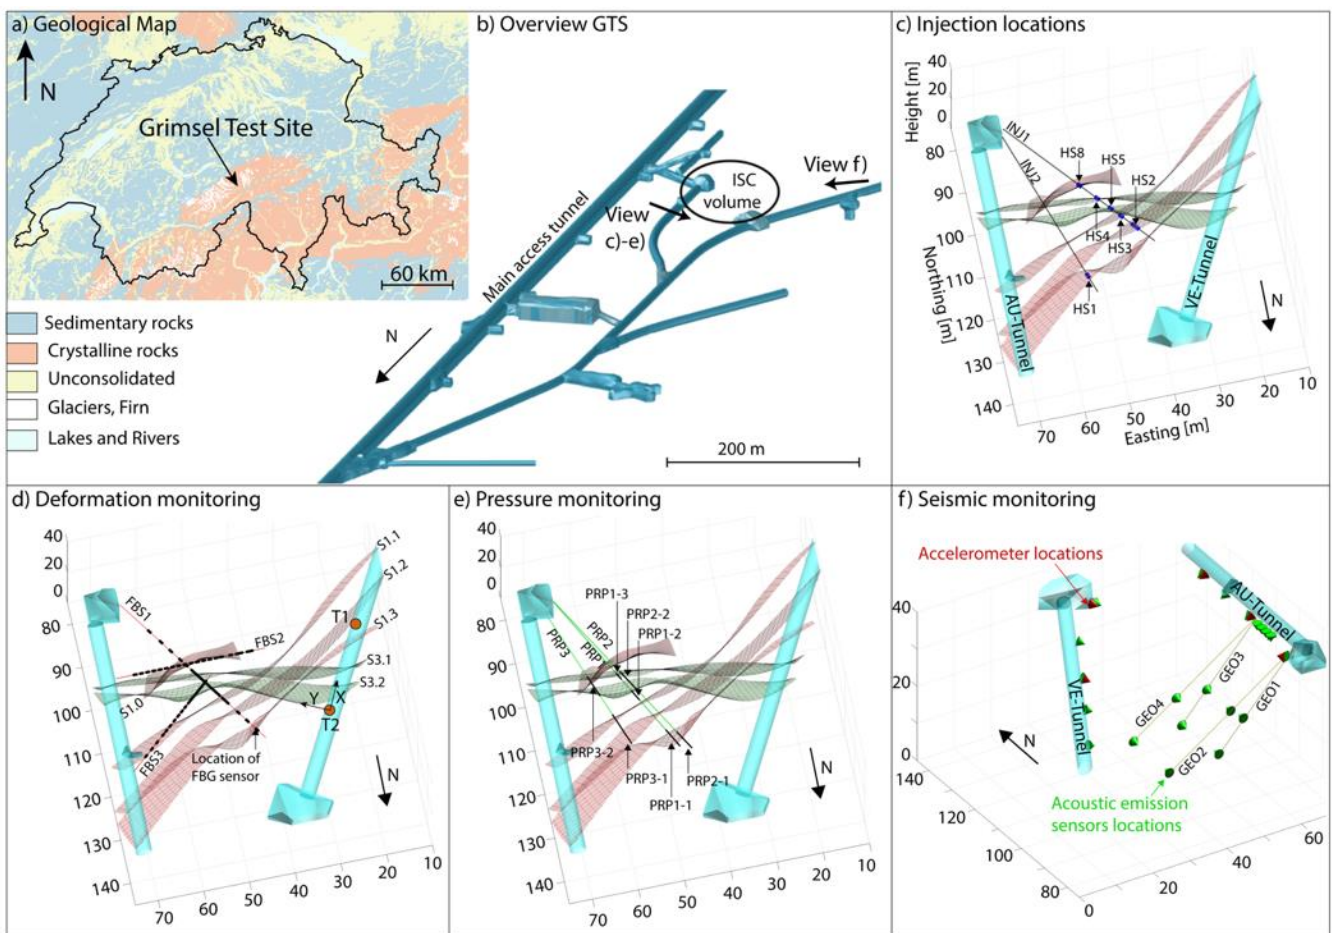

30 The patterns of micro-seismicity induced during reservoir-scale stimulation experiments in crystalline rock suggest that fracture zones and faults serve as the primary pathways for fluid penetration in the reservoir. Diffusion occurs mainly in an interconnected fracture network in the reservoir (Evans et al., 2005a; Fehler et al., 1987). Thus, the flow field is likely complex and does not conform to idealized radial or dipole geometries (Evans et al., 2005a).

For the majority of intermediate- to full-scale stimulations, the reservoir response can only be inferred from pressure and flow  
35 data acquired along the injection well. These data demonstrated that the injectivity can be irreversibly enhanced by several orders of magnitudes, primarily due to irreversible dislocation of fractures (Bao and Eaton, 2016; Davies et al., 2013; Evans et al., 2005b; Kaieda et al., 2000; Zoback and Harjes, 1997). Flow logging in injection wells conducted during various stimulation projects in crystalline rock show that the majority of the injected fluid volume entered the reservoir through a small number of natural fractures, whose transmissivities were permanently increased by the injections (e.g. Brown et al., 2012;  
40 Cornet & Morin, 1997; K. F. Evans, Genter, et al., 2005; K. Evans & Sikaneta, 2013; Parker, 1999). Although important insight in the stimulation induced reservoir response have been inferred from induced seismic data and observations in injection wells, direct observations of the pressure field evolution and HM-coupled responses away from the injection well are still missing.

We present here direct hydraulic and mechanical observations that were made during six hydraulic shearing experiments, conducted in February 2016 at the Grimsel Test Site (GTS), Switzerland. The experiments were part of the In-Situ Stimulation and Circulation (ISC) project (Amann et al., 2018). A comprehensive monitoring system - consisting of pressure intervals and longitudinal strain sensors - was distributed along 12 boreholes within the decameter-scale test volume. This monitoring system provided detailed information on the complex flow field and rock mass response during stimulation, and important constraints on the shape and size of the volume affected by the stimulations. We followed the same standardized injection protocol for all six HS experiments to study the influence of geological structures (i.e., shear zone) on the variability of HM-coupled rock mass responses. We also compared our hydro-mechanical observations with the observed induced seismicity (Villiger et al., 2020) and results from active seismic surveys (Doetsch et al., 2018b; Schopper et al., 2020) conducted during the stimulations.

## 10 2 Test volume characteristics

The test volume is located at the southern end of the Grimsel Test Site (GTS). This underground research facility is operated by Nagra (Swiss National Cooperative for the Disposal of Radioactive Waste).

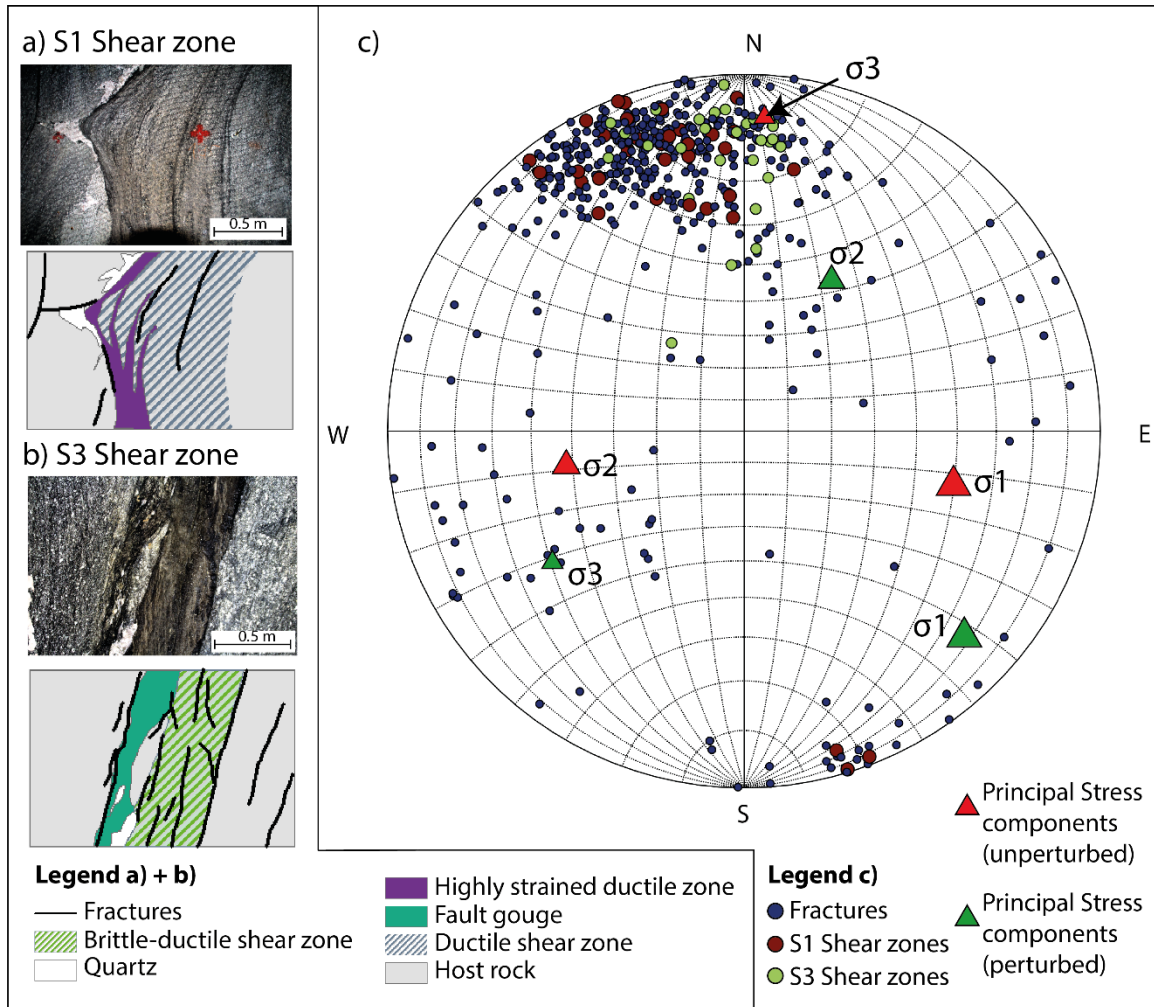

15 **Figure 1.** Location of the GTS in Switzerland indicated in the geological map a), and location of the test volume within the GTS b). c) shows the location of the injection intervals together with the target shear zones. d) illustrates locations of the strain sensors and tilt meters, with indicated tilt axes, and labels the target shear zones. The pressure monitoring intervals are shown in e) and the station locations of the seismic monitoring network is indicated in f) More details on the monitoring setup can be found in Doetsch et al. (2018a.)

The GTS is located in crystalline rocks and has an overburden of ~480 m. The Early Permian rocks (Grimsel Granodiorite and Central Aar Granite) intruded the crystalline crust 299±2 Ma ago (Keusen et al., 1989; Schaltegger and Corfu, 1992), and are close to the mineralogical transition between granodioritic and granitic rocks (Wenning et al., 2018). The rock mass in the test volume contains a pervasive foliation with an average orientation of 140/80 (i.e., dip-direction/dip) (Krietsch et al., 2018b). In addition, the rock mass is intersected by two sets of shear zones (see Figure 1c-f) that differ in their genetic history and present-

day architecture. The older set, referred to as *S1*, contains four subparallel shear zones (Figure 2a) which includes few poorly hydraulically connected fractures (Brixel et al., 2020b) with an average orientation of 142/77 (Figure 2c). The younger set, referred to as *S3*, includes subparallel shear zones with an average orientation of 183/65 (Figure 2b). Within the test volume, the two present *S3* shear zones coincide with a meta-basic dyke each which accommodated most of the past deformation.

5 Optical televiewer (OPTV) images suggest that the rock mass between the two *S3* shear zones is intensely fractured (>20 fractures/borehole meter). This has been confirmed by geophysical imaging (Doetsch et al., 2020). Thus, this zone differs from the relatively undisturbed rock mass surrounding these shear zones which has 1-3 fractures per meter (Krietsch et al., 2018b). During the deformation history of the rock mass, the *S1* shear zones were sheared in a right lateral manner by the *S3* shear zones. Therefore, the *S1* shear zones and the fractures included therein can have a local orientation that is sub-parallel to *S3*.

10 **Figure 2. Photographs (upper image) and interpretations (lower image) of the *S1* (a) and *S3* (b) shear zones as seen at the AU tunnel wall (modified after Krietsch et al., 2018b). c) A lower hemisphere stereo net showing the poles of all mapped fractures and shear zones. The orientations of the principal stress components from the unperturbed and perturbed tensor are also shown.**

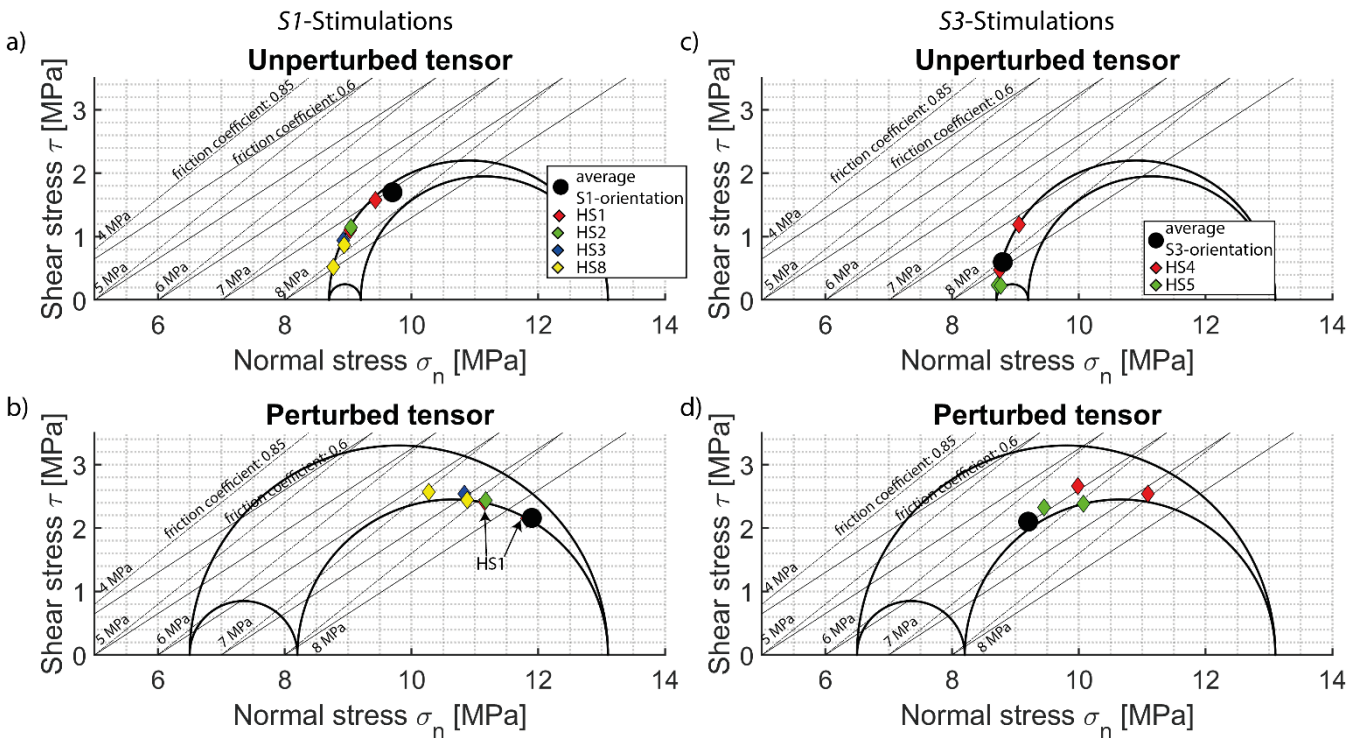

In addition to the geological characterization, the in-situ stress field was characterized prior to stimulation within the test volume by Krietsch et al. (2018c). A progressive stress field perturbation to an otherwise relatively uniform ‘far-field’ stress state was observed. It begins 11 m from the shear zones, as they are approached from south (Krietsch et al., 2018c). The estimated unperturbed ‘far-field’ principal stress magnitudes (measured 40 m away from the target shear zones) are 13.1 MPa ( $\sigma_1$ ), 9.2 MPa ( $\sigma_2$ ) and 8.7 MPa ( $\sigma_3$ ). At a distance of ~5 m from the shear zone the principal stress magnitudes dropped to 13.1 MPa ( $\sigma_1$ ), 8.2 MPa ( $\sigma_2$ ) and 6.5 MPa ( $\sigma_3$ ). In addition, the principal axis orientations differed from those of the unperturbed tensor (Figure 2c) (This solution is referred to as the perturbed tensor). As the shear zone is approached,  $\sigma_3$  declines to as low as 2.9 MPa immediately before the zone. Although the perturbed stress tensors have been measured closer to the target stimulation volume and shear zones, also the unperturbed stress tensor is considered in our analyses; through the conceivable

15

20

substantial stress heterogeneities, it remains unclear whether the perturbed or unperturbed stress tensor explains our observations better.

The unperturbed stress tensor would imply that the shear stresses  $\tau$  acting on the *S1* shear zones tend to be higher than those acting on the *S3* shear zones, whereas they are similar for the perturbed stress tensor (Figure 3). We assume that the perturbed stress tensor is better representative for locations near the stimulation injection well, and the unperturbed stress tensor for the far-field.

