12 **Abstract.** The dynamic evolution of fault zones at the seismogenic brittle-ductile transition zone (BDTZ) expresses the delicate
13 interplay between numerous physical and chemical processes. Deformation and fluid flow at the BDTZ are closely related and
14 mutually dependent during repeating and transient cycles of frictional and viscous deformation. Despite numerous studies
15 documenting in detail seismogenic faults exhumed from the BDTZ, uncertainties remain as to the exact role of fluids in facilitating
16 broadly coeval brittle and ductile deformation at that structural level. We combine structural analysis, fluid inclusion and mineral
17 chemistry data from synkinematic and authigenic minerals to reconstruct the temporal variations in fluid pressure (P_f),
18 temperature (T), and bulk composition (X) of the fluids that mediated deformation and steered strain localization along BFZ300,
19 a strike-slip fault originally active at the BDTZ. BFZ300 deforms the Paleoproterozoic migmatitic basement of southwestern
20 Finland and hosts in its core two laterally continuous quartz veins formed by two texturally distinct types of quartz – Qtz I and
21 Qtz II, with Qtz I older than Qtz II. Veins within the damage zone are formed exclusively by Qtz I. Meso- and microstructural
22 analysis combined with fluid compositional data indicate recurrent cycles of mutually overprinting brittle and ductile deformation
23 triggered by oscillations of fluid pressure peaking at 210 MPa. Fluid inclusion microthermometry and mineral pair
24 geothermometry indicate that the two documented quartz types precipitated from different fluid batches, with bulk salinities in
25 the 1-5 wt% NaCleq range for Qtz I and in the 6-11 wt% NaCleq range for Qtz II. The temperature of the fluids involved with
26 initial strain localization and later fault reactivation evolved through time from > 350 °C during Qtz I precipitation to < 300 °C
27 at the time of Qtz II crystallization. The peak fluid pressure estimates constrain pore pressure oscillations between 80 and 210
28 MPa during the recorded faulting episodes. Our results suggest variability of the physico-chemical conditions of the fluids steering
29 deformation (P_f , T , X) reflecting the ingress and effects of multiple batches of fluid in the fault zone. Initial, fluid-mediated
30 embrittlement generated a diffuse network of joints and/or hybrid/shear fractures in the damage zone; subsequent strain
31 localization led to more localized deformation within the fault core. Localization was guided by cyclically increasing fluid
32 pressure and transient embrittlement of a system that was otherwise under overall ductile conditions.

33 Our analysis suggests that fluid overpressure at the BDTZ can play a key role in the initial embrittlement of the deforming rock
34 and steer subsequent strain localization.

35

36 **1 Introduction**

37 The physical and chemical properties of fault systems play a fundamental role in controlling the rheological behaviour of the
38 Earth's crust and in steering channelled fluid flow (e.g. Caine et al., 1996). Deformation and fluid flow are closely related and
39 mutually dependent via a number of feedbacks, such as the control that fluids exert upon the effectiveness of deformation
40 processes and the development of fault systems at all scales, and the control by rock heterogeneities and/or fracture system
41 topology on the net fault transmissivity (e.g. Crider and Peacock, 2004). The nucleation and development of permeable fault
42 systems and the mechanisms whereby individual faults may weaken and eventually fail are, therefore, complex functions of a
43 number of processes. In this perspective, the interaction between fluid and mineral phases within fault rocks needs to be studied
44 with a system approach in order to single-out the role and importance of all processes involved (Kaduri et al., 2017).

45 An obvious effect of fluid involvement, particularly in crustal volumes that have experienced large deformation-controlled fluid
46 fluxes, is the precipitation of authigenic and hydrothermal minerals within faults (Oliver and Bons, 2001; Viola et al., 2016) and
47 their immediately adjacent host rock (Mancktelow and Pennacchioni, 2005; Garofalo, 2004). In the seismogenic region of the
48 crust, where fluids may even be the primary driver of the seismic cycle (e.g. Miller, 2013), faults have been shown to have the
49 potential to function like a “fluid-activated valve”, whereby they experience transient and cyclic fluid pressure build-up before
50 sudden fluid venting, pore pressure- and mechanical strength drop concomitant with seismic failure (e.g. Sibson, 1989, 1992b,
51 1993; Cox, 1995; Viola et al., 2006; De Paola et al., 2007; Wehrens et al., 2016). Hydrothermal ore deposits, where fault networks
52 focus relatively large volumes of ore fluids and precipitate economic minerals (Cox et al. 2001; Boiron et al., 2003; Moritz et al.,
53 2006; Scheffer et al., 2017a) are also pertinent examples of significant deformation-controlled fluid ingress.

54 The seismogenic depth down to 10-15 km (e.g. Kohlstedt et al., 1995) is thus a key region of the crust where to study the whole
55 range of fluid-rock interaction processes occurring within fault zones. Deformation at that depth might be accommodated under
56 overall brittle-ductile conditions along fault systems crossing or rooting into the brittle ductile transition zone (BDTZ). In detail,
57 the deformation style in the BDTZ is generally characterized by the cyclicity, also at the short time scale, between brittle and
58 ductile behaviour (Famin et al., 2004; Famin et al., 2005; Siebenaller et al., 2013). This is induced and regulated by the complex
59 and transient interplay of numerous parameters, among which the lithological composition and transient variation of temperature,
60 pore pressure and strain rate within the deforming system. Field studies have documented unequivocally that ductile and brittle
61 deformation may even be simultaneously active during deformation as a function of the transient and spatially heterogeneous
62 evolution of the chemical and physical parameters steering deformation, leading to the broad coexistence of geological features
63 expressing frictional deformation and viscous creep, and to mutual crosscutting relationships thereof (e.g., Guermani and
64 Pennacchioni, 1998; Kjøl et al., 2015; Pennacchioni et al., 2006; Wehrens et al., 2016; Scheffer et al., 2017b).

65 Veins are particularly important in this context because they attest to the relative abundance of aqueous fluids in the deformation
66 history (e.g. Cox et al., 2001). Portions of the seismogenic crust that experience large fluid fluxes host pervasive and vertically
67 extensive vein networks (Sibson et al., 1988), within which up to several millions of m³ of hydrothermal minerals may deposit
68 from the flowing fluid (e.g. Heinrich et al., 2000; Cox, 2005; Bons, 2001; Garofalo et al., 2002). In contrast, portions of the crust
69 deforming in the absence of significant fluid flow would show scarce evidence of- or no veining, with only synkinematic H₂O-
70 rich minerals within the fault rock attesting to hydrous conditions (cf. Mancktelow and Pennacchioni, 2004; Menegon et al.,
71 2017).

72 The physical-chemical conditions of fluid-rock interaction in the BDTZ have been studied within exhumed faults by applying a
73 set of geochemical tools that include fluid inclusion analysis (e.g. Morrison, 1994; Morrison and Anderson, 1998; Mulch et al.,
74 2004; Ault and Selverstone, 2008; Garofalo et al., 2014; Siebenaller et al., 2016; Compton et al., 2017), determination of the
75 isotopic compositions of fault fluids, and mass transfer calculations between host rock and fault rocks (e.g. Goddard and Evans,
76 1995; Garofalo, 2004; Mittempergher et al., 2014; Spruzeniec and Piazzolo, 2015). This approach yields important constraints
77 on the PT conditions of fluid-rock interaction within the BDTZ, on the source region of the fluids reaching and flowing within
78 the deformation zones, and on element mobility during syn-tectonic fluid flow. These studies, however, do not specifically address
79 the role of fluids on the mechanisms that trigger and permit the aforementioned cycles of brittle-ductile deformation. Open
80 questions thus remain, such as, for example, which pressure, temperature, composition (P, T, X) conditions are best for a fluid to
81 trigger brittle-ductile deformation cycles in a fault system within the BDTZ and which fluid property is specifically most effective
82 in controlling the cycles.

83 In this work, we follow a multidisciplinary approach by combining meso- and microstructural observations with the geochemical
84 analysis of fluids, petrographic documentation of fault rocks and veins, microthermometric properties of fluid inclusion
85 assemblages, electron probe microanalyses (EPMA) of fault minerals, Raman spectrometry of fluid inclusions, and electron probe
86 cathodoluminescence imaging to study the effects of numerous cycles of fluid-rock interaction that have occurred in a vein-rich
87 deformation zone at the seismogenic BDTZ and now exhumed as part of the Paleoproterozoic continental crust of southwestern
88 Finland. The studied deformation zone belongs to an exhumed conjugate fault system that experienced a complex history of
89 structural reactivation and fluid flow. Deformation zone BFZ300, the target of our study, crops out at c. 426 m below sea level
90 within the deep Onkalo nuclear waste repository that is presently being built in the island of Olkiluoto (Fig. 1a).

91 Our results allow us to constrain and describe the progressive evolution of the deformation processes and the role of fluids
92 involved both at fault initiation and during the subsequent reactivation phases. We propose that fluid pressure fluctuation cycles
93 within an overall ductile environment at the BDTZ triggered brittle-ductile cyclicity encompassing fracturing, vein precipitation
94 and crystal-plastic deformation before renewed and fluid-induced embrittlement. Our multitechnique approach made it possible
95 to determine many of the actual chemical and physical properties of the fluids involved in the deformation process, leading to a
96 well-constrained conceptual mechanical model for the fault nucleation and subsequent development.

97 **2 Geological setting**

98 The study area is located in southwestern Finland, on the island of Olkiluoto (Fig. 1a) within the Paleoproterozoic Svecofennian
99 orogenic province, which is formed by supracrustal high-grade metamorphic sequences and plutonic rocks. The most abundant
100 lithologies in the study area are variably migmatitic metasedimentary rocks interleaved with up to several meter thick levels of
101 metavolcanic rocks in addition to calc-alkaline synorogenic TTG-type granitoids, as well as late orogenic leucogranites (Figs. 1a,
102 1b). For a detailed lithological characterization of the area, we refer the reader to Hudson and Cosgrove (2006) and Aaltonen et
103 al. (2016).

104 Numerous studies carried out on Olkiluoto have highlighted the long geological evolution of the region, which is commonly
105 summarised by tectonic models proposing either an evolution during a single and semi-continuous Svecofennian orogenic event
106 (Gorbatshev and Bogdanova, 1993) or, alternatively, a sequence of up to five distinct accretion events leading to the
107 amalgamation of several microcontinents and island arcs at the margin of the Archean craton between 1.92 and 1.79 Ga (e.g.
108 Lahtinen et al., 2005). In this scenario, several subduction systems developed, and the collision of the involved microcontinents
109 and island arc complexes resulted in conspicuous continental growth, forming the major part of the Paleoproterozoic domain of
110 the Fennoscandian Shield (1.89-1.87 Ga). According to Lahtinen et al. (2005), this “Fennian accretionary event” ended with a
111 phase of orogenic collapse associated with regional extension and remarkable crustal thinning between c. 1.86 and 1.84 Ga.
112 Renewed compression ensued during collision of the “Sarmatian Plate” with the previously consolidated Svecofennian Shield,
113 causing major crustal shortening, high temperature regional metamorphism (Kukkonen and Lauri, 2009) and the emplacement of
114 S-type granites (e.g. Ehlers et al., 1993). Tectonic activity ascribable to this orogenic phase ceased with a distinct orogenic
115 collapse phase at 1.79-1.77 Ga (Lahtinen et al., 2005).

116 Pervasive reworking of the Svecofennian domain took place in the Mesoproterozoic when the crust underwent significant
117 stretching and was intruded by voluminous Rapakivi granites and diabase dykes resulting from the widespread melting of the
118 lower crust at c. 1.65-1.50 Ga. This tectonic phase was probably due to the development of a rift along the present Baltic Sea
119 (Korja et al., 2001). Crustal thinning caused also the formation of the “Satakunta Graben”, a NW-SE trending graben located c.
120 50 km to the north of Olkiluoto, which was later filled by Mesoproterozoic sandstone (Jotnian sandstones, Fig. 1a). The latest
121 stage of crustal evolution in southern Finland is expressed by the intrusion of 1.27-1.25 Ga, N-S striking olivine diabase dikes
122 (Fig. 1a; e.g., Suominen, 1991).