**Figure 3. Stress states associated with the perturbed and unperturbed tensors for S1 and S3 shear zones.. The implied average shear and normal stresses acting on the S1 and S3 shear zones (estimated over all mapped borehole intersections of these shear zones) are indicated in black. Also shown are the shear and normal stress acting on the principal fractures imaged in the S1 and S3 intersections with INJ-boreholes. Additionally, a range of injection pressures is indicated as black lined failure criterion with different friction coefficients.**

### 3 Monitoring and methods

The ISC test volume can be accessed from three tunnels. A total of 12 boreholes were drilled into the test volume for high pressure fluid injection (referred to as INJ-boreholes), and monitoring of pressure (PRP-boreholes), strain (FBS-boreholes) and seismicity (GEO-boreholes) (Figure 1).

The six stimulation experiments targeted the four *S1* shear zones and two *S3* shear zones along the INJ-boreholes (Table 1 and Figure 1c). The injection intervals for the stimulation experiments were defined on the basis of optical televiewer (OPTV) images and the 3D geological model by Krietsch et al. (2018b). They had a length of 1 m or 2 m, and covered the target shear zones plus adjacent fractures. To quantify the near-wellbore transmissivity changes of the intervals resulting from the experiments, low-pressure ( $P_{injection} < 0.5$  MPa) hydraulic tests consisting of pulse and constant rate injections were conducted before and after the hydraulic stimulation campaign in each injection interval (Brixel et al., 2020a, 2020b; Jalali et al., 2018a, 2018b). The hydraulic properties of the intervals (i.e. transmissivity, storativity, and wellbore storage) were estimated using the numerical simulator nSight<sup>1</sup>.

### 3.1 Injection protocol

The standardized protocol consisted of four injection cycles, which each consisted of progressively-increased pressure or flow-rate steps (Figure 4). In all cases, the steps were kept constant until quasi steady-state flow conditions were reached. The first two cycles were step-pressure injections, and were intended to estimate the pre-stimulation jacking pressure and injectivity of the injection interval. Here, the first cycle serves to break down the injection interval, so that the near-wellbore fracture responses during subsequent cycles are largely elastic. The third cycle was a step-rate injection that constituted the actual stimulation. The majority of the fluid volume was injected during this cycle, and was intended to propagate the stimulation effects away from the injection well. The last cycle was performed to estimate the post-stimulation jacking pressure and injectivity, and began under pressure control but then switched to flow rate control to obtain higher flow rates in the last two injection steps. Each injection cycle was followed by a shut-in phase and a subsequent venting phase. During venting, the pressure lines were opened to the atmosphere in the AU Tunnel for 20 to 40 mins. However, the lines leading to the pressure monitoring intervals were opened only after the actual stimulation phase and the final injection cycle for intervals that showed a significant pressure change. Thus, the induced fluid pressure disturbances within the fractures of the rock mass were partly, but not entirely drained at the beginning of each injection cycle. Following each experiment, all intervals were allowed to drain for a minimum of 12 hours before the next experiment. The total volume of fluid injected in each experiment was limited to approximately 1000 liter to ensure low seismic hazard and little disturbances to nearby experiments (Gischig et al., 2016). The backflows from the injection borehole and all pressure monitoring intervals were measured during the venting phases.

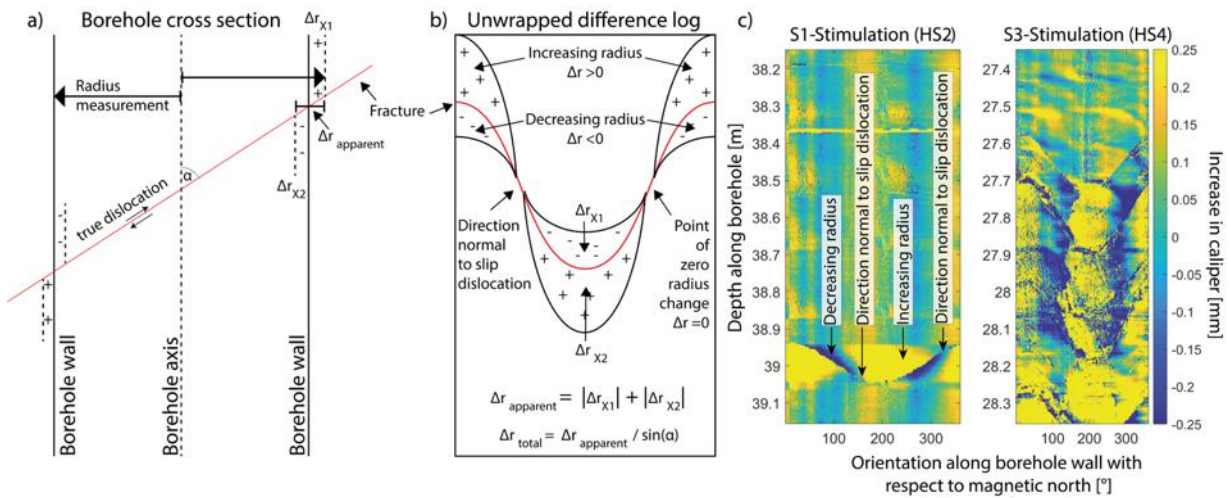

20 **Figure 4. Injection protocol for (a) experiment HS2, which targets S1 structure S1.2, and (b) experiment HS4, which targets S3 structure S3.1. The various phases of the four cycles performed in each experiment are indicated in b. Similar plots for all other intervals are presented in Figure A2 of the Appendix.**

### 3.2 Monitored properties at the injection well

Hydraulic jacking pressure and injectivity were determined from a P-Q cross-plot of the test data, where P presents the injection pressure and Q is the injection flow rate. Each point denotes the flow and pressure values at the end of each step when quasi steady-state conditions are reached, typically after 10 minutes. The injectivity of the test interval is taken as the ratio between the flow rate and injection pressure at low injection pressures, when mechanical effects are negligible. The intersection of the low-pressure linear trend with the pressure axis defines the initial formation pressure. Dahlø et al. (2003) noted that there is no consensus as to which feature in the P-Q plot provides the best estimation of the jacking pressure (i.e. the normal stress

across the fractures that supports the lowest normal stress) because it is unclear at which point along the steepening P-Q curve the compliant fracture response turns into lift-off of the fracture surfaces. We take our best estimate of the jacking pressures before and after the stimulation as the intersection of the low- and high-pressure trends of the second and fourth cycles respectively. In both these cycles it is assumed that the response of the fracture network to the step-increases in pressure is purely elastic and repeatable. Therefore, the low-pressure injectivity was also derived from the second and fourth injection cycle (Figures 6 and A3 in the appendix). In addition, we picked the injection pressure limit during the actual stimulation (injection cycle 3) for all experiments (Figure A3).

The induced slip dislocation within the injection intervals were estimated from acoustic televiewer (ATV) logs that were run before and after each HS experiment. The ATV probe has a travel time precision of  $0.1 \mu\text{s}$ , yielding a radius precision of  $0.07 \text{ mm}$  for borehole fluids with a P-wave velocity of  $1483 \text{ m/s}$ . The travel time precision of the ATV decreases as the measured amplitude of the received P-wave decreases. Thus, the precision strongly decreases as the borehole wall becomes very rough, or the borehole radius becomes strongly elliptical (Moor and Valley, 2018). Since the *S3* shear zones are located in weak metabasic dykes, which appear rougher at the borehole walls as the *S1* shear zones, the radius resolution is lower for *S3* shear zones than for *S1* shear zones. By comparing the pre- and post-stimulation geometry of the borehole cross-section across fractures it is possible to determine whether dislocation has occurred, and estimate the relative displacement vector (Cornet et al., 1998; Evans et al., 2005b). To enable comparability between the images, all logs were recentralized using an ellipse fit function. Afterwards, a difference log was produced for each test interval by subtracting the pre-stimulation log from the post-stimulation log. In this difference log, a positive caliper change at a location along the borehole wall indicates that the location has moved away from the borehole axis during stimulation (Figure b). The resolved radius changes can be due to: a) stimulation-induced fracture reactivation (i.e., sinusoidal traces along the borehole wall, see Figure c (*HS2*)), or b) damage along the borehole wall (i.e., diffuse traces, see Figure c (*HS4*)). To validate the orientations and locations of reactivated fractures, the ATV logs were compared with the brittle fractures mapped in the optical televiewer images.

**Figure 5. a) Illustration of the travel-time (i.e. radius) measurement of an ATV log across a sheared fracture. b) Observation of slip displacement direction and apparent magnitude estimate visualized in the unwrapped difference log. c) Difference logs for HS2 and HS4 experiments. A clear trace of a reactivated fracture is visible in the HS2 log, whereas a diffuse trace with potential borehole wall damage is shown in the HS4 log.**

To estimate the magnitude of slip dislocation across a reactivated fracture, the areas of radius increase and decrease are mapped along the fracture trace (Figure b). The sum of the absolute maximum radius changes on both sides of the fracture (i.e.  $\Delta r_{x1}$  and  $\Delta r_{x2}$ ) revealed the apparent amount of slip dislocation ( $\Delta r_{\text{apparent}}$ ). Since the radius changes are measured normal to borehole axis, the true slip dislocation  $\Delta r_{\text{total}}$  is calculated by correcting the apparent dislocation  $\Delta r_{\text{apparent}}$  with respect to the intersection angle between the borehole axis and the fracture plane ( $\alpha$ ).

Along the sinusoidal trace of the reactivated fracture within the difference log, the radius change varies from positive to negative and back. The location at which these radius change variations occur ( $\Delta r = 0$ ) is normal to the direction of induced permanent dislocation (Figure b).

### 3.3 Pressure monitoring

5 The three *PRP* boreholes were equipped with customized grouted packer systems to continuously monitor fluid pressure in a total of seven intervals within the test volume (Figure 1e). The pressure monitoring intervals were named according to the borehole name and the interval number counted from the borehole bottom upwards (e.g. PRP2-1 is the lowermost interval in PRP2). The intervals were chosen to cover the different target shear zones in the volume (Table 2). The distances between the monitoring intervals and the injection locations are listed in Table A2. The packer system consists of a grouted section  
 10 (uppermost part), the open pressure monitoring intervals (2 to 3 per borehole), resin sections in intervals without pressure monitoring, and inflatable packers to seal off the monitoring intervals. The packers have a length of 0.2 m and were inflated with pressures between 2 and 3 MPa. The seven intervals were connected to pressure sensors in the AU tunnel through saturated polyamide lines of 2 mm OD. The sensors used were Keller PAA33-X transmitters that had an accuracy of 0.025 MPa. A detailed description of this packer system can be found in Doetsch et al. (2018a).

15

**Table 2. Shear zones sampled by pressure monitoring intervals**

Interval name	Depth [m]	Number of fractures	<i>S1-type</i>	<i>S3-type</i>
PRP1-1	41.8 – 47.9	14	S1.2 & S1.3	
PRP1-2	28.9 – 32.0	6		S3.2
PRP1-3	23.2 – 25.2	6		S3.1
PRP2-1	40.0 – 45.0	8	S1.3	
PRP2-2	21.4 – 27.0	11		S3.1 & S3.2
PRP3-1	24.8 – 32.3	4	S1.1 & S1.2	
PRP3-2	15.0 - 20.5	10		S3.1&S3.2

In addition to the fixed pressure monitoring intervals in the *PRP*-holes, a double-packer system was installed in one of the two  
 20 *INJ*-borehole that was not used for injection. The system allowed pressure to be monitored between the two packers, and between the lower packer and borehole bottom. Similarly, the pressure was also monitored between the lower packer and the borehole bottom in the *INJ*-Borehole that was used for injection. The packer systems in the *INJ*-holes were moved for each experiment to allow injection into and monitoring of the target shear zone (Table A1).

### 3.4 Deformation monitoring

#### 3.4.1 Strain monitoring

25 The three *FBS* boreholes were dedicated to longitudinal strain monitoring (Figure 1d). Borehole *FBS1* intersects all target shear zones, *FBS2* is parallel to the *S3* shear zones, and *FBS3* is subparallel to the *S1* shear zones. A total of 20 longitudinal Fiber-Bragg-Grating (FBG) strain sensors (Type os3600 by Micron Optics Inc.) were installed in each of these boreholes. The sensors were placed along sections with intact rock, as well as with single or multiple fractures (Doetsch et al., 2018a; Krietsch et al., 2018b). Subsequently, the sensors were grouted in place. The FBG sensors have a base length of 1 m and recorded strain  
 30 signals with a resolution of 1 microstrain ( $\mu\epsilon$ ) at a sampling frequency of 1000 Hz.

As first processing step, the data were averaged over 1 s intervals before recording, giving a sampling rate of 1 Hz, and an improved resolution of  $0.1 \mu\epsilon$  (Krietsch et al., 2018a). Temperature corrections were not required for the FBG data since the injected fluid had the same temperature as the rock mass and temperature variations within the rock volume were negligible. To quantify deformation, we follow the geomechanics convention and take the compressional strain as positive.

### 5 3.4.2 Tilt monitoring

Two horizontal bi-axial inclinometers (Type A711-2 by Jewell Instruments) were installed at the bottom of approximately 50 cm deep boreholes were drilled on the floor of the VE-tunnel (*T1-T2* in Figure 1d). They monitor the deviation from horizontal in two orthogonal axes with an accuracy of  $\sim 0.5$  microradians ( $\mu\text{-rad}$ ) at a sampling rate of 100 Hz. The tilt data were processed with a low pass Butterworth filter with 100 Hz cut-off, which enhances resolution to  $\sim 0.05$  microradians. The instruments were oriented such that the x-axis was parallel to the tunnel axis and the y-axis normal to it. A positive tilt signal on the x-axis implies the tunnel floor has dipped towards SWS, and a positive signal on the y-axis implies a dip towards ESE (i.e. towards the test volume) (Figure 1d). Instrument T2 is placed near the intersection of the tunnel with the two *S3* shear zones, *S3.1* and *S3.2*, and instrument T1 lies some 13 m to the south, near the intersection of the tunnel with the *S1* zones *S1.2* and *S1.3*. The tiltmeters were covered with styrofoam balls to minimize temperature effects.

### 15 3.5 Seismic Monitoring

A total of 18 piezo-electric acoustic emission (AE) receivers (Type Ma-BIs-7-70m by GMuG) were installed along the tunnel walls around the test volume. Additionally, eight sensors of the same type were deployed in four dedicated boreholes (i.e., referred to as *GEO* boreholes, Figure 1f). The eight borehole sensors are closest to the injection locations (3 m – 25 m distance) for all six experiments. The sensors have a bandwidth of 1 to 100 kHz. Additionally, five calibrated one-component accelerometers (Type 736T by Wilcoxon) were collocated with the five AE sensors at the tunnel wall for magnitude calibration purposes.

Seismic data were recorded continuously throughout the experiments at a sampling rate of 200 kHz, using a 32-channel acquisition system, with 31 active channels. Induced seismic events were located using an anisotropic velocity model based on manually picked P-wave onsets. For more details on the seismic monitoring and event localization, see (Doetsch et al., 2018a; Gischig et al., 2018; Villiger et al., 2019) .

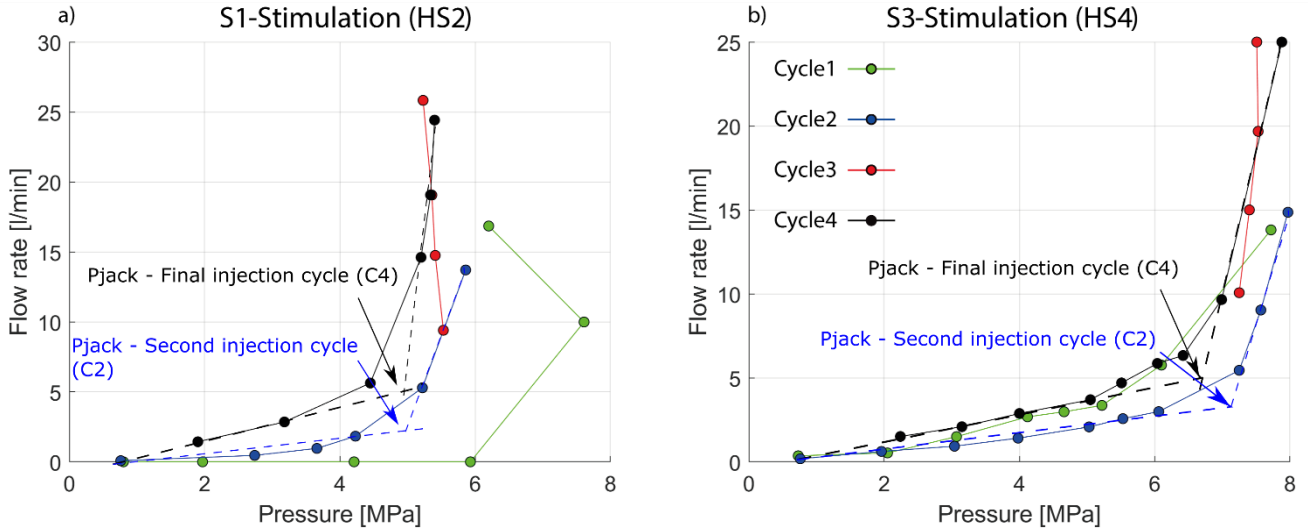

## 4. Results

Given the large volume of data recorded, we will for the most part restrict to illustrating the hydraulic and mechanical observations using the figures for two stimulation experiments as representative for all six hydraulic shearing experiments which are documented in the appendix. We use the experiments called *HS2* and *HS4* as representatives for stimulations that targeted *S1*- and *S3*-fault zones, respectively.

### 4.1 Near-wellbore observations

The initial injectivity and near-well transmissivity for the *S1*-intervals were systematically lower than those for the *S3*-intervals by 1-3 orders of magnitude (Table 1). Despite this difference, the post-stimulation transmissivities were remarkably similar, all lying between  $5.5\text{e-}8 \text{ m}^2/\text{s}$  and  $2.3\text{e-}7 \text{ m}^2/\text{s}$ . Thus, substantial transmissivity increases of up to 3 orders of magnitude were realized for the *S1* shear zones, whereas the increases for the *S3* shear zones were limited to less than an order of magnitude (Figure 7). The final low-pressure injectivities, measured during the last injection cycle, ranged between 0.4 – 1.7 l/min/MPa (Table 1).

The initial jacking pressures in the two injection intervals covering *S3* shear zones are systematically larger than those for the *S1* shear zones, in most cases by  $\sim 1.5$  MPa. Following the stimulations, four of the intervals showed the same or slightly reduced jacking pressure, with one showing a significant decrease (*S1 stimulation - HS1*) and one a significant increase (*S3 stimulation - HS5*) (see Table 1). The final jacking pressures for the *S1*-intervals varied between 3.9 and 5.5 MPa, whereas for the *S3*-intervals the variation was 6.8 and 7.4 MPa. As opposed to *S3* intervals, the maximum recorded interval pressure during cycle 1 in *S1* intervals exceeded the jacking pressure.

**Figure 6.** Cross-plots of flow versus pressure data for the four injection cycles of the *S1* and *S3* stimulation experiment in a) and b), respectively. The points defining the curves for each cycle denote flow/pressure data pairs defined at the end of each step of the test in question. The first cycle frequently reaches high pressures, which may reflect the inelastic processes of the breakage of cohesive bonds and/or the slippage of fractures supporting shear stress. In subsequent cycles, the response to pressurization is largely elastic and reversible.

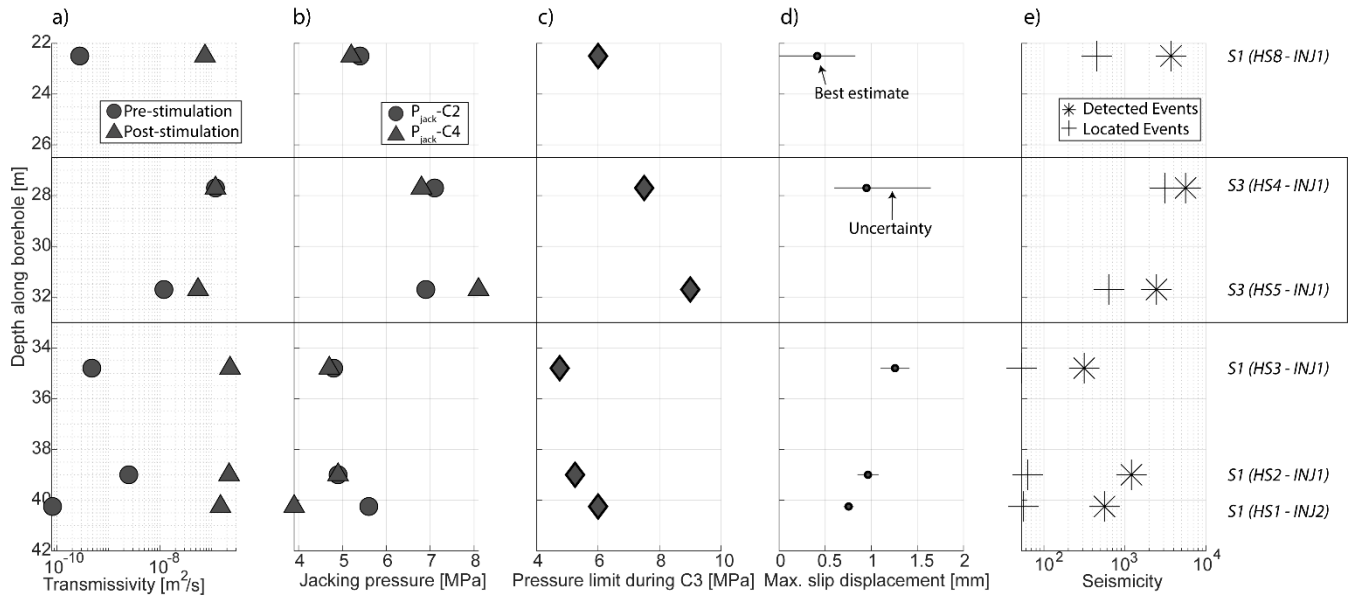

An upper limit of injection pressure despite increasing flow rates (referred to as pressure limiting behavior) was observed during the main stimulation injection cycle in all experiments, with some slight systematic differences between the *S1* and *S3* intervals. For the *S3*-stimulations, a slight increase in pressure with increased flow rate was evident, as the P-Q curves becoming progressively steeper with increased flow rate when a pressure limit was approached on the final step (Figure 6). In contrast, the P-Q curves for the *S1*-stimulations showed pressure monotonically declining with higher flow rate in some cases (i.e. *HS2*, *HS3*), and declining before recovering in others (e.g. *HS1*, *HS8*). As for the jacking pressures, the maximum injection pressures attained in the stimulation injections were consistently higher for the *S3* shear zones than for *S1* shear zones (Table 3).

**Table 3.** Injection pressures measured at the end of the first and last (before shut-in) injection steps of the stimulation injection cycle (C3). The difference between the two values is listed in the lower row.

	HS2 ( <i>S1</i> )	HS4 ( <i>S3</i> )	HS5 ( <i>S3</i> )	HS3 ( <i>S1</i> )	HS8 ( <i>S1</i> )	HS1 ( <i>S1</i> )
$P_{\text{Step1-C3}}$ [MPa]	5.53	7.25	7.3	5.13	5.39	5.91
$P_{\text{LastStep-C3}}$ [MPa]	5.23	7.51	8.85	4.72	5.94	5.97
Difference [MPa]	-0.3	+0.26	+1.55	-0.41	+0.55	+0.06

The resolved slip was localized on a single fracture, as in *HS2*, or distributed over various fractures as in *HS4* (Figure ). The maximum value of  $\sim 1.4$  mm was found for an *S1*-stimulation (*HS3* in Figure 7d). Dislocations slightly less than a millimeter were also identified for other stimulated *S1* shear zones (*HS1* and *HS2*, and perhaps also *HS8*), although the uncertainty is large. A value of  $\sim 1$  mm was obtained for an *S3* stimulation (*HS4*), but the uncertainty in this estimate was large because of the greater borehole wall roughness at the *S3* shear zones (Figure A4). The direction of the slip vector could only be determined

for two zones: for *HS2* it was 261/02 (i.e., dip direction/dip) and for the two reactivated fractures in *HS3* it was 264/01 and 286/04. All three fractures were reactivated in a right lateral strike-slip dislocation in an east-west direction.

5 **Figure 7. Hydro-mechanical responses of the target intervals to the stimulation experiments. Indicated are (a) pre-and post-stimulation transmissivity, (b) pre- and post-stimulation jacking pressure ( $P_{\text{jack-C2}}$  &  $P_{\text{jack-C4}}$ ), (c) injection pressure limit observed during C3, (d) estimated cumulative slip displacement, and (e) number of detected and located seismic events.**

#### 4.2 Fluid pressure inside the rock mass

10 No systematic differences in the recorded pressure magnitude responses to injection into *S1* and *S3* shear zones were evident away from the injection well. The highest fluid pressure perturbations were detected in monitoring intervals that cross the target shear zones. Transient fluid pressure perturbations were observed on almost all *PRP* pressure monitoring intervals during all six stimulation experiments. In four experiments, the pressure increases rarely exceeded 1 MPa, even though peak injection pressures ranged between 5 – 9 MPa (Figure and A5). However, fluid-pressures up to 6.7 MPa and 4.2 MPa in magnitude

15 were observed during a *S3* stimulation (*HS5*) and a *S1* stimulation (*HS8*), respectively (Figure A5). These perturbations were only seen in few pressure monitoring intervals during these two experiments. Although one of the monitoring intervals that detected the strong pressure signals covered the target shear zone that was being injected (i.e. *PRP1-2* during *HS5*), the remainder of the strong responses were from intervals that covered other zones, indicating the that shear zones are interconnected.

20 A tendency for the pressure in the *PRP* intervals to react more immediately to shut-in after injections into *S1* intervals compared to *S3* intervals can be discerned, particularly at the end of the stimulation injection cycle (Figure and Table A3). The immediate pressure response of *S1* shear zones (e.g. *PRP1-1*) to shut-in after injection into another *S1* shear zone (e.g. *HS2*) contrasts the delayed reaction of pressure intervals sampling *S3* structures (*PRP1-3* and *PRP2-2*) that were target during *HS4* stimulation (Figure 8). Indeed, for the *S3*-stimulations, almost all monitoring intervals that included the target shear zone showed a delayed

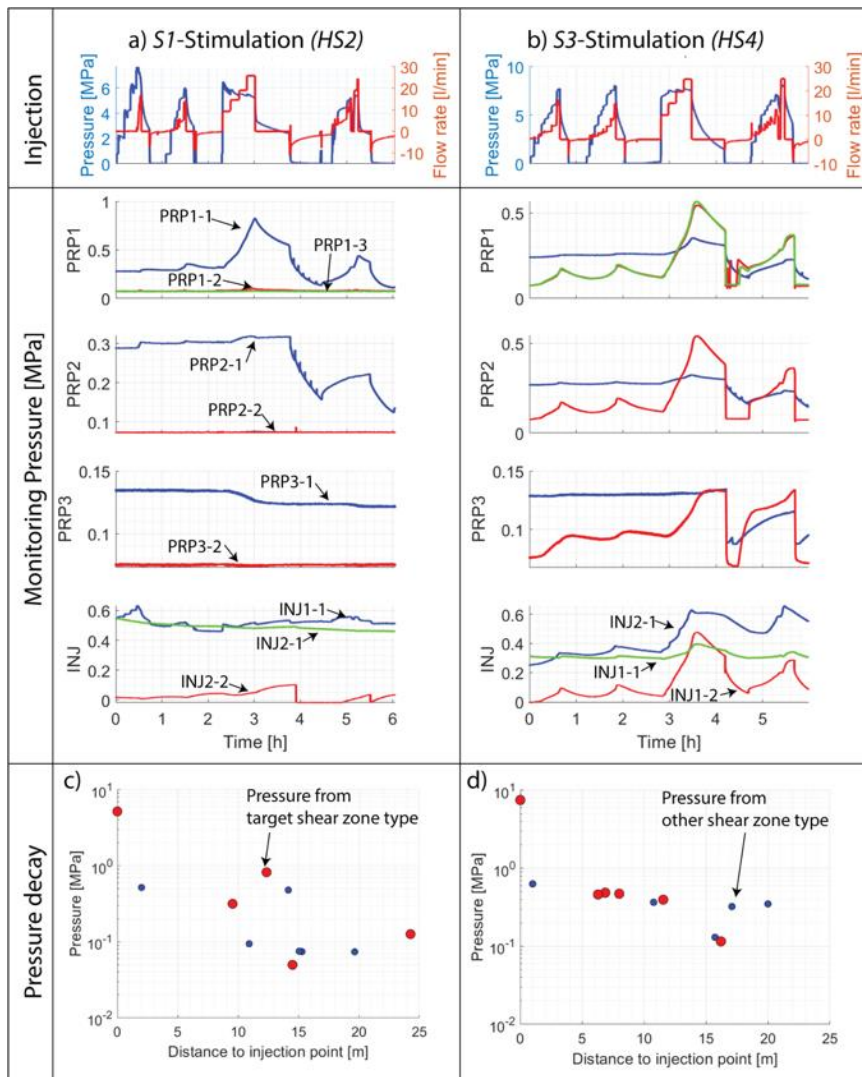

25 response to the shut-ins.

The fluid pressure in most monitoring intervals at the end of the experiments remained perturbed from their initial values, but in all cases had returned to initial values by the start of the subsequent experiment the following morning (Figure A5). The pressures prevailing in *PRP1-1*, *PRP2-1*, and *PRP3-1* at the end of the experiments were below the initial values due to the effect of venting the intervals following the stimulation injection cycle and last injection cycle (Figures 8, A5). The venting

30 responses of intervals covering the *S1.3* shearzone (*PRP1-1* and *PRP2-1*) consistently differed from all other intervals in that significant backflow occurred during venting so that the interval pressure declined relatively slowly. In contrast, the pressure

in all other intervals declined rapidly to the atmospheric pressure in the tunnel when the valve was opened, although it was clear in some cases that backflow into the interval was occurring as the pressure began to climb once the valve was closed (e.g. *S1* covering pressure interval *PRP3-1* in *HS4*) (Figure 8). Thus, backflow into *S1* intervals upon venting tended to be greater than for intervals cutting *S3* fracture zones.

- 5 Pressure perturbations were also detected at remote monitoring intervals. The largest distance to injection was 25 m for *PRP1-1* during *HS8* (Figure A6e), and typically 15-19 m for the other stimulations (Figures 8 and A6). These distances are Euclidean distances. Thus, the true distances of pressure diffusion along hydraulically active fluid pathways might be underestimated. No systematic difference in pressure transmission distances for *S1*- and *S3*-stimulations was evident. For both shear zone types, the pressure perturbations registered in intervals that cut the target shear zone tended to be greater than at other intervals located
- 10 at a comparable distance. For *HS4* however, a relatively weak response was observed at an interval (*PRP3-2*), that covered the shear zone into which the fluid was injected (Figure 8).

- 15 **Figure 8.** Pressure data *HS2* and *HS4* are shown in the left and right column (a & b), respectively. Injection protocols for both experiments are shown in the upper most row. In the second row, the corresponding time series of pressure recorded at the various intervals of the *PRP* boreholes are plotted. The lower frames c) and d) show the pressures prevailing in the intervals at the end of the final step of the stimulation injection cycle plotted against the distance to injection point for *HS2* (left column) and *HS4* (right column), respectively.

### 4.3 Spatial-temporal rock mass deformation

During all experiments, the FBG sensors measured compressional and extensional strain perturbations in response to the injections. The largest strain magnitudes were observed during periods of fluid injection and the magnitudes decreased during shut-in and venting (see Figure 10a-b for the experiments HS2 and HS4). For each strain signature, we define the permanent (i.e. irreversible) strain as the strain remaining at the end of the experiment, and the reversible strain as the difference between the peak strain and the permanent strain (Figure 9). Here, the peak strain corresponds to the largest strain excursion in the coda, and may be positive (i.e., compressional) or negative (i.e., extensional). In most cases, the peak strain was observed during the stimulation injection cycle, *C3* (Figure 9a-b), when the largest amount of fluid was injected. Generally, we observed that the reversible strain amplitudes were often larger than the irreversible amplitudes (Table 4). Non-zero permanent strains were detected for each experiment on all operational gauges.

**Table 4. Ratio between reversible peak strain magnitude ( $\epsilon_{rp}$ ) and permanent strain magnitude ( $\epsilon_p$ ), averaged over all operational gauges and all experiments**

Experiment	HS2 ( <i>S1</i> )	HS4 ( <i>S3</i> )	HS5 ( <i>S3</i> )	HS3 ( <i>S1</i> )	HS8 ( <i>S1</i> )	HS1 ( <i>S1</i> )
Ratio $\epsilon_{rp}/\epsilon_p$	10.1	19.8	222.8	10.0	9.8	4.9

#### 4.3.1 Strain along borehole axis

Profiles of strain signals picked at the end of the *C2* and *C3* injections and permanent strains are shown along the three FBG borehole axes in Figure 99 and A7. Spatial coherence between neighboring gauges is evident along the strain profiles although heterogeneity is also present that in some cases appears to be related to shear zone intersection points (Figures 9 and A7). Within boreholes that are parallel to target shear zones (i.e., *FBS3* for *S1*-stimulations and *FBS2* for *S3*-stimulations), extensional strains were measured at the locations along the borehole axes that lay closest to the injection locations (Figure 99 and A7). This extension in most cases transitioned into compression within 5 m either up or down the boreholes from this point. In contrast, boreholes that are sub-normal to the target shear zone (i.e., *FBS1* and *FBS2* for *S1*-stimulations, and *FBS1* and *FBS3* for *S3*-stimulation) tended to show compressional strains near the point closest to the injection location (note that this point is not necessarily the borehole intersection of the target shear zone).