123 As to the structural evolution of the study area, the bedrock was affected by complex, polyphase ductile deformation between
124 1.86 and 1.81 Ga. According to the evolutionary deformation scheme by Aaltonen et al. (2010) the results of up to five different
125 phases, referred to as D₁-D₅, are preserved in the local structural record, each characterised by structures with distinctive mineral
126 composition, metamorphic grade, geometry and kinematics. The most relevant phases to our study are D₂ to D₄. During these
127 ductile episodes, a regional and pervasive NE-SW striking and moderately SE-dipping foliation developed, strain localized along
128 mesoscopic shear zones parallel to subparallel to the foliation and extensive migmatization occurred under amphibolite-facies
129 metamorphic conditions. NNE-SSW and N-S striking mylonitic shear zones also formed under those conditions, whereas later

130 ductile events developed under progressively lower-grade metamorphism until c. 1.7 Ga ago, when brittle deformation became
131 the dominant deformation style in response to progressive regional exhumation and cooling (Mattila and Viola, 2014; Aaltonen
132 et al., 2016). The penetrative, inherited ductile grain that by then characterised the crystalline basement and that was suitably
133 oriented with regard to the prevailing stress field was invariably reactivated. This is the case for several NNE-SSW striking faults
134 mapped underground in the Onkalo repository, which clearly overprint earlier D4 shear zones and fully exploit the pre-existing
135 ductile precursors. Other faults, such as BFZ300, do not show any clear genetic relation to the older ductile fabric and cut
136 it discordantly.

137 As shown in the following section, BFZ300 belongs to a set of subvertical, conjugate brittle-ductile to fully brittle strike-slip
138 faults characterized by N-S-trending sinistral and NW-SE dextral faults. Both sets document a complex history of reactivation
139 and contain evidence for cyclic and transient switches between brittle and ductile deformation at all scales. Meso- and
140 microstructural studies show that the sinistral faults overprint and probably reactivate a dextral mylonitic precursor related to
141 earlier, localized ductile deformation (Prando et al., in prep.). These faults locally contain pseudotachylyte injections, which
142 suggests seismic behaviour during deformation (Menegon et al., 2018). In contrast, dextral faults cut across the foliation, do not
143 exploit any ductile precursors and do not host pseudotachylytes. BFZ300 belongs to this second group of faults. In the following,
144 we describe its architecture, reconstruct its deformation history and constrain the deformation mechanisms and faulting conditions
145 that prevailed during its nucleation and subsequent development. The architecture and deformation history of the remarkably
146 different conjugate structure to BFZ300, which is a sinistral brittle-ductile deformation zone, is described in the Part II
147 companion paper (Prando et al., in prep.).

148 **3 Methods: Fluid inclusions, mineral chemistry and EBSD analyses**

149 Field documentation and sampling were carried out at the underground Onkalo exposures of BFZ300 (Fig. 1b) which were
150 necessarily limited in extent to the actual excavated volume of rock at the time of our study but that, together with the logged
151 diamond drill cores from the underground exploration, allow a well-constrained 3D reconstruction of the local geology.

152 Fluid inclusion measurements were conducted on “fluid inclusion assemblages” – FIAs, i.e. on petrographically discriminated,
153 cogenetic groups of fluid inclusions located along trails or (less commonly) within clusters (Bodnar, 2003a; Goldstein, 2003). By
154 definition, FIAs are groups of inclusions that have been trapped together (i.e., they are cogenetic) at a specific stage of mineral
155 formation and, as such, give the highest level of confidence when characterizing the properties of trapped fluids and discriminating
156 possible stages of post-entrapment re-equilibration (Bodnar, 2003b, and references therein). We applied Roedder’s identification
157 criteria of FIAs according to the timing of entrapment (i.e., primary, secondary, pseudosecondary) in order to link stages of fluid
158 entrapment with stages of brittle and ductile deformation of quartz. In this regard, we considered as cogenetic, and therefore
159 representative of one specific stage of brittle deformation and fluid circulation, only those FIAs that exhibited both similar
160 orientation and petrographic characteristics at the scale of the thin section.

161 In the selected samples, we studied 28 FIAs entrapped within two distinct generations of quartz (named Qtz I and Qtz II) forming
162 two different generations of veins and exhibiting the least petrographic evidence of post-entrapment overprinting by later ductile
163 and/or brittle deformation, which provided c. 800 microthermometric properties. Due to the well-documented tendency of fluid
164 inclusions to modify their shape, volume, and composition after their initial entrapment even at low deviatoric stress conditions
165 (e.g. Diamond et al., 2010; Kerrich, 1976; Tarantola et al., 2010; Wilkins and Barkas, 1978), working on FIAs that show the least
166 possible degree of textural re-equilibration is essential when aiming at constraining the physical and chemical properties of the
167 fluid(s) involved in the fault activity.

168 Microthermometric properties of fluid inclusions were determined at the Department of Biological, Geological and
169 Environmental Sciences of the University of Bologna using a Linkam THMSG 600 heating/freezing stage coupled with an
170 Olympus BX51 polarizing microscope. The microthermometry stage was calibrated by using synthetic fluid inclusion samples at
171 -56.6 , 0.0 , and 374 °C, which correspond to the melting of CO₂, ice melting, and final homogenization of H₂O inclusions,
172 respectively. Obtained accuracies were ± 0.3 °C for final ice melting temperature ($T_{m,ice}$) and ± 3 °C for final homogenization
173 temperature ($T_{h,tot}$). In order to produce an internally consistent dataset, all phase transitions were exclusively collected for
174 individual FIAs and measured with the same standard procedure. Samples were first rapidly cooled to c. -180 °C and then slowly
175 heated to detect the potential formation of a solid carbonic phase, eutectic phases, salt hydrates, ice, and clathrates. The $T_{h,tot}$ were
176 later determined in the FIAs by heating the samples from room temperature and recording the mode of homogenization (i.e., by
177 bubble or liquid disappearance). All phase transitions were measured by using the cycling method described by Goldstein and
178 Reynolds (1994), and care was taken also to record the minimum and maximum values for each assemblage. Volume fractions
179 of individual fluid inclusions determined as % of the ratio $\varphi = V_v/V_{tot}$ (cf. Diamond, 2003), were estimated optically at room
180 temperature using calibrated charts. Salinity, bulk densities and isochores were computed from the measured $T_{m,ice}$ values using
181 the HokieFlincs Excel spreadsheet (Steele-MacInnis et al., 2012 and references therein).

182 Fluid inclusions were also analysed using micro Raman spectrometry. Analyses were carried out at the Department of
183 Mathematical, Physical and Computer Sciences of the University of Parma (Italy) using a Jobin-Yvon Horiba LabRam
184 spectrometer equipped with He-Ne laser (emission line 632.8 nm) and motorized XY stage. The spectral resolution of the
185 measurements was determined as nearly 2 cm⁻¹. The confocal hole was adjusted to obtain a spatial (lateral and depth) resolution
186 of $1-2$ μm. Most spectra were obtained with a $50\times$ objective (N.A. 0.75), although for shallow inclusions also a $100\times$ objective
187 (N.A. 0.90) was used. The calibration was made using the 520.7 cm⁻¹ Raman line of silicon. A wide spectral range ($100-3600$
188 cm⁻¹) was scanned for each inclusion for the presence of CO₂, N₂, CH₄, and H₂S, but the final acquisitions were made mainly
189 between 1100 and 1800 cm⁻¹ for the study of CO₂ spectra, and between 2500 and 3300 cm⁻¹ for CH₄ and H₂S. The acquisition
190 time for each spectral window was $120-240$ s, with two accumulations. The power on the sample surface is nearly 1 mW but the
191 power on the analysed inclusions has to be considered lower due to reflections and scattering. Analyses were carried out on the
192 vapour bubbles of the fluid inclusions.

193 After the calculation of representative fluid inclusion isochores for each FIA, the pressure corrections were assessed by using the
194 crystallization temperatures of two mineral pairs – namely chlorite-quartz and stannite-sphalerite – as independent input
195 parameters. Chlorite-quartz temperatures were calculated by using the method of Bourdelle and Cathelineau (2015), which
196 assumes quartz-chlorite equilibrium and uses ratios of chlorite end-member activities to link the chlorite compositions with the
197 corresponding formation temperatures through the quartz-chlorite equilibrium constants. This method is based on the
198 measurements of the concentrations of the major chlorite components (Si, Fe, Mg) and can only be applied to chlorites with $(K_2O$
199 $+ Na_2O + CaO) < 1wt\%$, indeed the case of our chlorites. To estimate the formation temperature of cogenetic sulphides associated
200 with Qtz II we used the stannite-sphalerite formation temperature following the method proposed by Shimizu. and Shikazono
201 (1985). This geothermometer uses the temperature dependency of iron and zinc partitioning between stannite and sphalerite
202 (Nekrasov et al., 1979) as a temperature indicator of the association Qtz II-stannite and sphalerite.

203 Electron Probe Microanalysis (EPMA) of fault minerals was carried out with a JEOL-8200 wavelength-dispersive electron
204 microprobe housed at the Department of Earth Sciences of the University of Milan, Italy. The instrument fits 5 WDS
205 spectrometers utilizing lithium fluoride (LiFH), pentaerythritol (PETJ and PETH), and thallium acid pthalate (TAP) analysing
206 crystals and an optical microscope. Samples were probed with a beam size of $\sim 1 \mu m$ at 15 keV and 5 nA beam current. Synthetic
207 and natural materials were used as calibration standards at the beginning of each session. Analytical $1-\sigma$ errors are typically $< 4\%$
208 for major elements and for the minor elements.

209 Panchromatic cathodoluminescence (CL) imaging was also performed by using the CL CCD detector adjacent to the optical
210 microscope of the JEOL-8200 on the sections used for microstructural work. The electron beam was focused on the sections with
211 an accelerating voltage of 15 kV and 30 nA beam current. Black/white digital images were collected with a 40x magnification by
212 beam mapping with the CCD detector at a spatial resolution of $1 \mu m$ (beam resolution), which resulted in imaged areas of $27.8 \times$
213 $22.2 mm$. The exposure time for image acquisition was 120 s.

214 Petrographic thin sections were later used at the Scanning Electron Microprobe (SEM) to investigate the crystallographic
215 preferred orientation (CPO) of selected sites of the quartz veins from the fault core (sample name TPH-120-4, see Figure
216 2 for sample location). Samples were analysed with a JEOL 6610 SEM equipped with a Nordlys Nano EBSD detector,
217 hosted at the Electron Microscopy Centre of the University of Plymouth, UK. EBSD detailed results are reported in the
218 Supplementary Material.

219 **4 Results**

220 **4.1 BFZ300 fault architecture**

221 The studied BFZ300 section is located at a depth of 426 m b.s.l. and is about 8 m long (Fig. 2a). It strikes NNW-SSE and dips
222 very steeply to subvertically to the southwest (Fig. 2b). It cuts through high-grade veined migmatite, interlayered with gneiss and
223 pegmatitic granite. The fault is a strike-slip fault system formed by two main subparallel fault segments connected by a

224 mesoscopic sinistral step-over zone. Subhorizontal striae defined by elongated trails of chlorite grains and kinematic indicators
225 such as chlorite slickensides (Fig. 2c) and R and R' planes invariably indicate dextral strike-slip kinematics. The most striking
226 mesoscopic characteristic of BFZ300 is the presence in the fault core of a composite set of almost continuous quartz veins
227 (between 1 and 20 cm in thickness) along the entire exposed strike length. A schematic representation of the fault zone is shown
228 in Figure 3.

229 The fault contains a 0.5-2 m thick damage zone separated from the undeformed host rock by two discrete bounding surfaces (Y_I
230 planes according to Tchalenko, 1970 Fig. 2a). The damage zone can be defined in the field on the basis of the presence of a
231 fractured volume containing sets of conjugate dextral and sinistral hybrid fractures (Fig. 3a) intersecting to form a tight acute
232 angle of c. 38° (Figs. 2b, 3a). Laterally continuous, NNW-SSE striking Mode I fractures (joints) invariably bisect this angle (Figs.
233 2b), helping to constrain the stress field orientation at the time of fracture formation, with the greatest compressive stress axis σ_1
234 parallel to the Mode I fracture strike and oriented c. NNW-SSE. Joints are sharp and have a regular spacing of c. 10 cm. The
235 joints and the hybrid fractures of the damage zone contain quartz, referred to as Qtz I hereinafter, forming veins up to 1-1.5 cm
236 thick (Fig. 3a). Fractures and faults decorated by Qtz I have a translucent look that reflect the generally fine grain size of Qtz I (<
237 1 cm, Fig. 3b). Locally they are formed by en-echelon tensional segments connected by shear planes not decorated by any quartz
238 infill (Fig. 3b). Joints occur also as barren fractures defining a penetrative sympathetic fracture cleavage (*sensu* Basson and Viola,
239 2004; green lines in Fig. 2b). Field evidence also suggest that fracture density within the damage zone tends to increase towards
240 the fault core.

241 The fault core is bounded by two main discrete slip surfaces (Y_{II} , Figs. 2a, 3d, f, h). It contains, and is defined by, two distinct
242 generations of quartz veins (Fig. 3c) that are interrupted and offset laterally by a metric sinistral step-over zone (Fig. 3d-f). The
243 main quartz vein of the core is infilled by quartz exhibiting the same mesoscopic appearance of Qtz I in the damage zone; we
244 therefore refer to it as a Qtz I vein. It is accompanied by a younger, subparallel vein formed by a milky-white type of quartz with
245 a significantly larger grain size than Qtz I (>1 cm) that we refer to as Qtz II (Fig. 3c). Locally, pockets of cataclasite and breccia
246 formed at the expense of the host migmatitic gneiss are also observed along and in between the two veins (Figs. 3g, i). The Qtz
247 II vein exhibits a quite irregular, curved geometry (Figs. 3c, h) and a variable thickness up to a maximum of c. 20 cm. The
248 minimum Qtz II vein thickness coincides spatially with an apparent lateral displacement of the vein. The BFZ300 core varies in
249 thickness between 20 and 30 cm along most of the exposed fault length, but becomes thicker (up to 50 cm) in the compressional
250 step-over zone that connects the two fault segments that are offset laterally by c. 1 m. The sinistral step-over zone is defined by
251 synthetic T fractures (Figs. 3d, e) and contains a decimetric brecciated lens (Fig. 3d). T fractures are filled by Qtz I veins (Fig.
252 3e).

253 Chlorite is present as a secondary phase, with a modal abundance between 5 and 10 vol% in both Qtz I and Qtz II veins. In Qtz I
254 veins it occurs as euhedral/subhedral crystals up to 1-2 mm in size (Fig. 3g). Chlorite is present mostly as a disseminated,
255 interstitial phase, concentrated mainly in the internal part of the Qtz I veins (Fig. 3g). In the Qtz II vein, however, it occurs as
256 elongated crystals (5-8 mm in length) arranged perpendicularly to the walls of the vein, which suggests orthogonal dilation at the

257 time of opening (Fig. 3h). The Qtz II vein contains also small (1-2 cm) aggregates of sulphides (sphalerite, pyrite, galena, and
258 chalcopyrite) mainly concentrated in the central part of the vein (Fig. 3g).

259 As observed in the field, the presence of Qtz I veins along the joints in the damage zone and the continuity of the fault core Qtz I
260 vein suggest Mode I fracturing during Qtz I emplacement (Figs. 2a, 3a, c). The semi-continuous parallelism of Qtz I and Qtz II
261 veins in the fault core, combined with the location of the Qtz II vein along the walls of the Qtz I vein, suggest the partial
262 reactivation of the Qtz I vein during Qtz II emplacement. Dilation leading to Qtz II emplacement exploited and further reworked
263 the Qtz I-host rock contact, that seemingly had a lower tensile strength than the pristine migmatite. The reconstructed time
264 relationship between the two vein generations is also consistent with local evidence of the Qtz II vein partly crosscutting the Qtz
265 I vein (Fig. 3f).

266 **4.2 BFZ300 microstructural analysis**

267 To constrain the spatial and temporal association of fault rocks and the type of fluid involved in the deformation, several outcrop
268 samples, each representative of a specific structural domain, were collected (TPH-120-2, TPH-120-3, TPH-120-4, TPH-120-5
269 and TPH-120-6), in addition to samples PH21 and PH22 from diamond drill cores that intersect BFZ300 at the same depth in an
270 area that is currently not excavated. From these samples we prepared 10 petrographic thin sections (samples TPH-120-2, TPH-
271 120-4, TPH-120-6, PH21 and PH22) and 9 doubly-polished sections for fluid inclusion analysis (thickness ~150 μm , samples
272 TPH-120-2, TPH-120-4, TPH-120-6, PH21 and PH22). Due to the extensive reactivation of the fault zone and the consequent
273 obliteration of the FI record, the FI study was carried out only in samples TPH-120-4, TPH-120-6 and PH21. Hand samples and
274 drill cores localities are shown in Figure 3.

275 The microstructural work was carried out on oriented petrographic thin sections cut orthogonally to the migmatitic foliation and
276 parallel to the slickenlines.

277 In the following we provide a description of the microstructural characteristics of BFZ300 by detailing our findings and
278 observations separately for the main structural domains of the fault zone.

279

280 *4.2.1 Damage zone*

281 Qtz I veins within the damage zone cut across the migmatitic host rock and form the infill of conjugate sets of hybrid fractures,
282 which, when studied at the microscale, appear as formed by dilatant segments joined by cataclastic shear fractures (Fig. 4a).
283 Shearing on the latter is well documented by the asymptotic bending into the shear surfaces of foliation planes formed by the
284 alignment of chlorite and muscovite, both partly altered to sericite and chlorite, respectively (Fig. 4a). Qtz I infilling the tensional
285 segments has an average grain size between 200 μm and 3 mm and exhibits a rather heterogeneous texture, from purely blocky
286 to mixed elongated-blocky (Figs. 4b, c). The largest crystals (800 μm to 1 mm) are elongated and stretched from the vein walls
287 towards the inner part of the vein (Figs. 4c, 5a). At least two episodes of vein growth/renewed dilation, as indicated by the
288 presence of median lines (ML), are visible within one of the studied veins and confirm a syntaxial growth mechanism for the vein

289 (Fig. 5; e.g. Bons et al., 2012). Medial lines are defined by the alignment of chlorite, sericite, and carbonate aggregates (Figs. 5a,
290 b, d). Blocky euhedral quartz crystals are also found varying in grain size between 300 and 600 μm . These crystals are juxtaposed
291 against very fine grained quartz ($<200 \mu\text{m}$) within sericite-rich cataclastic bands (Fig. 4b). These cataclasites contain also
292 hydrothermally altered host-rock fragments including pervasively altered K-feldspar-bearing lithic fragments and
293 phyllosilicates.

294 With the exception of the blocky variety, Qtz I crystals exhibit various degrees of crystal-plastic deformation and recovery. They
295 contain widespread evidence of undulose extinction and extinction bands (Fig. 5b), and incipient bulging along grain boundaries
296 is also evident (Fig. 5c). Millimetric intracrystalline barren fractures are also recognized (e.g. Fig. 5c). Cathodoluminescence
297 imaging of Qtz I from the damage zone also shows the presence of a dense network of healed quartz microfractures (Fig. 4d),
298 which demonstrates healing subsequent to brittle deformation and fracturing.

299 Chlorite occurs along the ML of the veins, secondary cracks, along grain boundaries and as as inclusions within quartz crystals.
300 It has a vermicular texture (Fig. 5d) and crystal dimensions up to 50 μm .

301

302 4.2.2 Fault core

303 In the fault core, Qtz I grain size reaches the smallest observed value (range: 30-800 μm , Fig. 6a), although it is strongly variable
304 within the vein, suggesting the presence of heterogeneous and complex structural sub-domains. The earliest post-vein
305 emplacement deformation stage is reflected by the low-temperature, intracrystalline deformation of the largest crystals (400-800
306 μm in size). Undulose extinction, wide extinction bands (WEBs, Derez et al., 2015), and bulging along grain boundaries are the
307 most common microstructures ascribable to this deformation stage (Figs. 6a, b). A first brittle deformation event is documented
308 by narrow, intracrystalline fractures that crosscut the largest quartz crystals (Fig. 6c) and which locally contain new grains of
309 quartz ranging in size between 20-100 μm (Fig. 6d). More in detail, these new grains form parallel bands that are oriented at low
310 angle ($<30^\circ$) to the vein walls and that can be up to 2 mm in length and 200 μm in thickness. Plastically deformed Qtz I crystals
311 hosting these intracrystalline bands of new grains are cut across by another later set of subparallel intercrystalline fractures, which
312 are interpreted as the expression of yet another deformation event that occurred under overall brittle conditions. These fractures
313 are parallel to the strike of BFZ300 and are in turn sealed by partly recrystallized new quartz grains (grain size: 50-150 μm ; Fig.
314 6e). The cathodoluminescence imaging of these fractures shows that they are sealed, yielding an homogeneous dark signal (Fig.
315 S1 of the Supplementary Material). They are locally decorated by trails of fluid inclusions (Figs. S2a, d of the Supplementary
316 Material) and can be up to 2.5 cm in length and up to 500 μm in width (Fig. 6a). EBSD maps were acquired along some of these
317 intercrystalline bands, and results suggest that the new grains sealing the fractures reflect the combined effect of initial cracking,
318 grain nucleation and subsequent partial dynamic recrystallization (Figs. S2b, c of the Supplementary Material).

319 Qtz II within the fault core is typically coarse grained (individual crystals: 300 μm -1 cm in size) and exhibits a regular blocky
320 texture devoid of any shape or crystal preferred orientation (Fig. 7a). Locally, these large crystals display primary growth textures,
321 such as primary FIAs oriented parallel to specific crystallographic planes. With the exception of undulose extinction, Qtz II does

322 not show clear evidence of plastic deformation, although cathodoluminescence imaging of optically continuous Qtz II has also
323 shown that a dense network of healed quartz microfractures locally crosscuts Qtz II crystals (Fig. 7c). These are relatively thin
324 (hundreds of μm thick) networks that are poorly visible to invisible by standard petrographic analysis. The only petrographic
325 evidence for these healed microfractures within quartz are well defined trails of fluid inclusions crosscutting primary growth
326 bands (Fig. 7d).

327 Chlorite is the second most abundant phase within the fault core Qtz I and Qtz II veins and occurs with a variety of textures.
328 Aggregates of vermicular chlorite similar to that occurring in the damage zone are also present in Qtz I from the core (Fig. 8e),
329 although chlorite with flaky and radiate textures (Fig. 8f) is also present. The latter is generally 100-300 μm in size and is in
330 textural equilibrium with quartz and rare calcite. Radiate chlorite overgrowing fractured Qtz II (Fig. 7b) suggests late Qtz II
331 precipitation.

332 Associated with Qtz II, a sulphide assemblage made of pyrite, sphalerite, galena and chalcopyrite (Figs. 7d, e, see also Fig. 3g)
333 forms aggregates that are commonly located along quartz grain boundaries. These aggregates have dimensions between 10 and
334 600 μm .

335 Multiply reworked breccias and cataclasites occur within and crosscut BFZ300. In the studied sections, a cataclastic band between
336 5 and 8 mm thick crosscuts both Qtz I and Qtz II veins (Fig. 8a), but is in turn crosscut by a different quartz-radiate chlorite vein
337 displaying evidence of syntaxial growth. This cataclasite contains poorly sorted and angular quartz clasts between 8 and 12 mm
338 in size set in a finer (20-200 μm in size) white mica-quartz matrix. The largest quartz fragments show irregular, lobate grain
339 boundaries and are affected by undulose extinction. We interpret these textures as the product of dissolution and cataclastic
340 reworking of Qtz I.