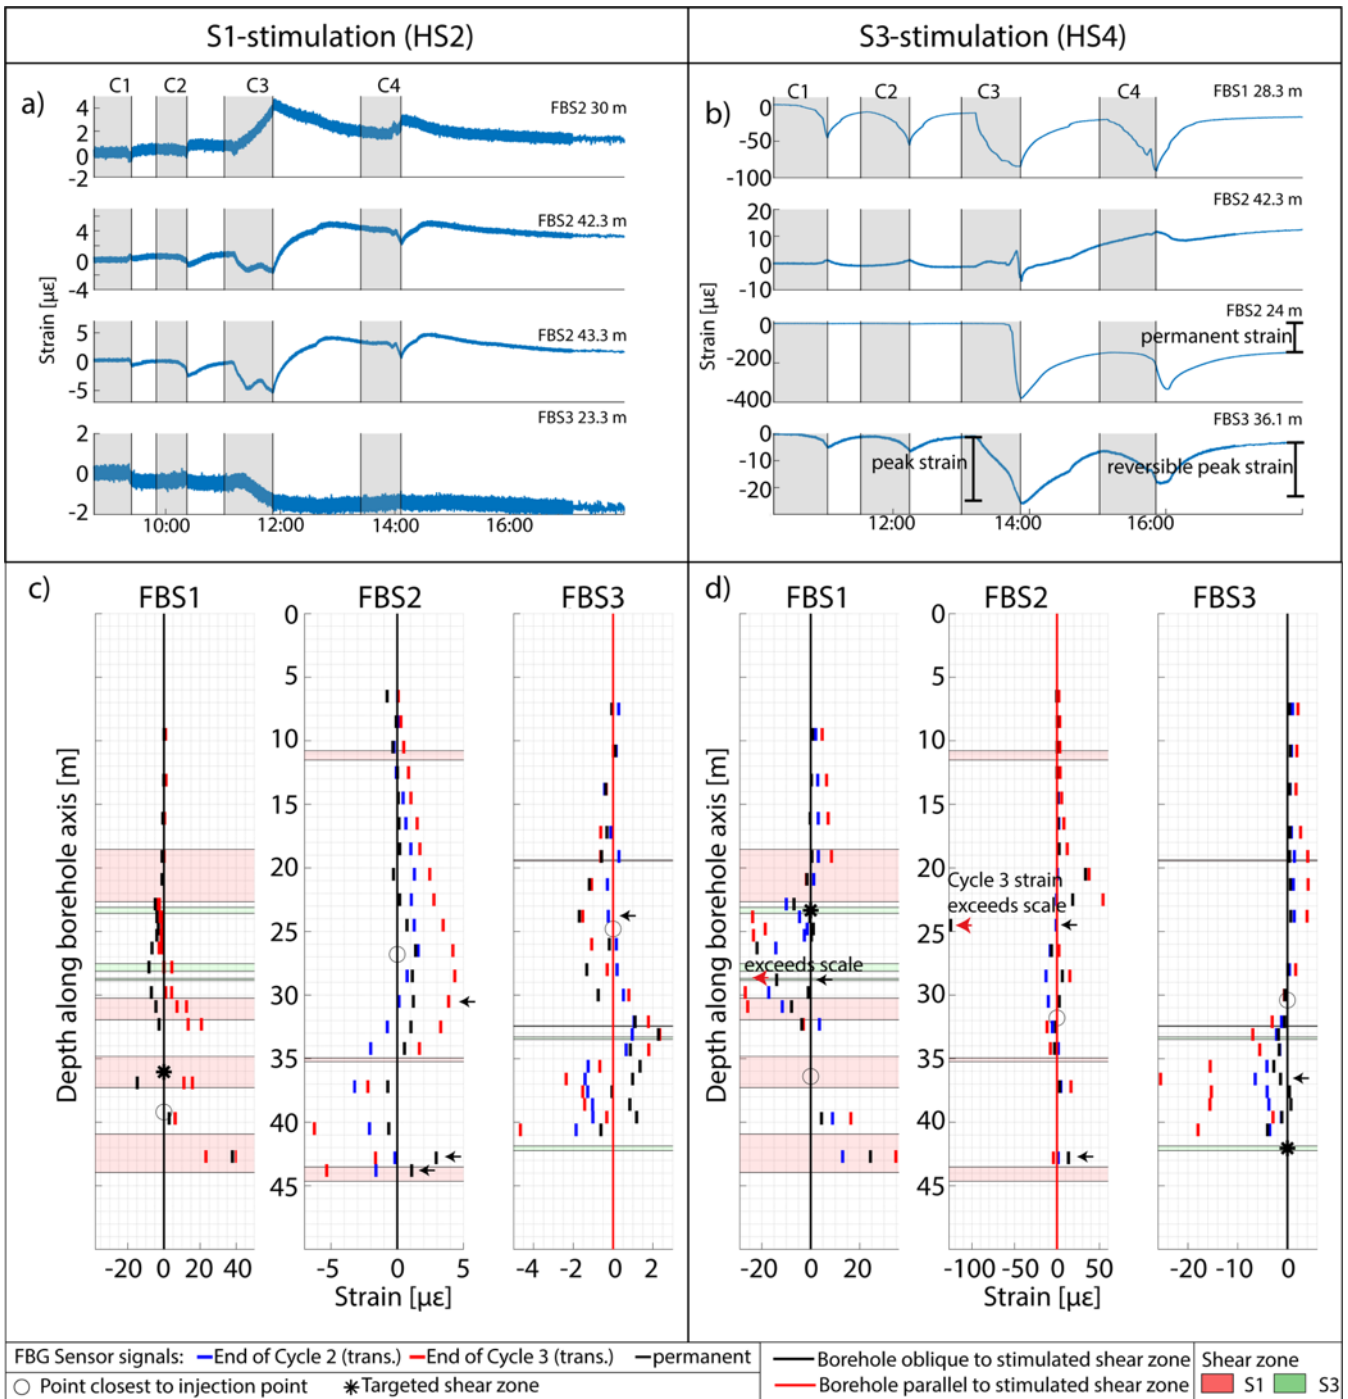

Figure 9. a) and b) Examples of strain time series from four FBGSs during HS2 and HS4 respectively. The vertical shading denotes periods of injection during the four cycles. Examples of the permanent strain, the peak strain and the reversible peak strain are indicated on the HS4 strain codas. c) and d) Profiles of permanent strain, and strain at the end of the injection phases of C2 and C3 along the three FBS boreholes for HS2 and HS4 respectively. The open circle along each borehole denotes the location that lie closest to the injection point for the experiment in question. The pink and green bands indicate places where the holes cut S1 and S3 shear zones respectively. The small black arrows indicate the sensors whose strain codas are shown in a) and b).

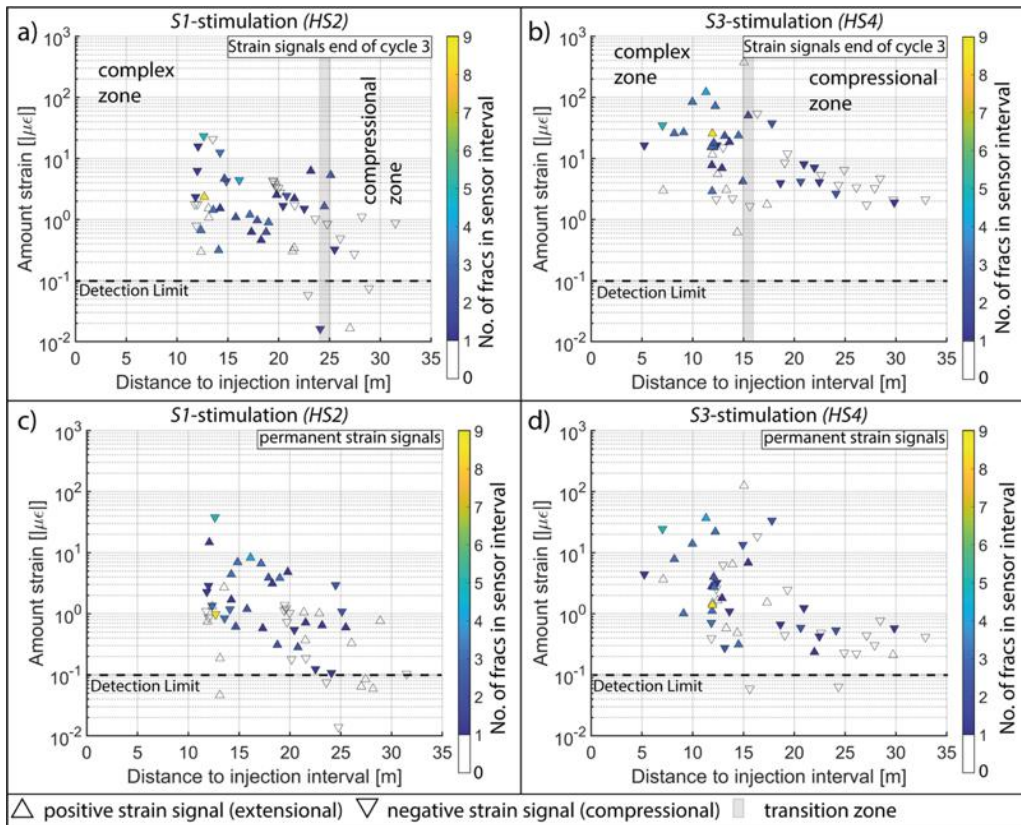

#### 4.3.2 Extent of deformation field

Figure 1010 and A8 show the absolute amplitude of the strain signals as a function of distance from the strain gage to the injection point for the end of injection C3 and permanent deformation after stimulation. In most experiments, a general tendency for lower strain amplitudes at greater distance is evident (Figures 10 and A8), with strain signals larger than  $1 \mu\epsilon$  furthest away from the injection locations. Thus, the overall extent of the mechanically effected zone was larger than 27-33 m, with respect to radial distance to the injection point. In the near-field to the injection location the *FBG* sensors showed complex signals, which included either extension or compression (or a transition between both with ongoing stimulation) depending on the orientation of the sensor axes and location with respect to the target shear zones. With increasing distance

from the injection location, the strains in most cases tended to be compressional (Figure 1010 and A8). The transition from this compressional field to a mix of compression and extension (i.e. complex strain field) seemed to occur at slightly larger distances from the injection point for *S1*- than *S3*-stimulations during *C3* (Table 5).

**Table 5. Distance of strain-transition-zone (change from a variable to compressional strain field) to the injection point, measured at shut-in of injection cycles 2, 3 and 4.**

Test name	Shut-in <i>C2</i>	Shut-in <i>C3</i>	Shut-in <i>C4</i>
HS2 ( <i>S1</i> )	26 m	25 m	23 m
HS4 ( <i>S3</i> )	16 m	16 m	16 m
HS5 ( <i>S3</i> )	16 m	12 m	18 m
HS3 ( <i>S1</i> )	18 m	18 m	18 m
HS8 ( <i>S1</i> )	16 m	17 m	17 m
HS1 ( <i>S1</i> )	18 m	18 m	18 m

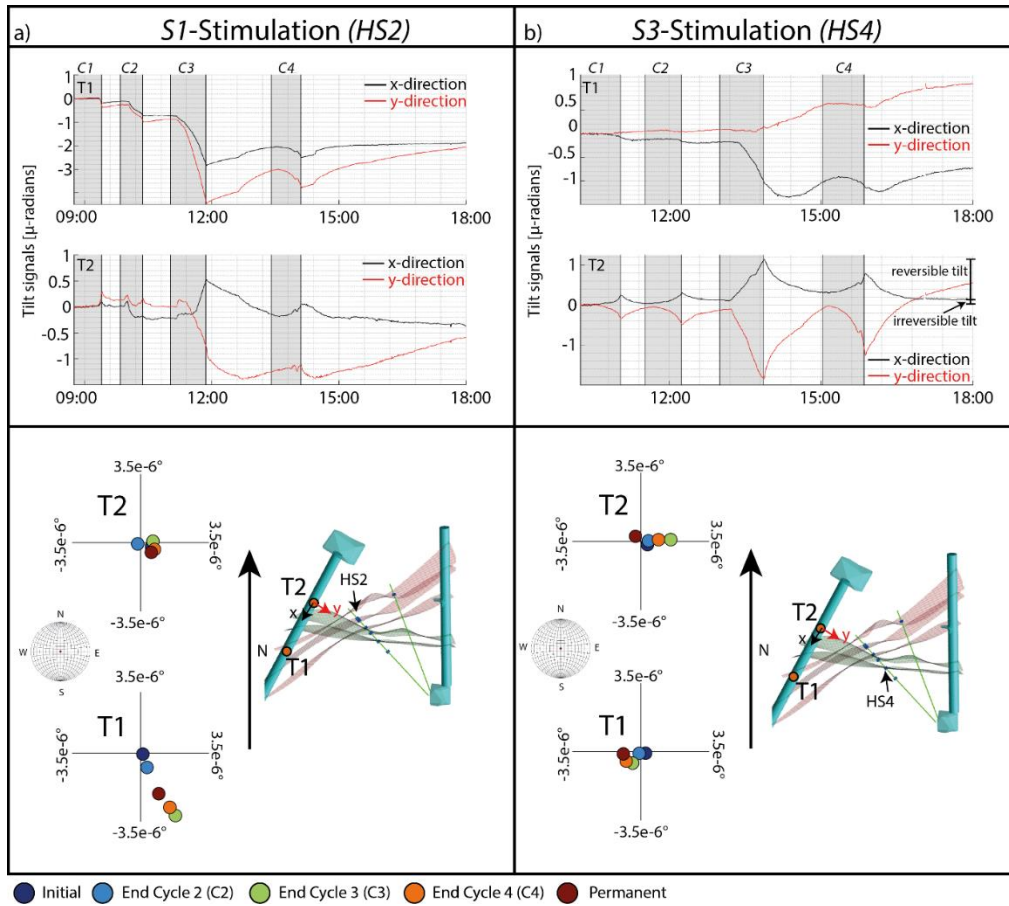

**Figure 10. Strain signals with respect to distance to the injection point for HS2 and HS4. Generally, the strain perturbations prevailing at the end of the injection phase of cycle 3 were compressive beyond a certain distance which varied between experiments. This distance is denoted by the vertical grey line in (a) and (b), and separates the compressional zone from the so-called ‘complex zone’ where a mix of extensile and compressive strains are observed. The color code of the triangle indicates the number of fractures located within the FBG sensor intervals.**

The floor of the VE-tunnel underwent tilting during all experiments, the magnitudes ranging from -4 to 2 μ-radians (i.e., -23.0e-4° to 11.5e-4°) for both tilt axes (Figures 11 and A9). Nearly immediate tilt responses were seen at the start and stop of injection in most cycles and most experiments. The largest tilt signals for each experiment tended to be observed on the instrument closest to the shear zone which was target for stimulation (Figure A9). Specifically, for injections into the *S1* shear zones, significantly larger signals were seen on instrument *T1* than *T2*. The sense of the tilt indicated that the tunnel floor tilted away from the target *S1* shear zone towards WNW during the stimulations. During the *S3* stimulation *HS4*, the tunnel floor near *T1* tilted temporarily towards east (i.e., towards the test volume), whereas the tunnel floor near *T2*, tilted towards west (i.e. away from the test volume). However, the permanent tilts at *T1* and *T2* both indicated tilting towards the east with a

similar magnitude. During the other *S3* stimulation (*HS5*), *T1* showed tilting to the NW whereas *T2* indicated tilting the SW, with no significant permanent tilt on either instrument. Thus, the transient tilts at both locations indicate similar E-W components of tilting of the tunnel floor away from the test volume, but with opposite north-south components (Figure A9). Significant permanent tilts remained only after the two *S1* stimulations (*HS2* and *HS1*). In general, the transient tilt signals were often much more pronounced than the permanent signals.

**Figure 11. Inclinometer data for a *S1*-stimulation (*HS2*) (a), and *S3*-stimulation (*HS4*) (b). The upper panel shows the tilt time series for both experiments with the injection periods marked by the shaded vertical bands. The lower panel shows for each experiment on the right side a horizontal cross-section through the study volume at the level of the tunnels. In these sections, the shear-zones, the injection locations and tiltmeter *T1* and *T2* positions are indicated. The x- and y-axes of the tilt data are indicated on *T2*. Axes orientations of *T1* are the same. Changes in the downward-oriented normal vector of the tunnel floor at *T1* and *T2* are shown in the lower-hemisphere plots at the left of the frames. These frames are zoomed in sections to the very center of the lower hemisphere stereo net. Thus, the axes appear as a cartesian coordinate system.**

15 During the stimulation injection cycle of an *S3* stimulation experiment (*HS4*) the *FBG* sensor installed at 24 m depth in *FBS2* indicated strong (up to  $\sim 370 \mu\epsilon$  peak strain), localized extension (Figure 12). No macroscopic fracture was evident on the OPTV images of the sensor location prior to the experiment. The large extension at 24 m began abruptly near the end of the stimulation injection cycle when flow rate was stepped from 20 to 25 l/min, and rapidly developed at rates up to  $-1.2 \mu\epsilon/s$ . Following the experiment, the sensor showed a permanent strain of  $-120 \mu\epsilon$ , implying a reversible peak strain component of  $-250 \mu\epsilon$ . This large extensile strain at 24 m coincides with the development of moderately large compressive strains recorded by the *FBGs* at 20 m and 22 m, and a complex reversal of an initial extensile strain to result in a compressive permanent strain at 26 m. Following injection, all strains progressively decayed to leave a permanent strain. Similar strains responses on the

20 four sensors were observed during the subsequent final injection cycle (*C4*).