341 Parallel sets of stylolitic seams trend c. N-S, parallel to the strike of BFZ300, and mark the two sides of the cataclastic band (Figs.
342 8a, c). They host anhedral sphalerite, stannite, galena, pyrite, and chalcopyrite (Fig. 8d), which are coeval with the formation of
343 the Qtz II vein. We interpret the presence of these anhedral sulphide minerals along the stylolite as the product of passive
344 concentration by pressure-solution.

345

346 **4.3. Fluid inclusion data**

347 *4.3.1 Fluid inclusion petrography*

348 The studied FIAs contain invariably a two-phase fluid (liquid-vapour) and are mainly arranged in secondary trails within Qtz I
349 crystals in the damage zone (Type S1) and also within Qtz I fault core, where they form dismembered (Type S2) trails and also
350 appear as individual clusters inside the crystals affected by crystal-plastic deformation (Type S3). Within Qtz II, FIAs are arranged
351 as pseudosecondary (Type PS) and secondary (Type S4) trails. Representative examples of FI petrographic features are shown
352 for each structural domain in Fig. 9. Table 1 provides a schematic representation of the location of the FI types, in addition to
353 their location within the fault architecture and their fluid properties.

354 *Damage Zone:* Within Qtz I grains (Figs. 9a, b), secondary FIAs are found as trails (Fig. 9a) that parallel what we interpret as
355 healed, old microfractures. In these assemblages, FIs have a maximum size between 2 and 20 μm , a regular equidimensional
356 shape (i.e. negative crystal morphology), and a volume fraction, ϕ ($\phi = V_v/V_{\text{tot}}$, see section 3), ranging between 5 and 15% (Fig.
357 9b).

358 *Fault Core:* Qtz I grains host secondary FIAs (Type S2), which are transgranular trails (Fig. 9c) along healed joints and hybrid
359 fractures. These trails are locally interrupted and dismembered by aggregates of new, fine-grained quartz grains (Fig. 9c), and
360 generate a texture that is indeed typical of Qtz I from the fault core (Fig. 6a). Fluid inclusions vary in size between 1 and 10 μm ,
361 have a ϕ of 10-20%, and show a negative crystal morphology (Fig. 9d). Fluid inclusions are also found as isolated clusters inside
362 intensely recrystallised quartz domains (Fig. 9c). FIAs inside these recrystallized quartz domains were pervasively obliterated
363 during later episodes of ductile deformation. The development of WEBs, intercrystalline bands and bulging resulted in the
364 remobilization (i.e., “transposition” *sensu* Anderson et al., 1990) of these assemblages. This is regularly observed and is
365 documented, for instance, by the presence of short, secondary trails of regularly shaped inclusion oriented at a high angle with
366 respect to a longer, parent trail (Fig. 9c). Morphologically, these trails resemble the transposed trails documented in high-grade
367 metamorphic rocks (Andersen et al., 1990; Van den Kerkhof et al., 2014). Different types of fluid inclusion morphologies are
368 found within the intensely recrystallized quartz domains (Fig. 9f). Negative crystal morphology is observed in some areas of the
369 selected samples, but it is uncommon. More typical is instead the “dismembered” morphology (cf: Vityk and Bodnar, 1995;
370 Tarantola et al., 2010), which is observed in the relatively large inclusions ($> 20 \mu\text{m}$). This morphology is made of a central (often
371 empty) inclusion, showing several tails and re-entrants, surrounded by three-dimensional clusters of small “satellite” inclusions.
372 These clusters might be arranged with a quasi-planar geometry inside the host (i.e. in a trail-like fashion). Another typical texture
373 found in most assemblages is the “scalloped” morphology of small- to medium-sized inclusions ($< 10\text{-}15 \mu\text{m}$), which is defined
374 by the presence of indentations, embayments, irregularities, and sharp tips of the inclusion walls (Fig. 9f). Small inclusions (< 1
375 μm) are also found at the edge of the straight, regular boundaries of new quartz grains; they are mostly dark, i.e. they are vapour-
376 rich or empty, and are equant in shape (Fig. 9e). Although small inclusions do not allow a microthermometric study of the fluid-
377 phase behaviour in this structural domain, they confirm the complex reactivation history of BFZ300.

378 Qtz II contains both pseudosecondary (Type PS) and secondary (Type S4) assemblages (Figs. 9g, i, h). The first type is arranged
379 in trails that cut at low angle the hosting quartz but not the neighbouring phases (e.g. chlorite). In these assemblages, FIs are
380 relatively large (2-45 μm) and exhibit elongated shape and ϕ values between 15 and 30 % (Fig. 9 g). Type S4 FIAs (Fig. 9h) host
381 two-phase inclusions whose size (5-35 μm) is similar to that of PS trails, but show a ϕ between 30 and 40 % (Fig. 9 i).

382 Primary FIAs are also present along growth planes of Qtz II, where they have a relatively large size (20-50 μm ; Figs. S3a, b, c of
383 the Supplementary Material). They present irregular and dismembered textures, which suggest intense post-entrapment re-
384 equilibration.

385 In summary, our microtextural study shows that the FIAs to be selected for the microthermometric study are only those hosted
386 within Qtz I and Qtz II crystals with little to no recrystallization and whose inclusions have textures corresponding to the least

387 intense post-entrapment re-equilibration (Bodnar, 2003b and references therein; Tarantola et al., 2010). These are the
388 pseudosecondary and secondary FIAs in which dendritic or transposed inclusions are absent, and in which the host quartz exhibits
389 only undulose extinction (S1, S2, S4 and PS).

390

391 4.3.2 Microthermometry

392 *Damage Zone:* Secondary FIAs hosted within Qtz I from the damage zone (Type S1) show a range of $T_{m_{ice}}$ between -5.9 and -
393 0.1 °C, which corresponds to a salinity of 0-9 wt% NaCleq (Fig. 10a). In these FIAs, final homogenization ($T_{h_{tot}}$) occurs into the
394 liquid phase (i.e. by disappearance of the vapour bubble) and mainly between 150-400 °C (Fig. 10e).

395 *Fault Core:* The secondary FIAs hosted within Qtz I in the fault core (Type S2) show a range of $T_{m_{ice}}$ between -8.2 and -0.4 °C,
396 which corresponds to salinities between 0 and 14 wt% NaCleq (Fig. 10b), and final homogenization occurs into the liquid phase
397 between 130 and 410 °C (Fig. 10f).

398 Pseudosecondary FIAs entrapped within Qtz II (Type PS) show a range of $T_{m_{ice}}$ between -13.6 and -0.1 °C, which corresponds
399 to a salinity range between 0 and 18 wt% NaCleq (Fig. 10c); final homogenization occurs into the liquid phase and is comprised
400 between 150 and 440 °C (Fig. 10g). Secondary FIAs in Qtz II (Type S4) show a range of $T_{m_{ice}}$ between -11 and 0 °C, which
401 corresponds to a 0-15 wt% NaCleq range of salinity (Fig. 10d), while final homogenization into the liquid phase is comprised
402 between 130 and 430 °C (Fig. 10h).

403 As no gases were determined during microthermometric analysis (i.e. melting of carbonic phase or clathrate hydrates were not
404 detected during the freezing experiments), additional micro Raman analysis was performed on a set of representative FIAs
405 (samples: TPH-120-4; TPH-120-6; PH21; PH22). Aqueous fluid inclusions hosted both by the Qtz I and Qtz II show peaks at the
406 characteristic wavenumbers of CH₄ (2917 cm⁻¹). and CO₂ (1388 cm⁻¹). These peaks were determined as weak in all spectra, and
407 CO₂ detection was sporadic in a few inclusions of only one sample of the fault core (TPH-120-4). Although spectroscopic
408 detections, the CO₂- and CH₄-bearing inclusions are not systematically associated with specific quartz vein generations or
409 microstructures (i.e. intracrystalline healed cracks, WEB's planes, intercrystalline fractures). We cannot therefore associate the
410 presence of CO₂ and/or CH₄ to any specific deformation stage of the fault.

411 Such spectroscopic determinations are consistent with the lack of microthermometric evidence of carbonic phase or clathrate
412 hydrates during the freezing experiments (cf. Rosso and Bodnar, 1995; Dubessy et al., 2001). The impossibility to detect CO₂-
413 and CH₄-bearing fluids during the freezing experiments indicate a gas pressure that is systematically lower than that required to
414 observe clathrate dissociation (e.g., 1.4 MPa in CO₂-H₂O fluids, Rosso and Bodnar, 1995), i.e. it shows low gas concentrations.

415 As a consequence, we have modelled the fluid phases as simple H₂O-NaCl systems..

416 4.4 Chlorite and sulphide geothermometry

417 Chlorite composition has been determined for several generations of chlorites in association with Qtz I and II, namely vermicular
418 chlorite associated with Qtz I from the damage zone, vermicular and radiate chlorite associated with Qtz I from the fault core,

419 and radiate chlorite associated with Qtz II from the fault core (Table 2). Chlorite compositions are shown in Figure 11a and are
420 expressed as function of the Fe/(Fe+Mg) ratio. Chlorite compositional data are presented according to the structural domain of
421 the fault they are associated with and to the corresponding texture. Vermicular chlorite associated with Qtz I in the damage zone
422 has a XFe range between 0.50 and 0.55, while vermicular chlorite associated with Qtz I from the fault core has a XFe of 0.53.
423 Radiate chlorite associated with Qtz I from the fault core has a XFe range between 0.71 and 0.81 while radiate chlorite associated
424 with Qtz II from the fault core is between 0.65 and 0.80, constraining compositions within the ripidolite and aphrusiderite end-
425 members.

426 Temperature-composition relationships for the quartz-chlorite pair portrayed in the T-R²⁺-Si diagram of Bourdelle and
427 Cathelineau (2015) show that, in the hypothesis of quartz-chlorite equilibrium, the precipitation of vermicular chlorite within the
428 Qtz I of the damage zone took place in the 175-240 °C range (green diamonds of Fig. 11a). This range is distinct from that of the
429 vermicular and radiate chlorite from Qtz I of the fault core, which is probably c. 350 °C because the measured R²⁺-Si
430 compositional parameters (R²⁺ = Mg+Fe) plot at the edge of, or slightly outside, the calibrated region of the Bourdelle and
431 Cathelineau plot (red diamonds of Fig. 11a). We stress that the high-T chlorite plots parallel to the 350 °C isotherm, suggesting
432 that it precipitated most probably at the same, or at a similar, temperature. Radiate chlorite associated with Qtz II from the fault
433 core is instead compatible with an equilibrium precipitation at 160-220 °C (light-blue diamonds in Fig. 11a).

434 The collected EPMA data show that the sulphides associated with Qtz II have compositions that approach those of pure phases
435 (Table 3). Pyrite has trace element concentrations (Cu, As, Pb, Ni, Zn) that are in general below the EPMA detection limit, while
436 galena, sphalerite, and chalcopyrite show only some significant trace contents of Fe and Zn (e.g., Fe: 0.22-1.00 wt% in galena;
437 Zn: 0.11-3.95 wt% in chalcopyrite). Pyrite and sphalerite from the Qtz II veins (Fig. 7e) have trace element concentrations that
438 are, again, mostly below detection limits.

439 The stylolites bordering the cataclasite bands described above and formed at the contact between the Qtz I and Qtz II vein contain
440 pyrite, galena, and the sphalerite-stannite pair (Figs. 8a, c, d), with the latter showing the largest compositional variation. This
441 pair represents a mineral geothermometer because the partitioning of Zn and Fe between sphalerite and stannite was demonstrated
442 to be temperature dependent but pressure independent (Nekrasov et al., 1979; Shimizu and Shikazono, 1985). In the fourteen
443 analysed pairs, stannite shows a range of Zn concentrations varying between 0.48 wt% and 3.25 wt%, while those of Fe, Cu and
444 Sn vary within narrow ranges (Fe: 12.74±0.56 wt%; Cu: 28.30 ±0.33 wt%; Sn: 27.65 ±0.71 wt%). Sphalerite in the pair has
445 concentrations of Fe and Zn of 7.63±0.87 wt% and 56.68 ±1.17 wt%, respectively. These ranges allow the calculation of the
446 partition coefficient (K_D) of the reaction: Cu₂FeSnS₄ (in stannite) + ZnS (in sphalerite) = Cu₂ZnSnS₄ (in stannite) + FeS (in
447 sphalerite). We have used the logK_D-T relationship of Shimizu and Shikazono (1985) to calculate the formation temperature of
448 the pair, which is portrayed in the (X_{Cu₂FeSnS₄}/X_{Cu₂ZnSnS₄})-(X_{FeS}/X_{ZnS}) plot of Shimizu and Shikazono (Fig. 11b). The resulting 220-
449 305 °C interval lies at the low end of, or slightly outside, the 250-350 °C interval of the geothermometer.

450 Therefore, we consider the 250-305 °C interval as the best estimation of the formation T of sphalerite-stannite in the stylolite.

451

452 **5 Discussion**

453 Our work constrains the architecture and the environmental conditions at which BFZ300 deformation took place. Field and
454 petrographic observations support the idea of transiently elevated fluid pressures, cyclic frictional-viscous deformation and
455 progressive, yet discrete strain localization (Figs. 2, 3). Analytical data suggest that these deformation cycles took place at the
456 BDTZ. In the following, we discuss these constraints by systematically considering our different analytical results.

457 **5.1. Fluid inclusion data and mineral-pair geothermometry**

458 Field evidence combined with microstructural observations, fluid inclusion analyses and the documented distinct generations of
459 synkinematic chlorites confirm that Qtz I and Qtz II veins precipitated from distinct batches of aqueous fluid (i.e. H₂O-NaCl),
460 that ingressed the fault zone during different stages of its evolution.

461 We documented a wide range of bulk salinity for each FIAs entrapped within the quartz veins in each structural domain (Figs.
462 10a-d). This suggests post-entrapment re-equilibration of fluid inclusions (cf. Bakker and Jansen, 1990; Diamond et al., 2010).
463 The T_{hot} varies between c. 130 and 440 °C without a clear mode or a skew (Figs. 10eh) indicating that no common range of
464 entrapment temperature can be identified in the dataset. Therefore, we conclude that even the properties of petrographically intact
465 FIAs do not correspond to chemically well-preserved assemblages. Indeed, the ranges of T_{hot} in individual FIAs are typically of
466 the order of 150-200 °C (Figs. 10e-h), i.e. a value that is much higher than the ~10 °C range expected for homogeneous FIAs
467 entrapped isochorically and isoplethically (Fall et al., 2009; Vityk and Bodnar, 1998) and that demonstrates post-entrapment re-
468 equilibration (cf. Vityk and Bodnar, 1998; Bodnar, 2003b; Sterner and Bodnar, 1989; Invernizzi et al., 1998). A major implication
469 of fluid inclusion re-equilibration in our study is that the calculated fluid properties do not rigorously reflect those of the pristine
470 fluid originally entrapped within BFZ300, but rather that of a fluid that modified its properties during the fault activity.

471 Then, a possible approach to interpret our FI dataset is the comparison with the experimental work on synthetic fluid inclusions
472 subjected to a range of post-entrapment re-equilibration conditions (Bakker, 2017; Bakker and Jansen, 1990, 1991, 1994; Vityk
473 and Bodnar, 1995, 1998; Vityk et al., 1994; Invernizzi et al., 1998). A straight comparison to the experiments is in our case
474 difficult because most experimental work was carried out at high TP conditions (500-900 °C; 90-300 MPa) and also only few
475 experiments were carried out under deviatoric stress conditions that approach those of natural rocks (Diamond et al., 2010;
476 Tarantola et al., 2010). Despite these limitations, however, some key experimental results provide fundamental constraints on our
477 dataset. First, both hydrostatic and uniaxial compression experiments showed that in each re-equilibrated FIA a number of
478 inclusions survive virtually intact the modified post-entrapment PT conditions, showing that only severe deformation brings to
479 total re-equilibration and complete obliteration of pristine inclusions (i.e., $\Delta\sigma > 100$ MPa in uniaxial compression experiments;
480 > 400 MPa change of confining P in hydrostatic experiments). Second, under conditions leading to only low to moderate re-
481 equilibration, the bulk chemical composition of the fluid inclusions does not change significantly from that of the pristine
482 inclusions.

483 All of this implies that natural quartz samples with microstructures typical of moderate T deformation, such as deformation
484 lamellae, deformation bands, undulose extinction and bulging, and hosting FIAs with moderately re-equilibrated textures, should
485 still contain a number of inclusions whose properties resemble those of the pristine fluid. In this scenario, our microthermometric
486 dataset can be used to constrain the more probable salinity ranges of the fluid batches which trigger BZ300 reactivation stages.
487 Two possible interpretations of the microthermometric dataset can be follow and we can give accordingly different salinity ranges
488 for the fluids.

489 One possibility is that the different quartz veins and the fluids trapped within fluid inclusions originated from multiple pulses of
490 a single, low salinity fluid, with a salinity between 0 and 7 wt%NaCleq, as shown by the distribution of >70% of the bulk salinities
491 skewed towards values of 7 wt% NaCleq or less (Fig. 10a-d). Thus, it is possible that aliquots of the 0-7 wt% NaCleq FIAs from
492 Qtz I and II crystals from both the damage zone and fault core is still representative of the pristine sampled fluid. These inclusions
493 would be those that survived or were relatively less affected by deformation events postdating their entrapment. Inclusions falling
494 outside the most typical 0-7wt% NaCleq salinity range would instead correspond to those which progressively modified their
495 properties as a consequence of fluid-rock interaction during faulting and that experienced significant H₂O loss and consequent
496 salinity increase during the successive stages of fault deformation (cf. Bakker and Jansen, 1990; Diamond et al., 2010). The large
497 documented range of Th_{tot} lacking a specific mode observed in individual FIAs is the product of fluid density changes caused by
498 fluid inclusion re-equilibration during post-entrapment deformation. This would have happened repeatedly and cyclically within
499 the host quartz during all ductile and brittle stages of deformation of the multi-stage deformation history of BFZ300.

500 Alternatively, multiple batches of fluids with different salinities (from low to intermediate salinity) may have ingressed and
501 evolved within BFZ300 during its activity. In fact, considering the salinity dataset presented for each structural domain, fluid
502 salinity can be seen clustering in restricted ranges typical for each domain: 1) the salinity of 60% of secondary fluid inclusions in
503 Qtz I from the damage zone is between 0 and 1 wt%NaCleq; 2) > 80% of the secondary inclusions in Qtz I from the fault core
504 preserve a salinity in the 1 to 5 range wt%NaCleq; 3) 75% of pseudosecondary inclusions in Qtz II show salinity values between
505 6 and 11 wt%NaCleq and 4) ~70% of the secondary inclusions trapped within Qtz II show salinity values between 0 and 3
506 wt%NaCleq. These clusters may best represent the original compositional ranges of different batches of fluids, each involved
507 during a different faulting stage. Salinities outside these clusters may instead be explained again as resulting from the post-
508 entrapment re-equilibration of those fluids with different salinities. This hypothetical scenario, in which chemically distinct fluids
509 ingressing the fault and interacting with the rock at different times (e.g. Selverstone et al., 1992; Boiron et al., 2003; Famin et al.,
510 2005) is also reinforced by several lines of observation such as: the variation of chlorite composition, the slight change in
511 paragenesis/redox state with Qtz II and Qtz I (i.e. the absence of massive sulphides in Qtz I) and by the prolonged history of
512 faulting (see below).

513 Fully aware of the interpretative uncertainties of our dataset, we have combined the microthermometric data of the studied FIAs
514 with the independent quartz-chlorite and sphalerite-stannite geothermometers to constrain the most probable fluid pressure during
515 the faulting events. With this approach, we use the formation temperatures of the mineral pairs as independent geothermometers
516 and consider the intersection between these values and the FIA isochores to derive the ranges of trapping pressure (cf. Roedder

517 and Bodnar, 1980). In Figure 12, we present the ranges of the possible pressure (P_f) of the fluids involved during faulting as
518 calculated by combining the fluid inclusion data with the constraints provided by the pair-mineral geothermometry and the hydro-
519 and lithostatic pressure gradients and a possible geothermal gradient (e.g. Van Noten et al., 2011; Selverstone et al., 1995; Jaques
520 and Pascal, 2017). The reconstructed regional gradients at the time of vein emplacement are derived from peak metamorphic
521 conditions (4-5 kbar; 650-700 °C leading to c. 40 °C/km; from Kärki and Paulamäki, 2006). Hydrostatic and lithostatic pressures
522 are then calculated by using pure water density and assuming a rock density of 2700 kgm⁻³, respectively. These gradients are used
523 to constrain the upper and lower bounds to physically possible fluid pressures. We computed the maximum and minimum
524 isochores by using the entire salinity and Th_{tot} ranges obtained from the FIAs in each structural domain (Fig. 10). We also
525 computed the isochores of the inclusions with the most representative salinity estimates for each structural domain obtained by
526 comparing the frequency diagrams (Fig. 10) with the Th_{tot} vs. salinity plots (Supplementary Material Fig. S4). Considering the
527 peak temperature of each structural zone from the geothermometric estimations in combination with the computed isochores, the
528 estimated peak conditions of the fluid pressure are: 1) 80 MPa for Qtz I from the damage zone, 2) 210 MPa for Qtz I from the
529 fault core; 3) 140 MPa from pseudosecondary inclusions in Qtz II from the core and 4) 180 MPa from secondary inclusions in
530 Qtz II, still from the core (Fig. 12; Table 1).

531 In addition to the P_f peak conditions we can also constrain the physically possible fluid pressure ranges for each stage of fluid
532 ingress, which are derived by considering the temperature range estimated for each structural domain. Thus, for the damage zone,
533 a P_f interval of 50-80 MPa (Fig. 12a) can be derived by intersecting the range of T obtained from the chlorite-quartz pair in the
534 Qtz I from the damage zone with the range of isochores from the same quartz. As to the fault core, we combine the 350 °C
535 constraint from the chlorite-quartz pair from Qtz I in the fault core with the isochores from the same quartz, which yields P_f
536 between c. 30 and 210 MPa (Fig. 12b). Similarly, the intersection between the equilibrium T of the sphalerite-stannite pair in the
537 Qtz II from the fault core and the range of isochores of the pseudosecondary FIAs of Qtz II defines P_f values between 50 and 140
538 MPa (Fig. 12c). Estimations from secondary FIAs in Qtz II constrain a range between 40 and 180 MPa (Fig. 12d).

539 As also supported by the microstructures described above, we propose that these values are sufficiently accurate to constrain at
540 least four stages of fault reactivation, each triggered by a fluid with distinct physical and compositional properties.

541 As shown by the T vs. P plots of Figure 12, the secondary FIAs entrapped in Qtz I from the damage zone constrain the lowest
542 value of P_f (i.e. 50-80 MPa) of the entire dataset. We interpret this not as representative of the early BFZ300 localization, but
543 rather as possibly resulting from fluid entrapment during a later stage of fault reactivation at T ~200 °C. This is also consistent
544 with the calculated temperature of crystallization of the vermicular chlorite associated with Qtz I from the damage zone (175-240
545 °C, Fig. 11b) and with the secondary nature of the entrapped FIAs. Also, the most abundant salinities observed in the Qtz I from
546 the damage zone (0-1 wt%NaCleq) coincide with the lowest Th_{tot} measured in the same structural domain. Later fracturing of Qtz
547 I in the damage zone may thus have been coeval with the formation of vermicular chlorite preserved therein, which is found along
548 secondary cracks and median lines (Fig. 5d).

549 In light of these considerations, we propose that initial BFZ300 localization occurred in the presence of a fluid with T and P of at
550 least 350 °C and 210 MPa, respectively. Later faulting continued by cyclic brittle-ductile switches induced and assisted by fluid
551 batches at progressively lower temperature and pressure.