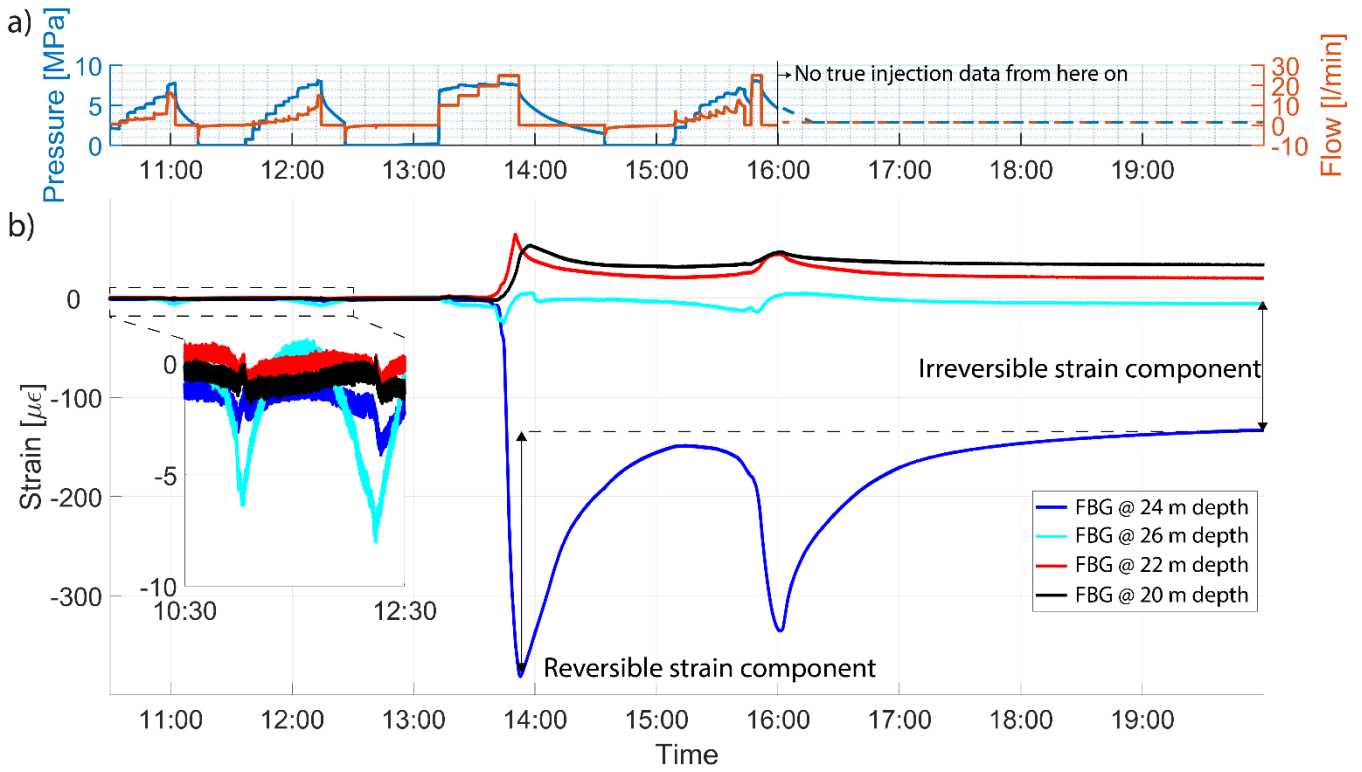

Figure 5. a) injection protocol during the stimulation experiment of interval HS4 with interpolations as dashed line after experiment, b) Strain records at four neighboring FBG sensor locations in FBS2 during HS4. The inset shows the strains at an expanded scale during the first two cycles.

## 5 Discussion and interpretation

### 5.1 Reactivation of pre-existing fractures

Stress information retrieved from the injection and pressure observations at the injection interval revealed a distinct behavior of  $S1$  and  $S3$  stimulations: During the first injection cycle of  $S1$  stimulations, the peak injection pressure exceeded the jacking pressure and the maximum injection pressure of the stimulation cycle (i.e. limiting pressure). This indicates that  $S1$  shear zones had a tensile strength component that had to be overcome to open the fracture. This was not observed during  $S3$  stimulation. Such tensile strength at  $S1$  shear zones is consistent with the observation that  $S1$  shear zones had much lower initial transmissivity compared to  $S3$  shear zones (Figure 7). Prior to the stimulations, the jacking pressures of the two  $S3$  intervals were systematically higher ( $\sim 7-8$  MPa) than the values obtained for the  $S1$  intervals ( $\sim 5$  MPa). For all experiments, an injection pressure limit was observed during the stimulation cycle, which we interpret as lift-off of fractures (Pearson, 1981). Again, the limiting pressure was systematically higher for  $S3$  stimulation (7-9 MPa) than for the  $S1$  stimulation (5-6 MPa). We interpret this as higher normal stress acting across  $S3$  shear zones than across  $S1$  shear zones. This disagrees with the stress tensors established by (Krietsch et al., 2018c) (Figure 3), from which one would expect slightly higher normal stress across  $S1$  than across  $S3$ . Further, the expected normal stresses would be higher ( $> 8.5$  MPa for the unperturbed stress tensor and  $> 10.5$  MPa for the perturbed stress tensor) than observed during the stimulations. We explain this inconsistency with stress heterogeneity in the stimulated rock volume (note that the perturbed stress tensor has been measured at about 40 m from the stimulated rock volume). Indeed, during the stress measurements a jacking pressure of 3 MPa was obtained at the margins of the  $S3.1$  structure, which is lower than across the same structure at the  $INJI$  borehole.

The induced slip displacements imaged at the injection intervals occurred along single or multiple fractures (Figure 5 and A4). The number of reactivated fractures was larger for the initially high transmissive  $S3$  intervals, compared to the initially low transmissive  $S1$  intervals. In all cases with multiple reactivated fractures, one fracture trace experienced distinct large shear dislocation, similar as observed by Evans et al. (2005b) for the Soultz-sous Forêt stimulation projects. The slip direction of

each reactivated fracture was compared with the direction of the maximum shear stress vector resolved for the individual fractures using the perturbed stress tensors. The angle between the maximum shear stress vectors and the azimuth of induced slip dislocations varied between 28° and 33° (Table 6). Thus, the derived slip direction corresponds to right-lateral shear sense, while the predictions of the stress tensor measured nearby point to oblique right-lateral shear sense with a thrust faulting component. The angular misfit might be explained by a transient local stress transfer between adjacent fractures during fluid injection at the injection well (Kakurina et al., 2019). However, stress heterogeneity, as already inferred above may also explain, why slip direction are not well predicted by the measured stress tensor.

Given the different architectures and properties of the *S1* and *S3* shear zones, stress heterogeneity is expected. High fracture densities and the presence of meta-basic dikes produce elasticity contrasts around the *S3* shear zones (Doetsch et al., 2020). Enhanced foliation and associated elastic anisotropy have been measured for the *S1* shear zones (Krietsch et al. 2018b; Doetsch et al. 2020). Additionally, these material properties do not only vary between shear zone type, but also laterally along individual shear zones (see seismic velocity distributions along *S3* shear zones, Doetsch et al. 2020). Thus, we argue that stress variations related to material contrasts (both changes in magnitude as well as stress rotations) give rise to larger change in normal stress along the different shear zones types than their orientation in a constant stress field.

15

**Table 6. Orientation of slip dislocation on the fractures estimated from the pre- and post-stimulation ATV logs, and the maximum shear stresses resolved on the fractures from the perturbed stress tensor. All orientations are given as dip-direction/dip.**

		Perturbed Tensor	
Experiment	Slip direction	$\tau_{\max}$	Misfit [°]
HS2	081/02	077/35	33
HS3	084/01	078/27	28
	106/04		30

### 5.2 Near-wellbore transmissivity enhancement

We found that the near-wellbore transmissivity enhancement was most efficient for structures that had low initial transmissivities. After stimulation, the near-wellbore transmissivities were similar in magnitude for all experiments. This may reflect an upper limit on shear-induced irreversible transmissivity enhancement. Lee and Cho (2002) found similar effects on the laboratory experiments which suggest the achievable, shear induced transmissivity enhancement depends on the height of asperities along the fracture surface. Nonetheless, in our case, the magnitude of transmissivity enhancement depends on the architecture of the stimulated structures. Stimulation of the intensely fractured rock mass around *S3* shear zones was associated with only limited transmissivity enhancement, while the less intensely fractured *S1* shear zones contributed larger transmissivity enhancement. We argue that stimulation of long open-hole sections would have led to less advantageous stimulation outcomes. Prior to stimulation, the fractures in all intervals differed in near-wellbore transmissivities, but had similar slip tendencies (Figure 3). Thus, a combination of low transmissive structures (i.e. *S1* shear zones) in the same packer interval with initially high transmissivity structures (i.e. *S3* shear zones) would not led to a transmissivity enhancement of the low transmissive structures, because the highly-transmissive structures would have taken most of the injected fluid. This highlights the advantage of short injection intervals over long open hole injections.

### 5.3 Complex flow field

The monitored pressure signals indicated that the pressure diffused pre-dominantly along the target shear zones, similar to observations of stimulations at other EGS sites (e.g. Evans et al., 2005a). Because individual fractures associated with the target shear zone often intersected the same pressure monitoring intervals as the target shear zones, it was impossible to resolve

which portion of the pressure signal propagated along which individual fracture. We observed rapid increases of high fluid pressures (i.e. on the order magnitude of the injection pressure) only during one *S1*- and one *S3*-stimulation (*HS8* and *HS5*, respectively, Figure A5). During most experiments and the majority of monitoring intervals, the pressure signals are far below the injection pressure and rarely exceeds 1 MPa (Figure A5). These findings are somewhat unexpected: According to Murphy et al. (2004), among others, fracture dilation during fluid injection leads to non-linear pressure diffusion and promotes higher fluid pressures and pressure increases further away from the borehole as linear pressure diffusion would produce. Most pressure signals in our case resemble a linear diffusive pressure field. Nonetheless, FBG strain measurements and P-Q curves (Figure 7) confirm that fracture dilation occurred during stimulation. Thus, our observations suggest that the flow field in the fault planes is heterogeneous and high-pressure signals away from the injection point may be limited to flow channels. As shown by Krietsch et al. (2020) flow along channels may change during ongoing injections. This observation challenges common conceptual models of the stimulation treatments based on oversimplified fault geometries (i.e. single penny-shaped fracture) and pressure diffusion models (radially or spherically symmetric diffusion models) (e.g. Cappa et al., 2019).

#### 5.4 Hydro-mechanical rock mass responses

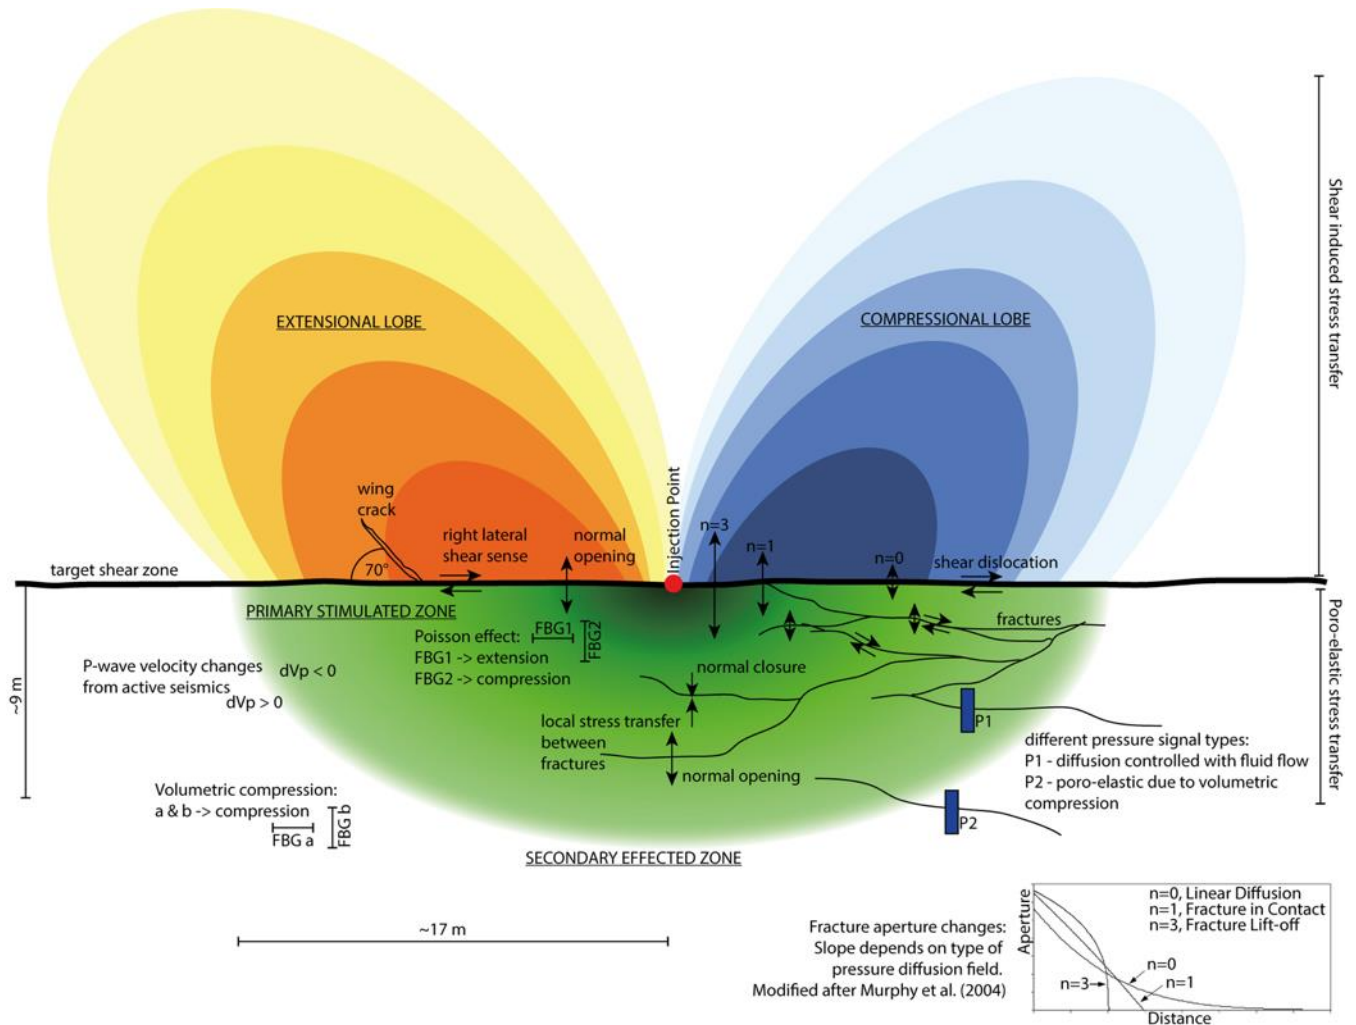

Based on the observed pressure response upon shut-in, we divided our pressure signals into two different types. 1) The pressure monitoring intervals that cover the target shear zone often observed a delayed response to shut-in, indicating a diffusion-controlled pressure signal. 2) In contrast to this, pressure intervals outside of the target shear zone often responded immediately to shut-in (Figure A5 and Table A3). In some cases, this behavior was detected further away from the injection location than the diffusion-controlled signals. These signals are most likely associated with a poro-elastic far-field response (Segall, 1989). Similarly, the observed deformation signals can loosely be divided into a near- and a far-field response. The deformations in the near-field to the injection reflect stress field changes, arising predominantly from effective normal stress reductions across fractures which can produce both normal opening and also relaxation of shear stress through slip (Stein, 1999). The observed magnitude and sign (tension or compression) of these hydro-mechanical deformations strongly depend on the position and orientation of the strain sensor with respect to the stimulated zone. This interpretation is consistent with McClure and Horne (2014) and Rutledge et al. (2004) who note that deformations arising from mode I- and mode II & III-dislocations can occur simultaneously. It is noteworthy, that the observed peak strain often by far exceed the permanent strain remaining after stimulation. This implies that the reversible component of fracture dislocation (a combination of normal and shear compliance) may be larger than the irreversible component (a combination of slip and shear dilatancy). In the near-field, we also observed the formation of new fractures that propagated away from the stimulated shear zone (Figure 12). These fractures are interpreted as tensile fractures, that formed due to stress concentrations induced by shear dislocation along irregularities (asperities) of the main shear zone (McClure and Horne, 2014), or by gradients of the slip magnitude.

In the far-field, i.e. outside this complex strain field, the vast majority of strain measurements show compression. We interpret that these compressive signals in the far-field are produced by volumetric compression as a consequence of the volumetric expansion in the near-field to the injection (Segall and Fitzgerald, 1998). The tilt signals also belong to this category of far-field responses, as they do not directly measure fluid pressure induced effective normal stress changes and the corresponding elastic and inelastic consequences (e.g. fracture opening and closure, slip, etc.). Similarly, also the rapid pressure increases some distance away from injection may be related to far-field volumetric compression (Segall, 1989).

#### 5.5 Stimulated volume

Based on hydraulic and mechanical observations, we suggest two distinct zones around the injection point: 1) A complex near-field zone dominated by pressure diffusion, fracture opening, closure, shear slip and the formation of new fractures, and 2) a far-field zone dominated by stress transfer and the associated poro-elastic response (Figure 14). Thus, we subdivide the overall

effected rock volume into a primary stimulation zone which is close to the injection point and a secondary effected zone, that captures the far-field responses (Figure 13).

5 Figure 6. Schematic overview of hydro-mechanical mechanisms active within the 'Primary stimulated zone' about an injection interval. The black arrows indicate fracture surface dislocations. The shape of the shear induced stress change lobes was modified after Karakostas et al. (2014) and Preisig et al. (2015). For sake of simplicity, both the shear induced and the poro-elastic processes are drawn individually on either side of the main fracture and not superimposed.

10 The pressure monitoring observations indicate that the radial extent of the diffusion-controlled pressure changes extended up to 15 m from the injection point (Figures 14 & A6). Beyond this distance, between 15 m and ~22 m, the poro-elastic response was dominant. Due to the sparse monitoring, we cannot exclude that poro-elastic responses reach much further into the rock mass. The transition between the two different responses was taken as 15 m from injection point along the shear zone. This also corresponds to the transition between the 'complex' strain field, which appeared to be directly affected by active fracture slip and normal opening, and the compressional strain field, which decayed in magnitude with distance and appeared to be a far-field effect. As for the pressure, we cannot determine the outer limit of the compressional strain field, because strains larger than the detection limit were observed on the most remote FBG sensors during all stimulations.

15 The extent of the primary stimulation zone depends on the target shear zone properties, such as initial transmissivity and number of reactivated fractures.