552 **5.2. Structural evolution and fluid flow: a conceptual model**

553 Based on the integration of field, microstructural, thermometric and fluid inclusions constraints (Table 1), we propose a
554 conceptual model for the structural evolution of BFZ300 (Fig. 13). The fault's finite strain results from several slip episodes
555 mediated by multiple events of fluid ingress and fluid-rock interaction. A first constraint provided by our study is that the analysis
556 of the bulk chemical composition of the fluids that cyclically ingressed the fault suggests the likely presence of several batches
557 of fluids of varying salinity and composition.

558 The embrittlement of the Olkiluoto metamorphic basement (time t_1 of Figs. 13a, b) represents the initial stage of the deformational
559 history of BFZ300, when conditions for brittle dilation and fracturing of the Paleoproterozoic basement were first met in a
560 transient fashion. We propose that brittle failure under still ductile environmental conditions was caused by transiently elevated
561 P_f (> 210 MPa), as also demonstrated by field evidence of hydrofracturing (pure tensional en echelon veins at the BDTZ depth).
562 Hydrofracturing of the host basement is also indicated by the emplacement of Qtz I veins within the diffuse network of joints and
563 conjugate hybrid/shear fractures of the damage zone (Figs. 13a, 3a, b). These brittle features are quite broadly distributed
564 suggesting an initial volumetrically diffuse strain distribution. Their formation caused the overall mechanical weakening of the
565 host rock volume, which in turn facilitated later strain localization. Brittle structures formed during this stage are discordant to
566 the ENE-WSW striking metamorphic foliation (Fig. 1b), which they cut at high angle (Fig. 13a). Conditions for tensional and
567 hybrid failure require low differential stress, i.e. $\sigma_1 - \sigma_3 \sim 4T$, where T is the tensional strength of the rock. Opening of fractures
568 caused a stress drop, sudden increase of permeability, fluid venting and inhibited further build-up of P_f . Dilatant fractures were
569 partially infilled by Qtz I, which precipitated from a first fluid, with inferred low salinity (in the range between 1 and 5
570 wt%NaCleq). Precipitation of Qtz I and formation of veins within these fractures caused hardening of the system. The progressive
571 recovery of shear stresses altered the overall background stress conditions such that failure, after causing initial pure dilation, was
572 later accommodated by hybrid extensional - and, eventually, by shear fracturing (Fig. 13b), thus forming laterally continuous and
573 interconnected shear fractures associated with breccia pockets and cataclasites (Figs. 3d, g, i). Conjugate shear fractures connected
574 the previously formed extensional fractures through fracture coalescence (e.g. Griffith, 1921; Sibson, 1996; Fig. 13a). At the
575 micro-scale this is demonstrated by the elongated blocky texture of Qtz I crystals from the damage zone (Figs. 4c and 5a), where
576 crystals grew at high angle to the vein boundaries (thus suggesting initial near-orthogonal dilation) and are physically connected
577 by cataclastic shear bands to form a fault-fracture mesh (e.g. Sibson, 1996). Cataclastic bands formed at the expense of the
578 migmatitic host rock are enriched in authigenic, synkinematic sericite, likely due to the interaction between K-feldspar and fluids
579 circulating in the dilatant fault zone (Fig. 4b). Shear fractures thus deformed the migmatitic host rock to connect dilatant and
580 mostly Qtz I-filled tension gashes during a continuum of deformation. The conjugate shear fractures ascribable to this stage

581 invariably define tight acute angles (Figs. 2b, 3a), which we take as further evidence of overall low differential stress conditions
582 at the time of failure (Fig. 13b).

583 In synthesis, Qtz I veins from the damage zone are interpreted as the expression of the earliest stage of fault nucleation, before
584 strain localization affected a progressively narrower rock volume to eventually form the main fault core. Indeed, the meso- and
585 microscale features observed in Qtz I-damage zone, lacking of pervasive crystal-plastic deformation as otherwise occurred in Qtz
586 I-fault core, are used to document the initial stage of embrittlement. Based on geometric, kinematic and deformation style
587 characteristics, we tentatively assign this deformation episode to Stage 1 by Mattila and Viola (2014, their Fig. 18), i.e. to a
588 discrete brittle episode considered the expression of the earliest onset of brittle conditions in southwestern Finland c. 1.75 Ga ago,
589 under overall NW-SE to NNW-SSE transpressive conditions.

590 Further deformation of the BFZ300 (time t_2 of Fig. 13c) occurred by progressive inward strain localization and narrowing of the
591 actively deforming volume of the deformation zone (from a wide damage zone to a narrow fault core). The early BFZ300 core,
592 consisting of the main Qtz I vein is interpreted as having formed at this stage, within an overall dextral strike-slip kinematic
593 framework. Emplacement of the Qtz I vein in the core represents the last pulse of this brittle deformational episode (Fig. 13b).
594 Major fluid venting was likely associated with it, such that the system, once brittle failure in the core had occurred by
595 hydrofracturing, moved back to a more diffuse deformation style typical of the still prevailing ductile conditions. Microscopic
596 evidence of crystal-plastic deformation and dynamic recrystallization (Figs. 6a, b; Table 1) overprinting the early brittle structures
597 of Qtz I in the fault core supports slow strain rate conditions during deformation. However, this ductile background deformation
598 was punctuated by renewed and cyclically transient embrittlement as documented by healed fractures shown by trails of secondary
599 fluid inclusions cutting across both the ductile fabrics and the earlier brittle deformational features (Figs. 6c, S2a, b). EBSD
600 analysis of the new grains documented along healed microcracks also suggests that they likely nucleated from fluids circulating
601 in the early fractures before being later deformed in the low-temperature plasticity regime. Thus, we show that at the BDTZ
602 ‘neocrystallisation’ by nucleation and growth in fractured fragments and dynamic recrystallisation (typically by bulging and
603 subgrain rotation) coexist and compete in the overall microstructural evolution of quartz (e.g. Kjøl et al., 2015). Repeated fluid
604 ingresses and related deformation would, in addition, also have caused some of the post-entrapment equilibration of the FI, as
605 discussed above.

606 Mattila and Viola (2014) described a second brittle stage (referred to as Stage 2, their Fig. 18) during which a c. N-S to NNE-
607 SSW-oriented episode of transpressional deformation affected southwestern Finland. Geometric and temporal relationships
608 between structures of Stages 1 and 2 (see also Viola et al., 2009) were used to infer a clockwise rotation of the horizontal
609 compression direction from NW-SE (Stage 1) to NNE-SSW (Stage 2). Consistent with the kinematic framework of Stage 2, we
610 propose here that during progressive regional exhumation and cooling to entirely brittle conditions, the BFZ300 deformation
611 continued through a further, distinct deformation phase (t_3 of Fig. 13e). This stage accommodated the selective reactivation of the
612 BFZ300 core, with renewed dilation due to the rotated σ_1 during Stage 2 acting subparallel to the strike of the Qtz I vein in the
613 BFZ300 core. Localised dilation in a still fluid-rich system allowed the emplacement of the Qtz II vein (Fig. 13e). Our estimations
614 indicate peak conditions of P_f 140 MPa and $T \approx 305^\circ$ C. The BFZ300 core was reactivated by an intermediate salinity fluid (in

615 the range between 6 and 11 wt%NaCleq) under overall hybrid conditions (Fig. 13f), as suggested by the irregular thickness and
616 curved geometry of the Qtz II vein therein, and by the synkinematic chlorite crystals that are stretched orthogonally to the vein
617 boundaries (Fig. 3h). The Qtz II vein invariably localized along at the contact between Qtz I and the host rock (Figs. 3f, 13e)
618 suggesting selective reactivation along the pre-existing principal slip zones, which represented the weakest part of the fault (Fig.
619 13h). Evidence for mesoscale hybrid fracturing and our P_f estimates (Fig. 12) suggest that P_f was lower than that of the earlier
620 deformation stages during Qtz I emplacement.

621 BFZ300 underwent one or more events of brittle fracturing and induration (Fig. 13g), as suggested by the CL imaging of Qtz II
622 crystals (Fig. 7c). The fluid pressure peak value for this structural stage is c. 180 MPa.

623 A possible, very late reactivation stage of unknown age is also documented by the secondary chlorite associated with Qtz I in the
624 damage zone (Figs. 5a, d). Also, the stylolitic seams striking parallel to BFZ300 fault zone suggest compression oriented c. E-W,
625 i.e. subparallel to the inferred Sveconorwegian main shortening direction (e.g., Viola et al., 2011). The sphalerite-stannite mineral
626 pairs arranged along these structures were possibly concentrated through a pressure-solution during this deformational stage.

627 Skyttä and Torvela (2018) proposed that the BFZ300 is a brittle structure localized onto a zone of incomplete structural
628 transposition inherited from the earlier ductile history of the Oikiluoto basement. However, in our mesoscale and microstructural
629 analysis we did not find evidence of any ductile precursor, and we note that BFZ300 cuts the ductile structural grain at high angle,
630 which excludes any reactivation of precursor ductile fabrics.

631 **5.3. Implications for seismic deformation at the base of the BDTZ**

632 This study demonstrates the role of overpressured fluids on strain localisation during the incipient stages of fault nucleation and
633 subsequent reactivation(s) at the BDTZ. The maximum estimated fluid pressure and fluid temperature conditions derived in this
634 study (peak conditions of 210 MPa and 350 °C) are indeed realistic for the base of the seismogenic zone in the continental
635 lithosphere (e.g., Scholz, 1990, and references therein) where the brittle-ductile transition for quartz occurs.

636 Mechanical models of long-term deformation (Rolandone and Jaupart, 2002) propose that deformation at the brittle-ductile
637 transition can be reasonably described as being mostly accommodated by intermittent and concomitant coseismic slip and ductile
638 flow. Hydrofracturing, as that documented in this study by the Qtz I and II veins, is possibly related in that context to seismic
639 failure. Faults accommodating hydrofracturing are indeed commonly interpreted as seismogenic (e.g. Sibson, 1992a; Cox, 1995)
640 particularly at depth.

641 Our study confirms this view because BFZ300 contains not only brittle fault rocks overprinting and overprinted by veins, but also
642 clearcut evidence of mutually overprinting brittle and ductile deformation (Fig. 6). In light of the field observations discussed and
643 of the constraints derived, we suggest therefore that BFZ300 behaved in a seismic way at least during the emplacement of the
644 principal Qtz I and Qtz II veins. In this perspective, two possible scenarios can be considered to explain the genetic relationships
645 between BFZ300 and a possible seismic behaviour of the crust during the Svecofennian orogeny. In a first scenario, the quartz
646 veins of the fault core would represent the result of coseismic rupture during the mainshocks of a fully developed seismic cycle.

647 Pore pressure fluctuations caused the repeated transient embrittlement of the rock mass, which was otherwise under overall ductile
648 conditions. The documented brittle-ductile cycles are thus the expression of coseismic fracturing and aseismic creep between the
649 individual shocks, as shown by viscous deformation overprinting the brittle features, guided by the residual differential stress.
650 A second possibility is that faulting occurred in the absence of a well-defined sequence of main- and aftershocks. As in the case
651 of man-induced earthquakes triggered by high-pressure fluids during injection of fluids (e.g. Healy et al., 1968), where
652 deformation is typically accommodated by diffuse swarms of low magnitude seismicity rather than well-defined mainshock-
653 aftershock sequences (Cox, 2016), we propose that BFZ300 might have localised strain by diffuse veining with crack and seal
654 textures (Cox, 2016). Breccias and cataclasites (Figs. 3, 8) mutually overprinting with veins show that failure and veining were
655 indeed broadly coeval (e.g. Cox, 1995; Cox, 2016). Healing in fluid-rich environments can occur over short periods of time (days-
656 months) when compared with recurrence time of large earthquakes (10-100 years) (Olsen et al., 1998; Tenthorey and Cox, 2006).
657 Therefore, the documented repeated switches between brittle and ductile deformations would then be steered again by transient
658 episodes of fluid overpressuring but in this case would express the accommodation of swarms of minor background earthquakes
659 within overall ductile conditions.
660 Microstructures of fault-rocks exhumed from the brittle-ductile transition in other geological settings, are mostly in agreement
661 with our hypotheses of seismic deformation. Transient and short term high-stress deformation followed by phases of stress
662 relaxation, which is prevalently characterized by recovery and recrystallization processes, has been documented by several
663 authors in deformed quartz (Trepmann and Stöckhert, 2003; Trepmann et al., 2007; Bestmann et al., 2012; Trepmann and
664 Stöckhert, 2013; Trepmann et al., 2017).

665 **6 Conclusions**

666 This study shows that a multi-scale and multi-technique approach leading to the generation of independent constraints offers the
667 potential to reconstruct in detail the evolutionary history of also fault zones that have experienced multiple events of reactivation
668 triggered by fluid overpressure and in which intense fluid-rock re-equilibration processes have taken place. We document the
669 localised, initial embrittlement of the Paleoproterozoic basement of southwestern Finland at the BDTZ, which occurred by brittle
670 failure under overall ductile conditions in response to transiently high fluid pressure and temperature (peak conditions: $P_f > 210$
671 MPa; $T \sim 350$ °C). Our results further constrain the importance of cyclic seismicity and fluids in the fragmentation of Precambrian
672 cratons when deformed at the BDTZ, something that is not yet that well understood for the Fennoscandian Shield. Our study,
673 moreover, provides potentially important inputs to many modern geological applications, including site characterization of deep
674 geological disposal facilities for spent nuclear fuel. Results from the detailed geological characterization of faults at the Olkiluoto
675 site can thus be used toward the continuous updating of the geological site description and yield further constraints on the
676 mechanics of faulting at the BDTZ.

677

678

679 ACKNOWLEDGMENTS

680 This research was funded by Posiva Oy. We thank Oliver Vanderhaeghe and two anonymous reviewers for their constructive
681 reviews, which led to a greatly improved manuscript. Stephen F. Cox, Michael Stipp and Alfons M. Van den Kerkhof are all
682 warmly thanked for fruitful discussions during the early stages of this work. Danilo Bersani and Andrea Risplendente are also
683 thanked for their help with the Raman and SEM analyses.

934

935 Figure 1. (a) Simplified geological map of southwestern Finland modified after Mattila and Viola (2014). (b) Geological sketch of the Olkiluoto
 936 Island. The upper right inset shows the poles to foliation planes measured from all available Olkiluoto drill cores (N = 4479, equal area, lower
 937 hemisphere projection; Mattila and Viola, 2014). The lower left inset is a panoramic photograph with an overlay drawing of the underground
 938 infrastructure (photo courtesy of Posiva Oy, Finland). The red circle shows the depth location of BFZ300. Coordinates are given in the local
 939 KKKJ1 coordinate system.

940

941 Figure 2. (a) View to the north and interpretation of the structural elements of BFZ300. (b) Lower-hemisphere, equiangular projection of
 942 conjugate fault segments (blue great circles: dextral faults; red great circles: sinistral faults), cleavage (green great circles) and Qtz I-chlorite
 943 veins infilling joints (black great circles). (c) Slickensides (white dashed line) and slickenlines (black dashed lines) on a chlorite-decorated, NW-
 944 SE striking fracture plane at the vein-host interface indicating dextral strike-slip kinematics.

946 Figure 3. BFZ300 architecture with examples of representative structural features. The red rectangles locate the areas where detailed outcrop
947 photos were taken. Stars locate hand and drill core samples. Stars with a black outline identify samples used for the microthermometric study.
948 Note that the fault is made of two main segments offset laterally at a sinistral compressive step-over zone. Fault core quartz veins are shown by
949 thicker black lines in the schematic model (centre of figure), while blue and white lines highlight the positions of the two types of quartz veins
950 in the outcrop pictures. (a) Damage zone made of mm-thick, en-echelon veins connected by conjugate shear segments. (b) Detail of (a) showing
951 fractures filled by the first quartz generation (Qtz I). (c) Two distinct generations of quartz-chlorite veins recognised in the fault core (Qtz I and
952 Qtz II). (d) Detail of the sinistral compressional step-over zone characterized by multiple and parallel T fractures, filled by Qtz I. A brecciated
953 body is crosscut by the Y planes. (e) Tensional fracture infilled by Qtz I. (f) Compressional structures (P shears) from the step-over zone and
954 relationships between Qtz I and Qtz II. The Riedel geometry suggests that the Qtz II vein formed due to the reactivation of the internal principal
955 slip zones (Y_{II}). Note the Qtz II vein cutting the Qtz I vein. (g) Juxtaposed Qtz I and Qtz II veins. Qtz I veins are thinner and made of a translucent,
956 small grained quartz. In contrast, Qtz II veins, which contain pockets of sulphide aggregates, are thicker and made of larger and euhedral quartz.
957 Chlorite occurs as minor phase in both veins. Notice the presence of a cataclastic band between the two veins. (h) Spatial continuity of the
958 chlorite aggregates within the Qtz II veins, which grow always orthogonal to the vein boundaries. This open space filling texture suggests hybrid
959 conditions of reactivation of the older Qtz I veins. (i) Small quartz breccia formed between the two generations of quartz veins.

960

961 Figure 4. Microtextural characteristics of Qtz I from the damage zone of BFZ300 (sample: TPH-120-2). (a) Stacked photomicrographs of a Qtz
 962 I vein interconnecting with a sinistral shear band (crossed nicols). Faulting kinematics is suggested by drag folds in the host rock. (b) Tip of Qtz
 963 I vein hosted by a sericite-rich cataclastic band of the host rock. (c) Detail of panel a showing open-space filling texture in the Qtz I vein. Notice
 964 the sericite microfractures crosscutting Qtz I. (d) Panchromatic cathodoluminescence image of Qtz I showing healed microfractures crosscutting
 965 the crystal.

968

969 Figure 5. Microtextural characteristics of Qtz I from the damage zone of BFZ300 (samples PH21 and TPH-120 2). (a) Stacked microphotographs
970 of a Qtz I vein showing elongate-blocky texture with crystals growing obliquely with respect to the vein boundaries, which suggests growth
971 under oblique dilatation. A series of median lines (ML) are marked by (b) sericite crystals suggesting repeated crack-and-seal. Quartz crystals
972 show low temperature crystal-plastic deformation by undulose extinction and extinction bands. (c) Detail of plastic deformation in damage zone
973 quartz veins: distorted crystals showing incipient bulging and intracrystalline fracturing. (d) Detail (plane polarized light) of a ML and secondary
974 fractures both decorated by vermicular chlorite and aggregates of REE-bearing carbonate.
975

976
 977 Figure 6. Microtextural characteristics of Qtz I from the BFZ300 core (sample TPH-120-4). (a) Stacked photomicrographs showing the typical
 978 heterogeneous grain size of Qtz I (30-800 μm). (b) Evidence of plastic deformation of Qtz I from the fault core given by bulging of the largest
 979 crystals, wide extinction bands and undulose extinction. Note the late brittle fractures crosscutting all the previously formed plastic features. (c)
 980 Intracrystalline deformation bands within a large crystal. (d) Detail of (c) showing the typical grain size of the band (50-250 μm). Intracrystalline
 981 deformation bands are oriented at $<30^\circ$ with respect to the BFZ300 vein walls and can be up to 2 mm in length. (e) Intercrystalline deformation
 982 band showing a thickening at the triple junction of larger grains. These intercrystalline bands are parallel to the strike of BFZ300.

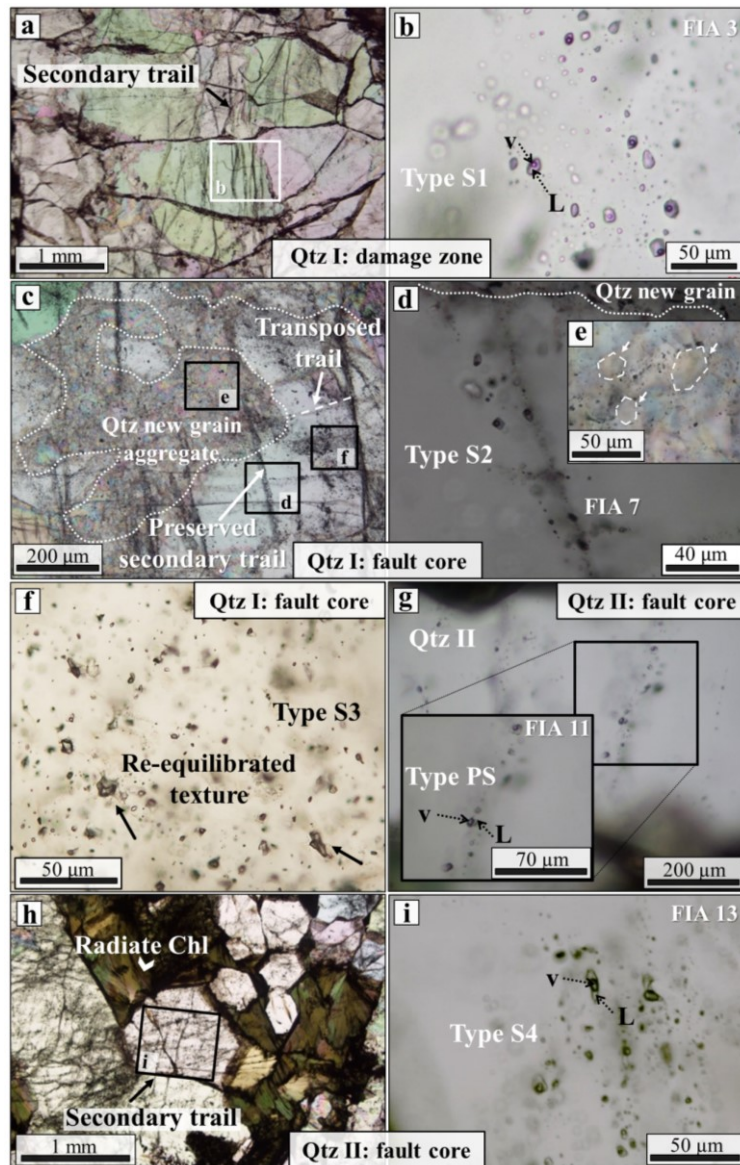

983

984 Figure 7. Microstructural characteristics of Qtz II from BFZ300 (samples TPH-120-6, PH22). (a) Stacked photomicrographs of Qtz II vein from
 985 the fault core. Notice the coarse quartz crystals and their elongated-blocky texture. Primary growth textures are sometimes visible and are marked
 986 by solid inclusions and decapitated FIAs. (b) Radiate chlorite crystals along a prismatic Qtz II crystal boundary. Note that Qtz II is crosscut by
 987 numerous trails of FIAs. (c) Panchromatic cathodoluminescence image of the same large Qtz II crystal from panel b, showing radiate chlorite
 988 along the crystal boundary and a primary growth zone cut by a set of healed fractures. (d) Euhedral quartz crystals set within opaque phases and
 989 crosscut by a network of thin microfractures. (e) Reflected light photomicrograph showing the opaque mineral assemblage typically associated
 990 with Qtz II, i.e. subhedral to anhedral sphalerite, pyrite, and galena. Chalcopyrite is a minor phase and occurs as small round inclusions within
 991 sphalerite (chalcopyrite “disease”) or as large subhedral/anhedral masses together with galena.