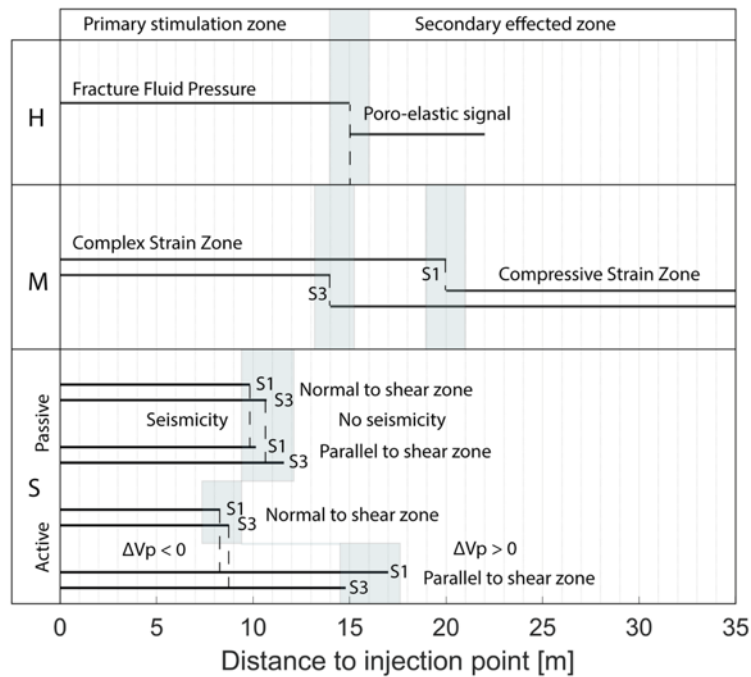

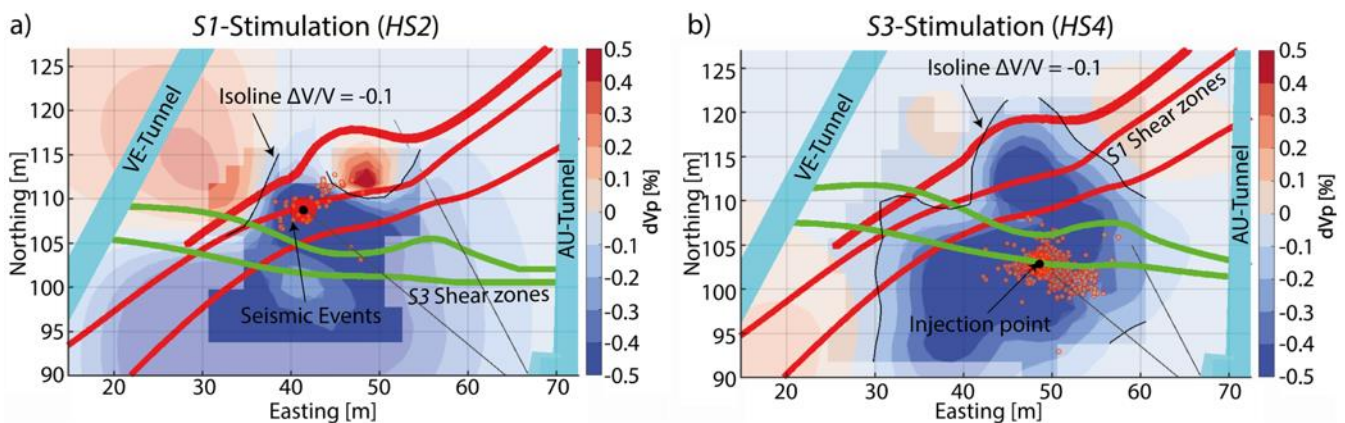

Figure 74. Comparison radial extension stimulated zones determined by hydraulics (H), deformation (M) and seismics (S). For the seismic observations, we distinguish between active seismics (velocity changes) and passive seismics (located seismic events). Note that we did not distinguish between measurement directions for the H and M estimates, as we did not have enough measurement locations to resolve it properly.

### 5.6 Comparison between hydro-mechanical observations and seismic responses

Doetsch et al. (2018b) and Schopper et al. (2020) used active seismic methods to analyze P-wave velocity changes that were observed during the stimulation experiments. They found that 4D seismic tomograms allowed tracking of fluid pressure and strain evolution. Close to the injection location, a zone with decreasing P-wave velocities was detected that was surrounded by a zone of increased P-wave velocities. These distinct zones of P-wave velocity changes correspond to the primary stimulated and secondary effected zone. We consider the isoline marking a 0.1 % P-wave velocity decrease to denote the boundary between the two stimulated zones (Figure 15). The extent of the boundary was measured parallel and normal to the target shear zone, and was found to be elongated along the target shear zone, which is consistent with the monitored pressure perturbations.

In general, the extend of the zone with decreased P-wave velocities decrease was larger during *S1*-stimulations than during *S3*-stimulations, which is in agreement with strain field observations. Based on the active seismic observations, the primary stimulated zone can be characterized as being ellipsoidal, as inferred from the strain data.

**Figure 85. Comparison between active and passive seismic observations during *S1*(a) and *S3*(b) stimulations in map view. The extent of the active seismic velocity change was traced with the -0.1% isoline. This figure was modified after (Schopper et al., 2020; Villiger et al., 2019)**

Villiger et al. (2019) analyzed the seismicity induced during the stimulation. For details on the network sensitivity and its impact on the estimate of the seismically active zones, we refer to their article published in this journal. The localization accuracy of the seismic events is better than 1.5 m. The radial extent of the clouds was found to be similar in both directions (i.e., parallel and normal) for *S1* and *S3* stimulations. However, more seismic events were detected along the target shear zone than normal to it. The seismic cloud has a smaller extent than the primary stimulation zone estimates from HM monitoring (Figure 15). Thus, it seems to underestimate the total volume that has been affected by the stimulation. This agrees with the suggestion of various authors Duboeuf et al. (2017) and Guglielmi et al. (2015a), who showed that a large portion of the stimulation induced dislocation is aseismic. However, it disagrees with Cappa et al. (2019) who argued that seismicity is induced ahead of the hydraulically pressurized zone.

## 6. Summary

The six decameter-scale hydraulic shearing experiments conducted at 480 m depth at the Grimsel Test Site, Switzerland have revealed exceptional insights into the seismo-hydro-mechanical responses of the crystalline rock mass and fractures to high-rate injections. This was facilitated by a dense array of instrumentation installed in the test volume that included seismometers, pore-pressure- and strain-monitoring boreholes, and inclinometers installed along tunnels. The test volume was cut by two sets of fracture zones, denoted *S1* and *S3*, that differ in orientations and deformation history.

Data acquired with the comprehensive monitoring system in this study demonstrate the complexity of fluid flow and coupled deformations during hydraulic stimulations. For the interpretation it has to be considered, that the hydraulic and mechanical data were not acquired at the same locations and thus do not directly capture couplings between the mechanical and the hydraulic response at the same location. Due to the spatial coverage of monitoring sensors it is likely that not all experiments have the same spatial data content. Further, the total size of the rock volume affected by the stimulation was not captured since the most remote strain sensors indicate deformations.

Two different shear zones sets (*S1* and *S3*) were the target of the stimulation injections. The key results of the experiments can be summarized as follows:

- Initially low transmissive structures were stimulated more efficiently than structures of higher initial transmissivity.
- Systematically lower initial transmissivities by up to 3 orders of magnitude were observed for all four of the intervals that cut *S1* target structures, with one *S3* interval having a high transmissivity of  $10^{-7}$  m<sup>2</sup>/s. Following the stimulation, all five other transmissivities were increased to this level. Evidence of shearing was seen on fractures cutting four of the six intervals, but could not be linked to the transmissivity increases as the normal component of dislocation was not estimated.
- Systematically higher initial jacking pressures of ~7 MPa were found for the two *S3* intervals, the values for *S1* intervals ranging between 4.8 and 5.6 MPa. With one exception, jacking pressures were unchanged by the stimulations. The measured jacking pressures are low compared to minimum principal stress magnitudes determined in the relatively undisturbed rock mass immediately to the south and almost certainly reflects strong stress heterogeneity in the decameter-scale test volume.
- During the stimulation injections, hydraulic pressure propagated heterogeneously through the target shear zone. Rapid relatively large pressure increases are interpreted as non-linear pressure diffusion. All other pressure perturbations that had delayed arrival times had markedly lower amplitudes, and could have involved linear or non-linear diffusion. Another class of pressure perturbation seen at some measurement points outside the target zone were coincident with changes in injection, and are believed to be poro-elastic in nature.

- All operational FBG strain sensors throughout the study volume detected significant signals during all experiments. Generally, the signals had both reversible and permanent strain components, the former being larger than the latter. Strains measured at distances less than 15 m to the injection points were a complex mix of compression and extension, whereas only compression was measured beyond, the magnitude diminishing with distance. The complex near-field zone is believed to correspond to local stress perturbations arising from reductions of effective normal stress along fractures due to a diffusion-controlled pressure field leading to normal and shear dislocation along fractures. The more distant compression is taken to be the response of the surrounding medium to the volume increase of the near-field volume and is a purely poro-elastic far-field effect.
- The dimensions of the microseismic cloud is smaller than the dimensions of the primary stimulated zone as derived from the pressure and strain monitoring systems. We propose that this is a better measure of the stimulated volume than the seismicity cloud. The latter is also in accord with the volume of transient seismic velocity decreases as inferred from 4D seismic tomography.

## Acknowledge

- 15 This study is part of the In-situ Stimulation and Circulation (ISC) project established by the Swiss Competence Center for Energy Research - Supply of Electricity (SCCER-SoE) with the support of Innosuisse. Funding for the ISC project was provided by the ETH Foundation with grants from Shell and EWZ and by the Swiss Federal Office of Energy through a P&D grant. Hannes Krietsch is supported by SNF grant 200021\_169178; Linus Villiger is supported by grant ETH-35 16-1. The Grimsel Test Site is operated by Nagra, the National Cooperative for the Disposal of Radioactive Waste. We are indebted to
- 20 Nagra for hosting the ISC project in their facility and to the Nagra technical staff for onsite support.

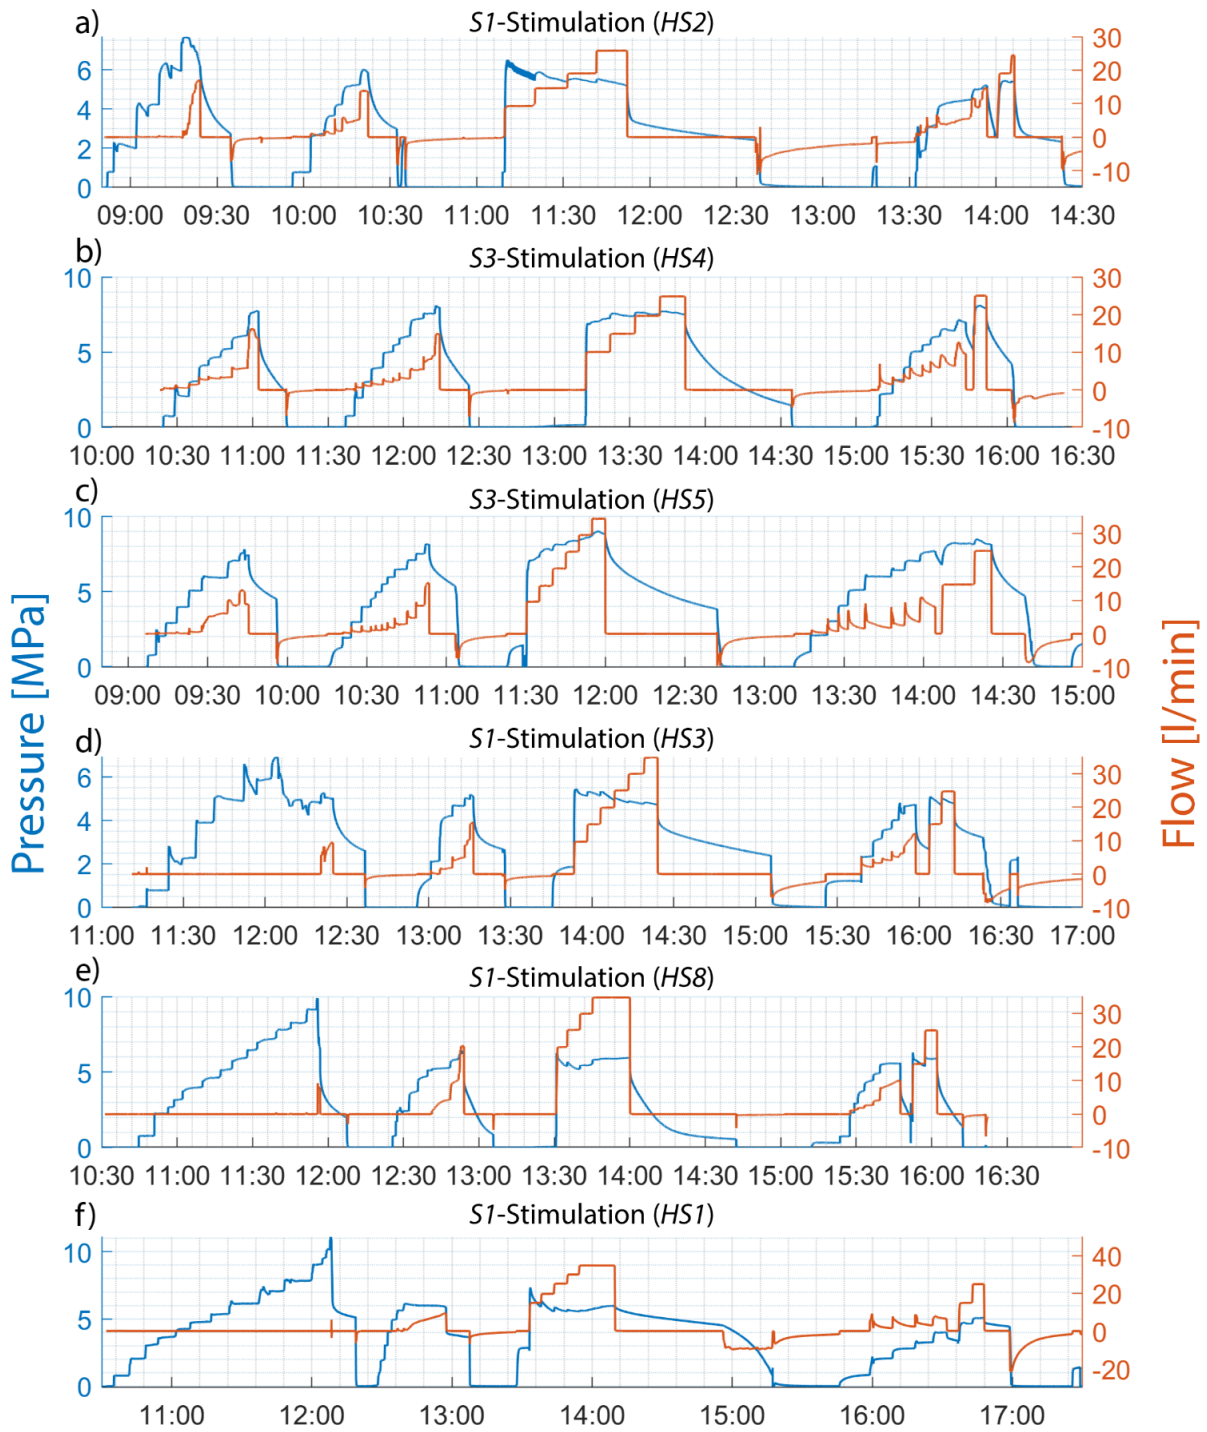

Figure A2. Injection protocols for all experiments. The tests are in chronological order.

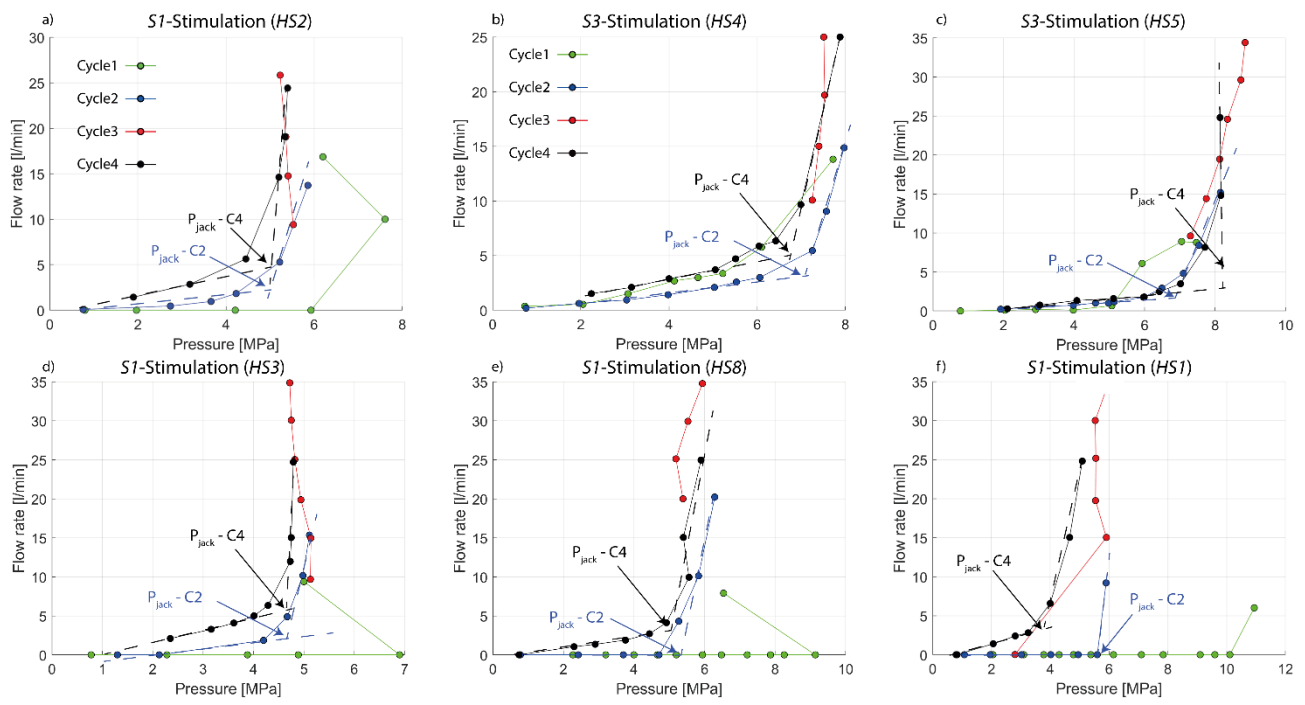

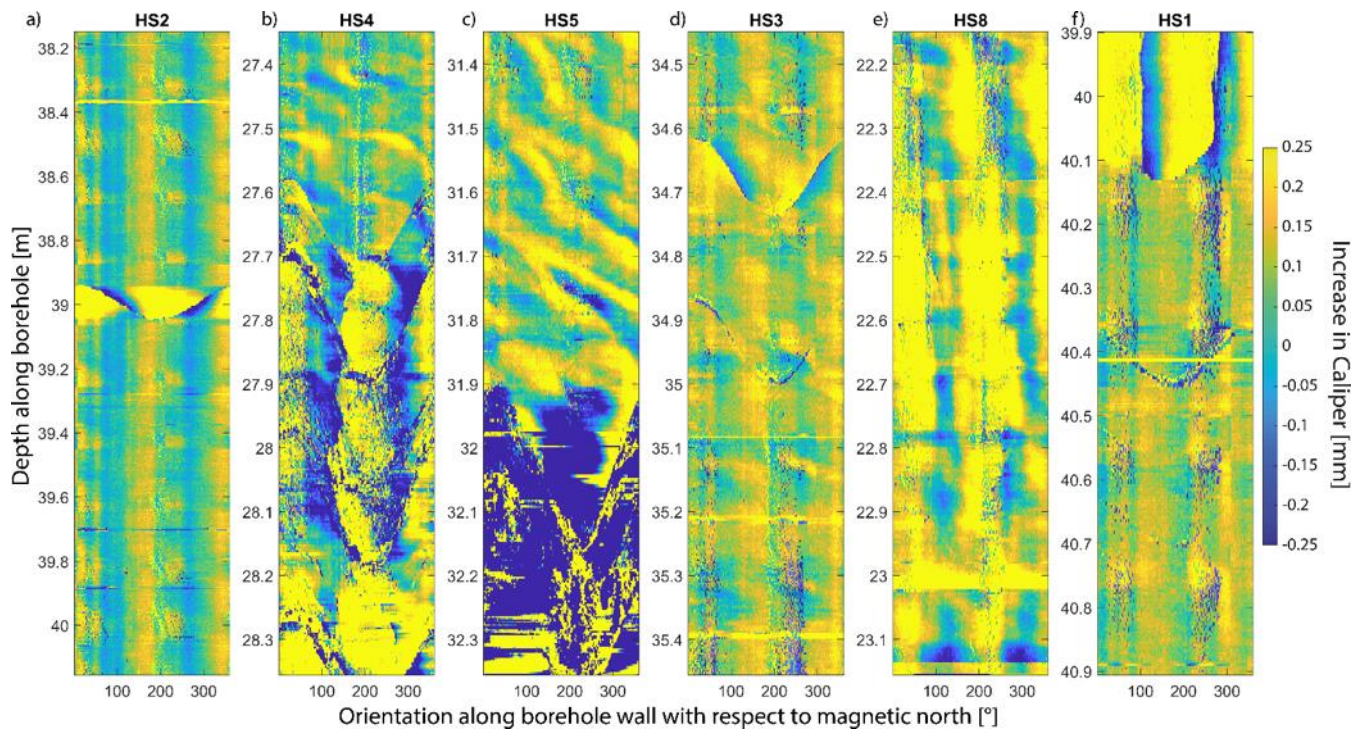

Figure A3. P-Q diagrams for all conducted HS experiments

5 Figure A4. Difference plots from ATV logs. Logs are in chronological order.

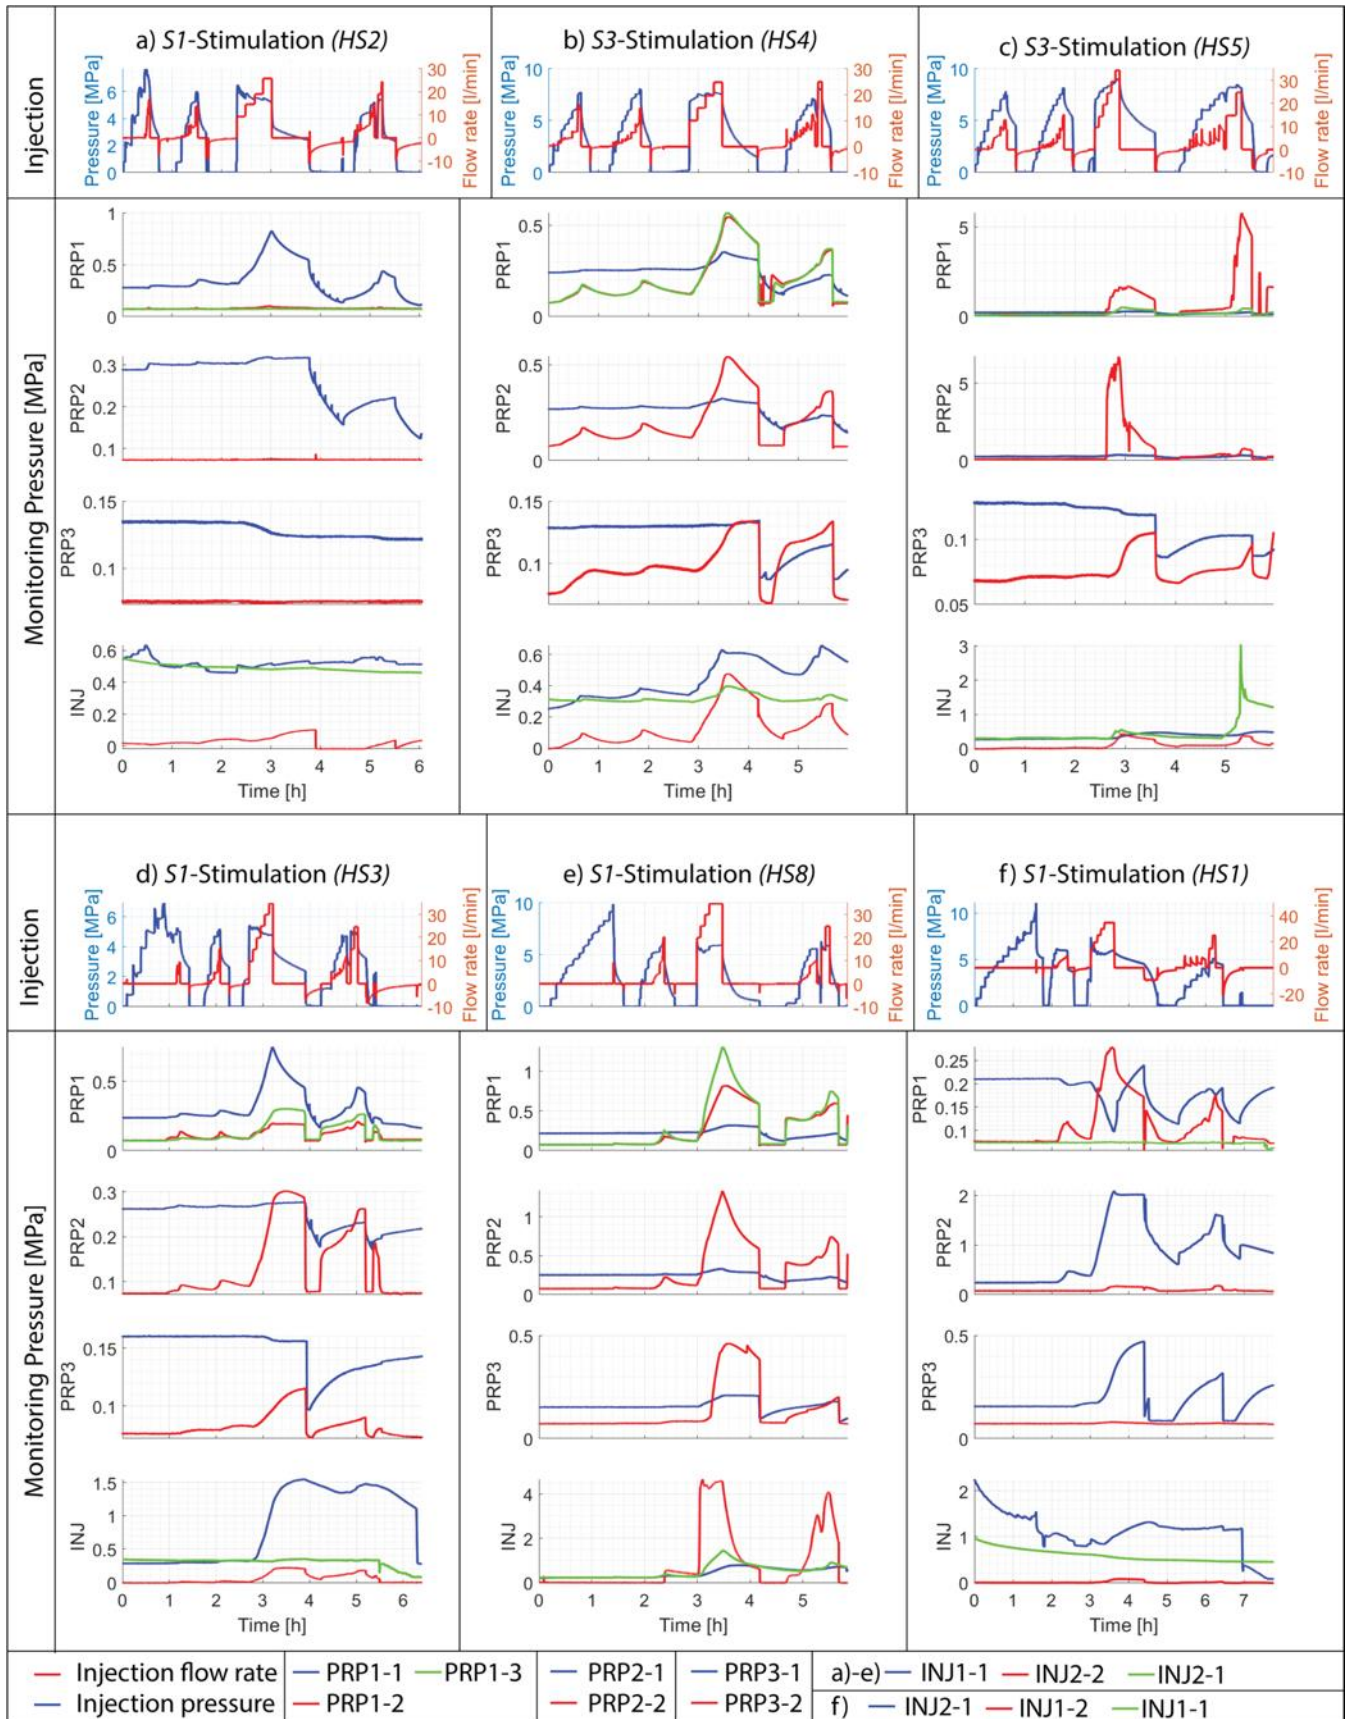

Figure A5. Pressure perturbation time series for all monitoring intervals. The shut-in moments are marked as vertical lines. Note that all intervals were vented after a period of shut-in.

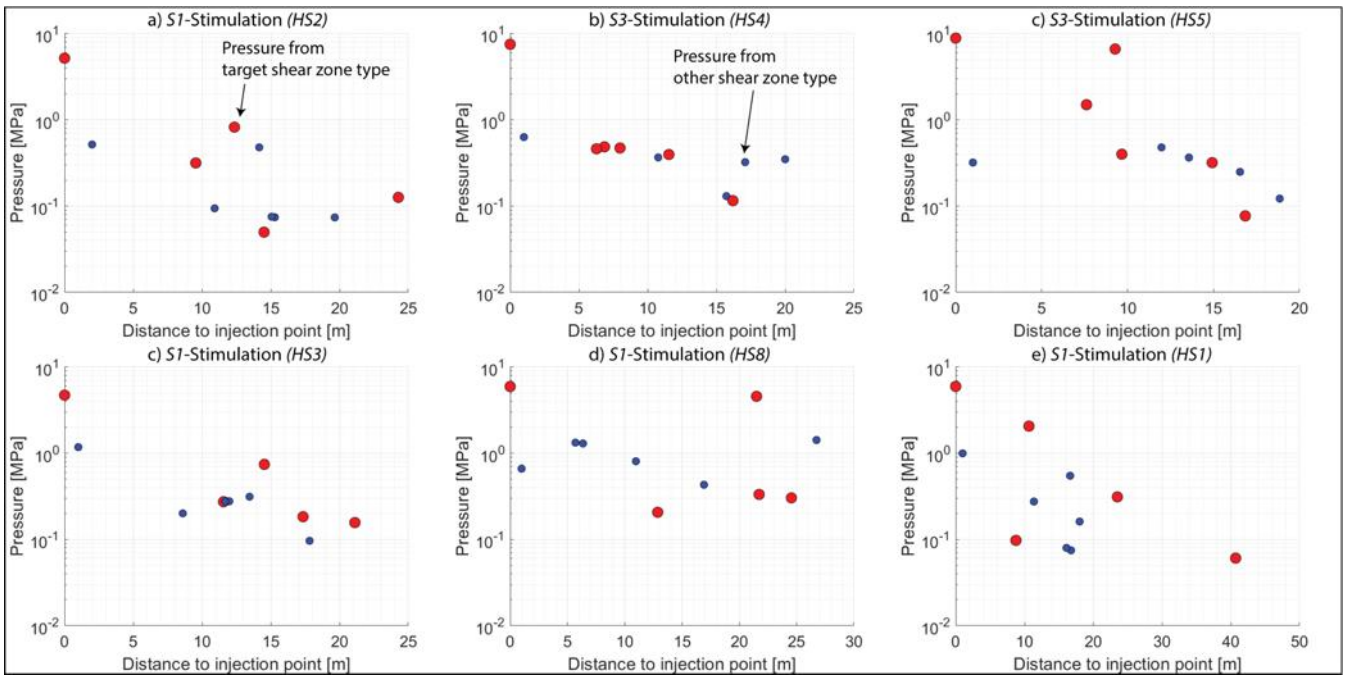

Figure A6. Pressure signals at the moment of shut-in after C3 with respect to radial distance to injection point.

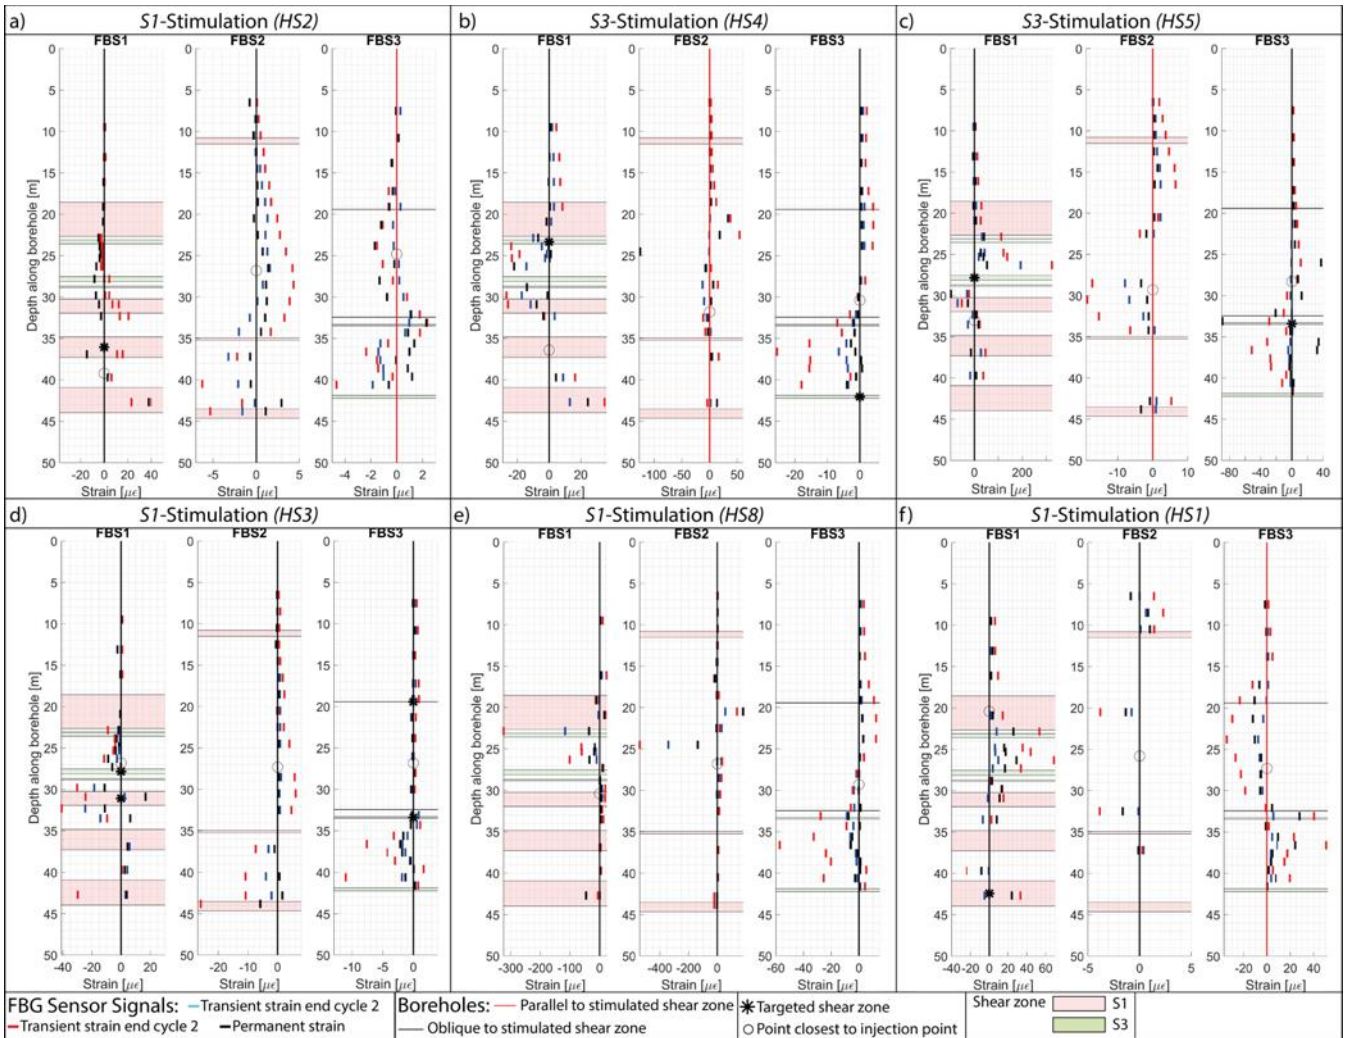

Figure A7. Strain along borehole axis picked transient at the end of injection cycle 2 and 3, and the permanent strain signal after the experiment.

5

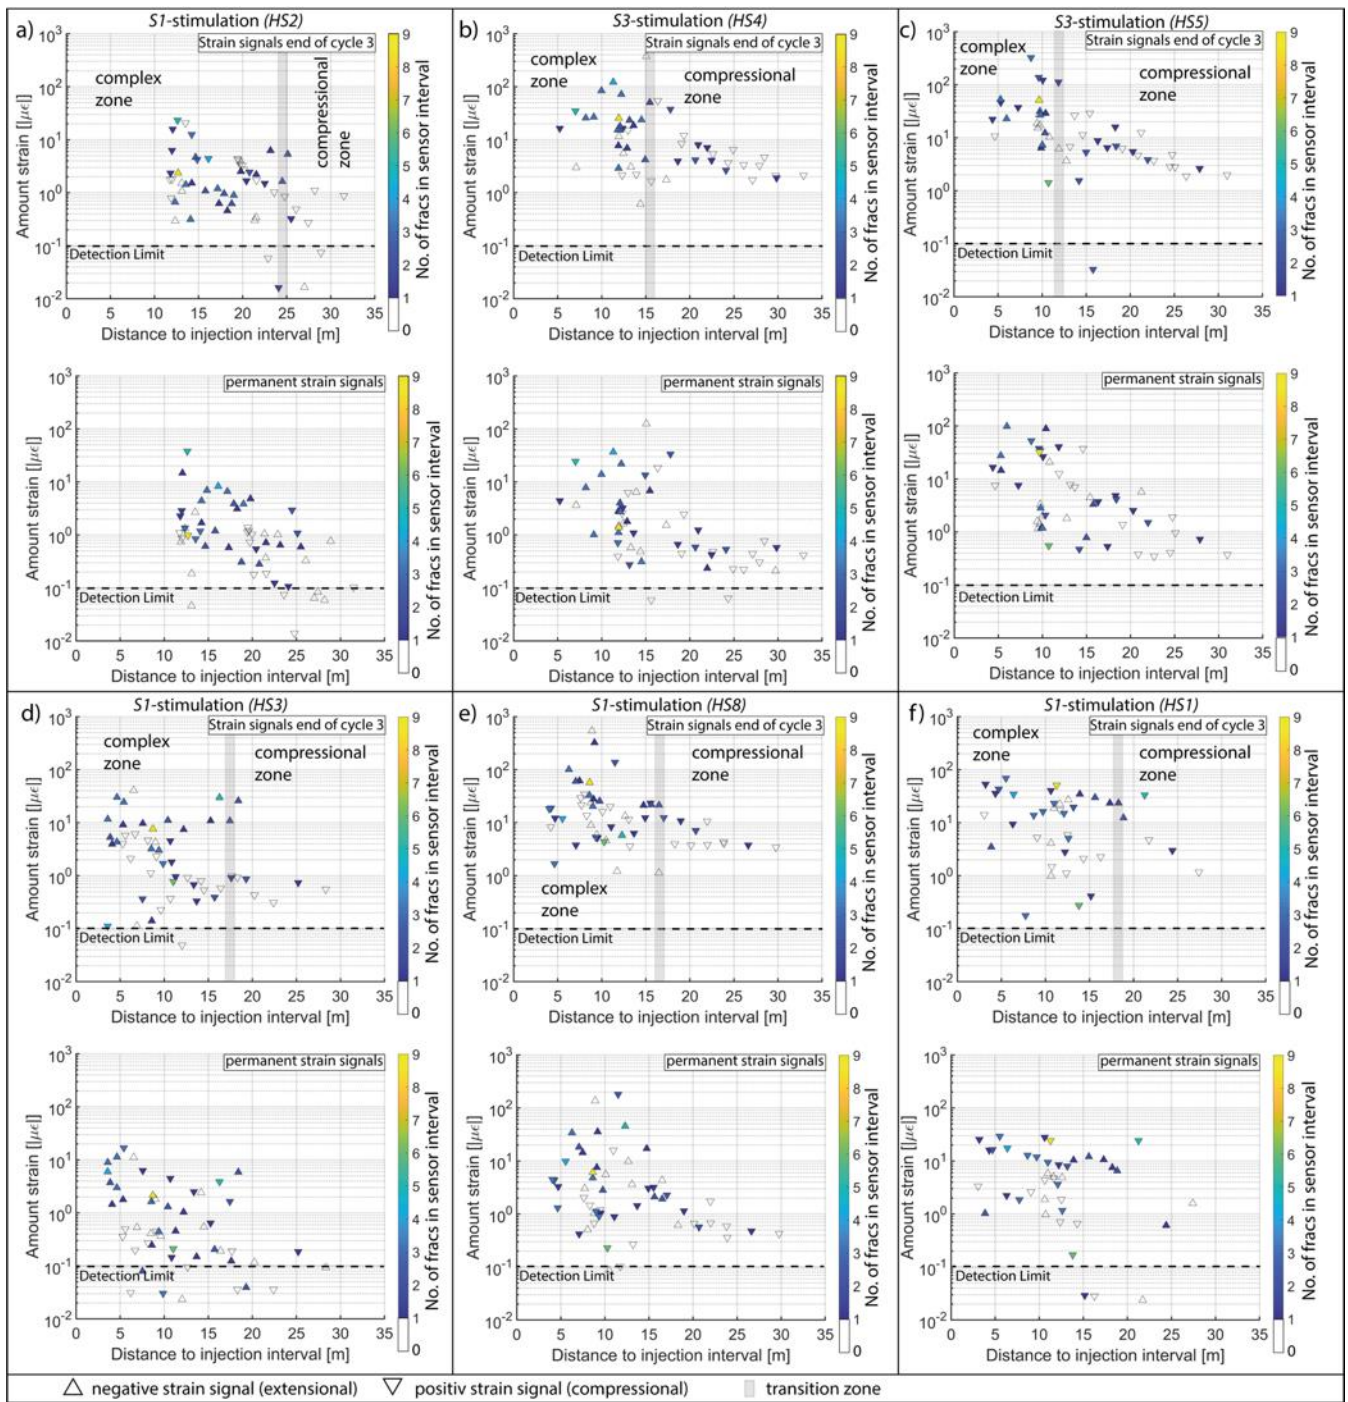

Figure A8 Strain signals with respect to distance to injection point for all experiments. The variable and compressional strain fields are labelled during C3.

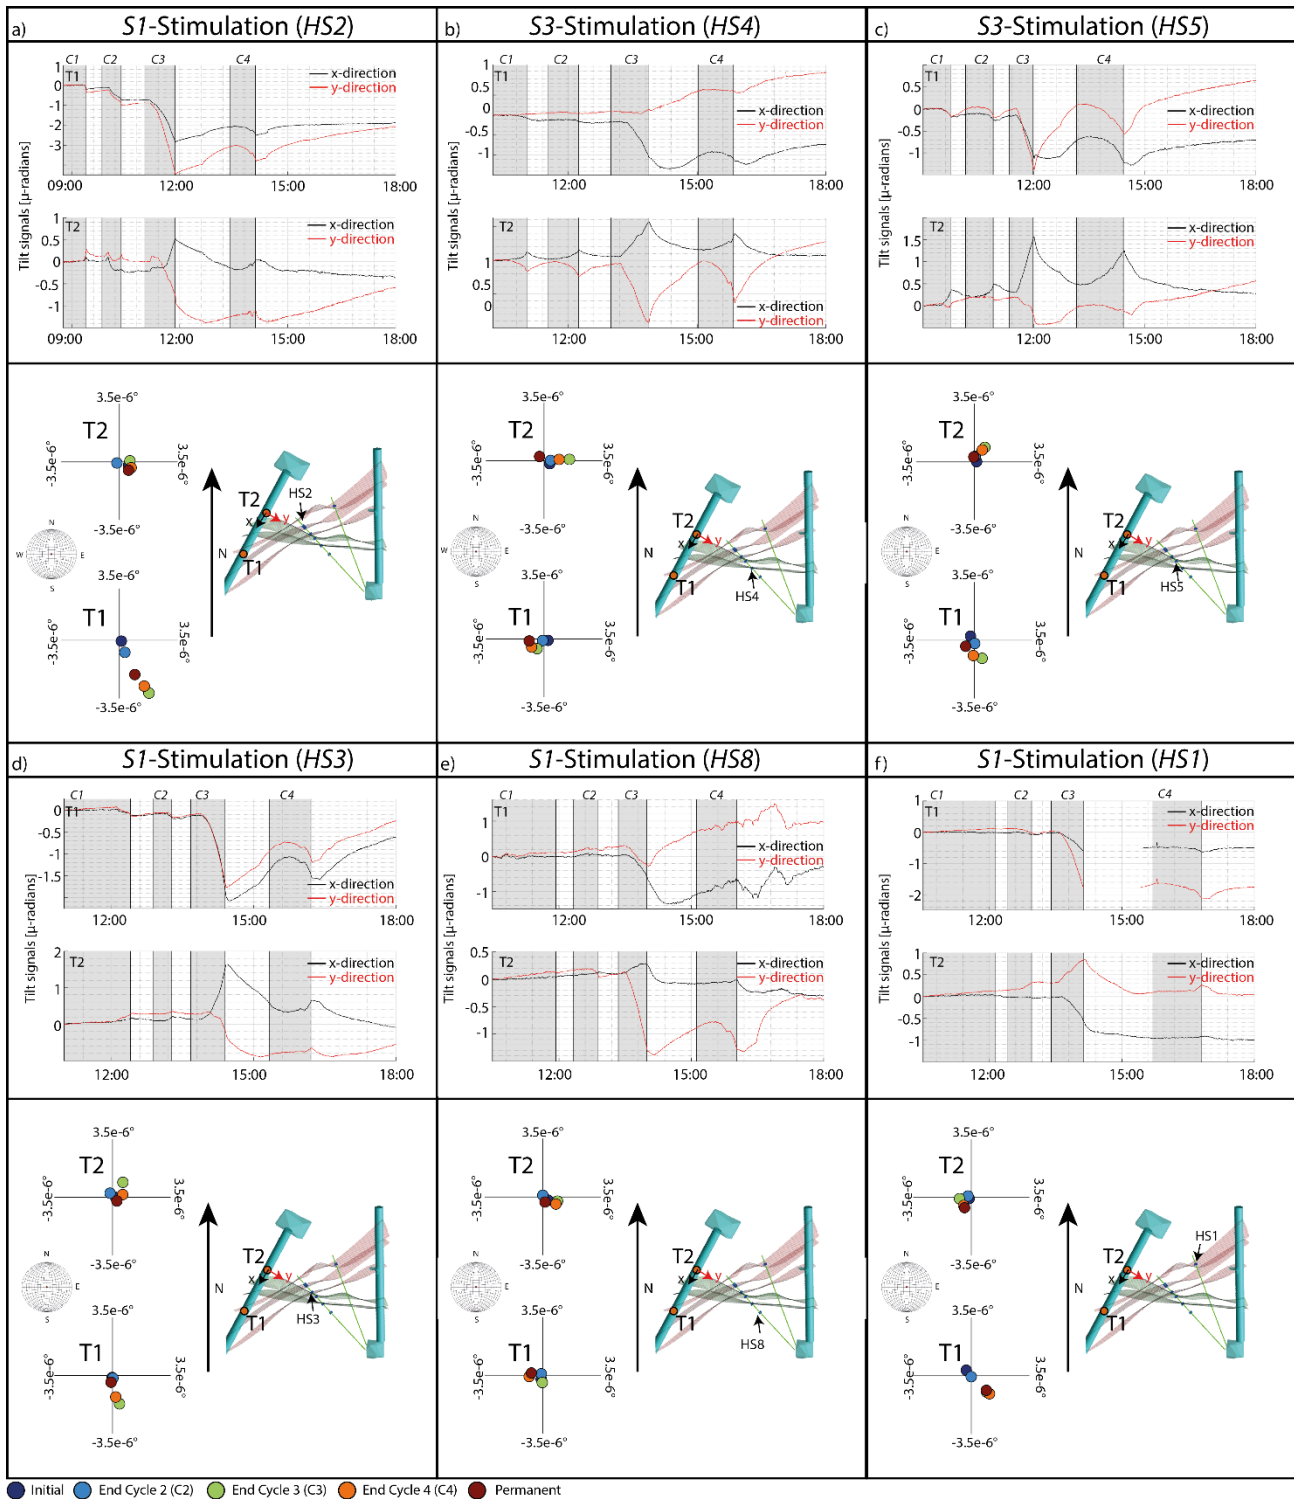

Figure A9. Inclinometer data for each of the six experiments. The upper panel shows the tilt time series for both experiments with the injection periods marked by the shaded vertical bands. The lower panel shows a horizontal section through the study volume at the level of the tunnels showing the shear-zones and tiltmeter T1 and T2 positions. The x- and y-axes of the tilt data are indicated on T2. Changes in the downward-oriented normal vector of the tunnel floor at T1 and T2 are shown in the lower-hemisphere plots at the left of the frames.

5

**Table A1. Locations and packed-off length of monitoring intervals in the INJ boreholes during the stimulation experiments. The fracture zones that intersect the interval are given in the adjacent column. Monitoring intervals that include the interval undergoing injection in the other INJ borehole are marked with (\*).**

Expt. (Zone)	INJ1-1		INJ1-2		INJ2-1		INJ2-2	
	Depth (m)	Zones	Depth (m)	Zones	Depth (m)	Zones	Depth (m)	Zones
HS2 (S1.2)	41.0 – 45.0	S1.3	38.0 – 40.0 (*)	S1.2	36.2 – 45.0	S1.3	31.5 – 35.2	S1.2
HS4 (S3.1)	29.2 – 45.0	S3.2, S1.1, S1.2, S1.3	27.2 – 28.2 (*)	S3.1	28.3 – 45.0	S1.1, S1.2, S1.3	19.6 – 27.3	S1.0, S3.1, S3.2

**Table A2. Radial distances between the midpoints of the pressure monitoring intervals and the injection interval for all HS tests. The “OBS” intervals represent the inactive INJ borehole.**

Interval	HS2	HS4	HS5	HS3	HS8	HS1
PRP1_1	11.9	19.6	16.4	14.2	24.1	15.2
PRP1_2	11.79	7.8	7.7	8.9	10.6	8.2
PRP1_3	16.3	7.1	9.9	12.5	6.2	11.2
PRP2_1	9.2	16.7	13.4	11.2	21.3	12.2
PRP2_2	16.0	6.6	9.4	12.1	5.5	10.8
PRP3_1	20.2	16.2	16.9	18.0	16.8	17.4
PRP3_2	25.0	16.0	18.9	21.4	13.1	20.2
OBS_2	14.7	10.7	13.1	15.4	11.8	16.0
OBS_1	15.3	15.7	14.3	14.0	15.0	18.1
INJ-1	4.0	9.4	7.4	5.9	12.0	9.5

Table A3. Response behavior of the pressure monitoring intervals at shut-in of injection cycle 3 for all HS tests. This table also makes the link to the shear zone targeted during each stimulation and covered by the monitoring intervals (both in bold). The responses are classified as immediate (in case of an immediate response to shut-in) and delayed (in case of a delayed response to shut-in). The underlined responses are from the intervals that covered the exact targeted shear zones. The ones in italic are taken from the intervals that do not cover the targeted shear zones.