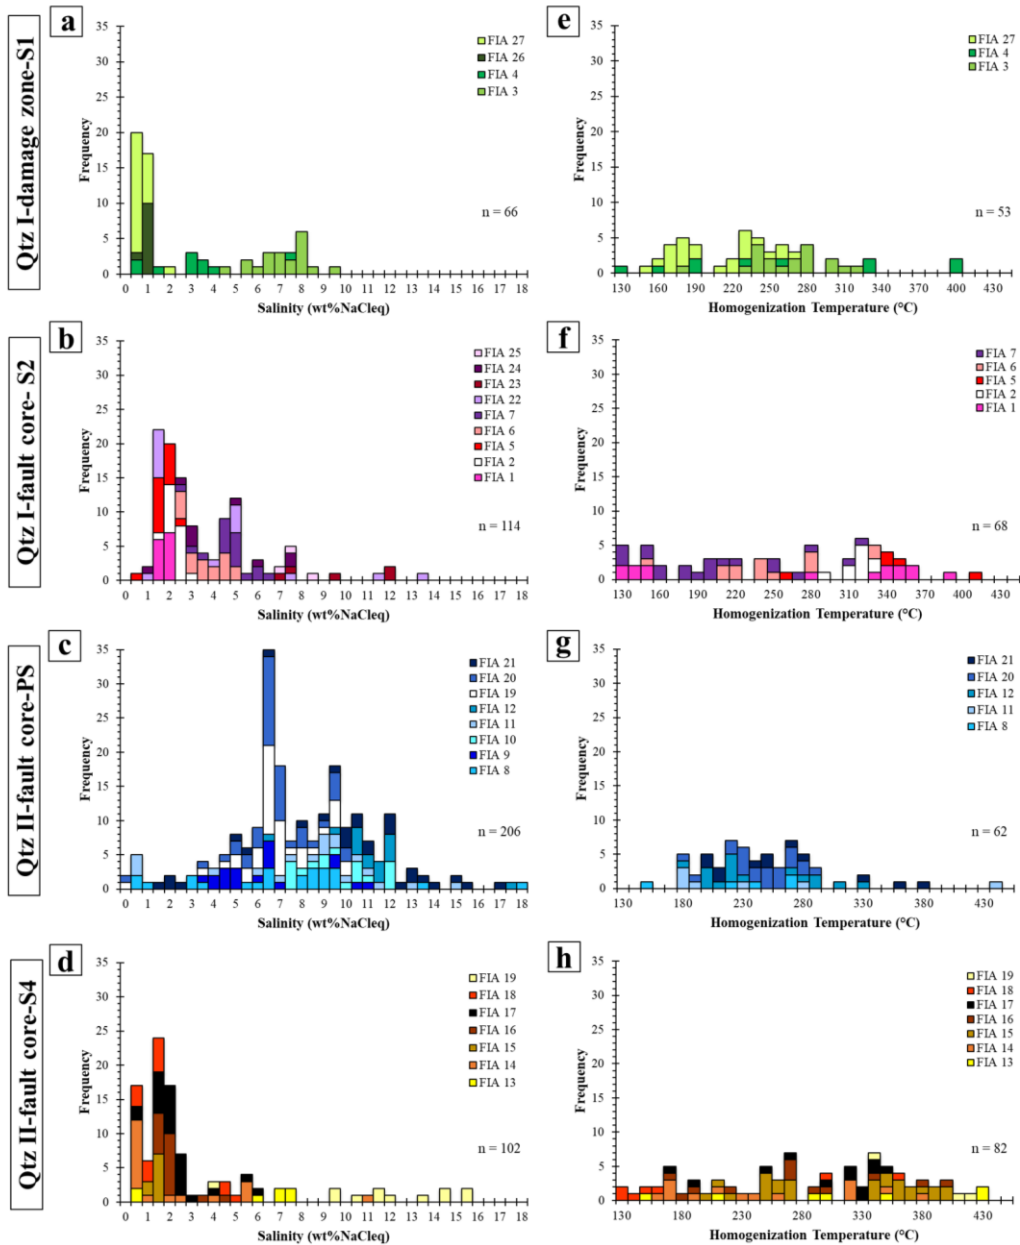

992

993 Figure 8. Microstructures of the cataclasite juxtaposing Qtz I and Qtz II veins (sample TPH-120-4). (a) Stacked photomicrographs covering the
 994 contact between the two quartz veins and the intervening 5 mm-thick cataclastic band. (b) Cataclastic band containing large Qtz I fragments (8-
 995 12 mm) embedded within a finer matrix (20-200 μm in size) of sericite and recrystallized quartz. The largest crystals show lobate boundaries,
 996 suggesting dissolution and local resorption along the clast-matrix interface. (c) Stylolite seams at the boundary of the cataclasite that strike
 997 parallel to the BFZ300. (d) Reflected-light photomicrograph showing anhedral to subhedral pyrite, chalcopyrite, stannite, and sphalerite arranged
 998 along the stylolite as residual products of pressure solution. (e) Vermicular and radiate (f) chlorite aggregates associated with Qtz I close to the
 999 cataclastic band.

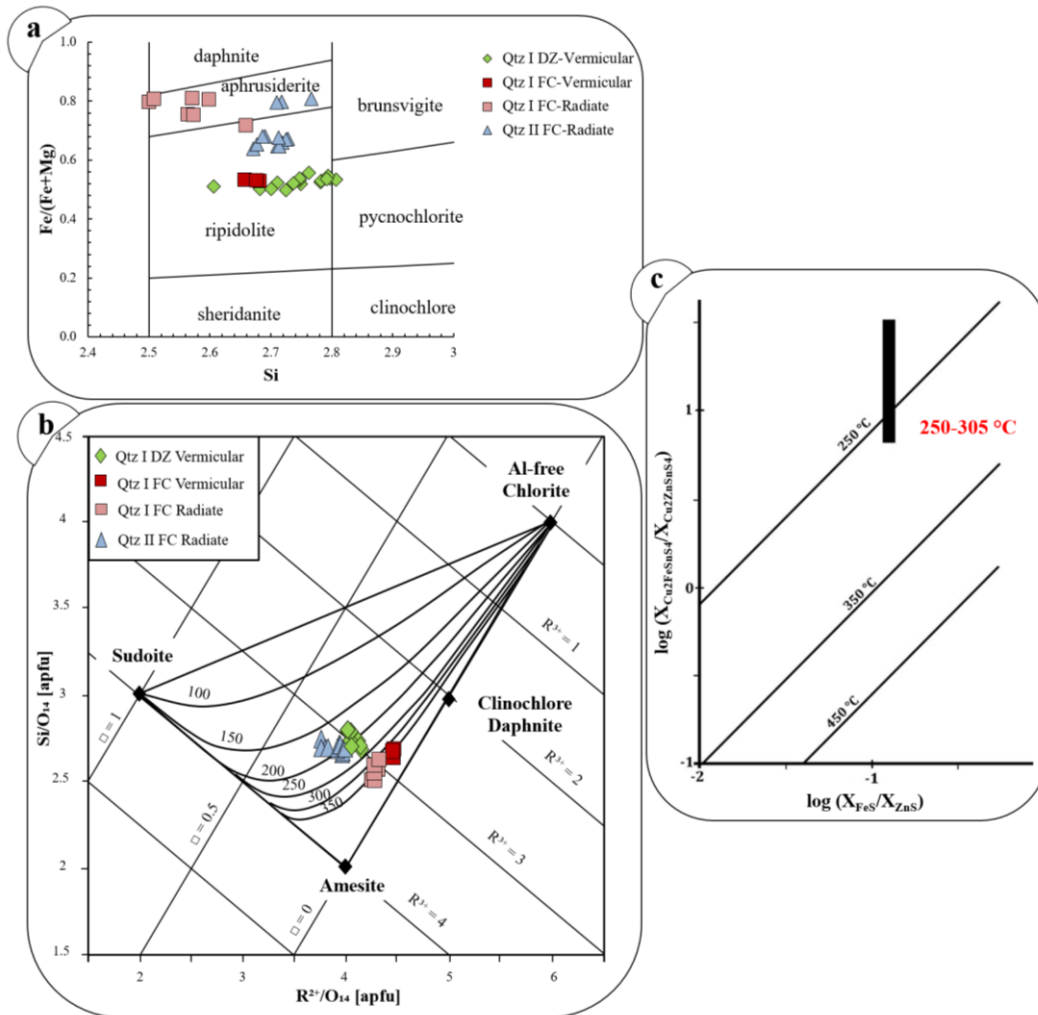

1001

1002 Figure 9. Characteristics textures of FIAs hosted within the BFZ300 quartz (samples PH21, TPH-120-4, TPH-120-6). (a) Secondary trails
 1003 crosscutting large Qtz I crystals of the damage zone. (b) Detail of (a) showing the phase ratios of one of the studied secondary assemblages
 1004 (FIA3), most representative of Type S1 FIA. (c) Long secondary transgranular trails crosscutting Qtz I of the fault core, dismembered by
 1005 intercrystalline fractures, infilled by quartz new grains. Qtz I fault core also hosts set of short sub-trails developed at high angle with respect to
 1006 the long trails. (d) Detail of Type S2 FIA entrapped along a preserved secondary fracture trail. (e) Small inclusions (<1 μm) arranged along the
 1007 boundaries of new polygonal quartz. (f) Example of Type S3 FIA arranged as isolated clusters inside ductile deformed fault core Qtz I. These
 1008 trails formed during a brittle deformation stage that pre-dates ductile re-crystallization. (g) Pseudosecondary FIA associated with Qtz II-chlorite
 1009 (FIA 11). The enlargement shows the phase ratio details. (h) Small scale view of secondary FIAs crosscutting Qtz II. (i) Detail of secondary trails
 1010 crosscutting euhedral Qtz II (FIA 13). In all photographs north points up.

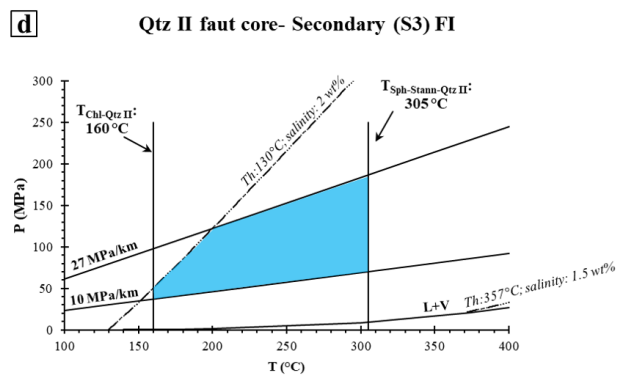

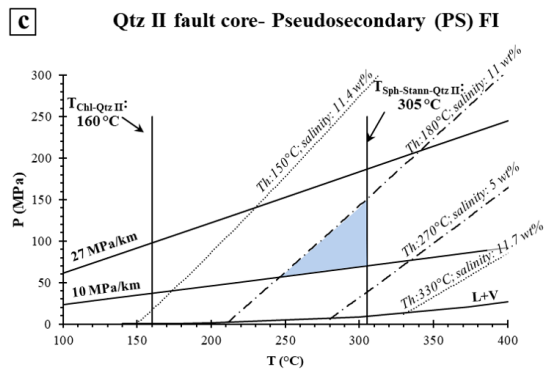

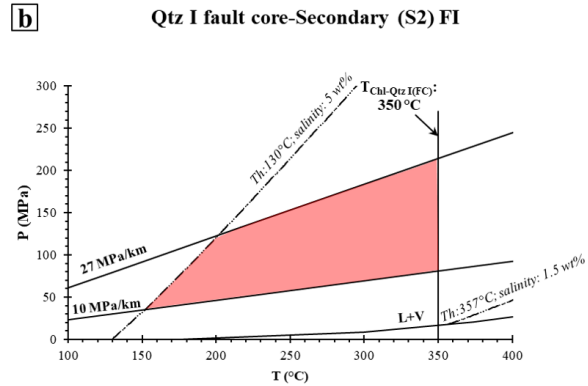

1011
 1012 Figure 10. Microthermometric data of the studied FIAs. Panels a-d show the bulk salinities of individual FIAs calculated from the T_{mice} data,
 1013 while panels e-h refer to the temperatures of final homogenization of the same assemblages. Notice that the data report the properties of individual
 1014 FIAs according to their occurrence within Qtz I of the damage zone, Qtz I from the fault core, and Qtz II from the fault core. Notice that
 1015 pseudosecondary (PS) and secondary (S) FIAs identify progressive later stages of fluid entrapment, and can be used to constrain the fluid
 1016 properties in the fault zone. Notice also that the measured ranges of T_{hot} spread across T intervals that are too large to represent entrapment at
 1017 equilibrium (e.g., FIA7 of Qtz I from fault core: 130-320 °C), which suggests post-entrapment re-equilibration of the inclusions. Fluid bulk
 1018 composition is expressed as salinity, which is conventionally reported as weight percent of NaCl equivalents (wt%NaCleq, Roedder, 1984).
 1019

1020

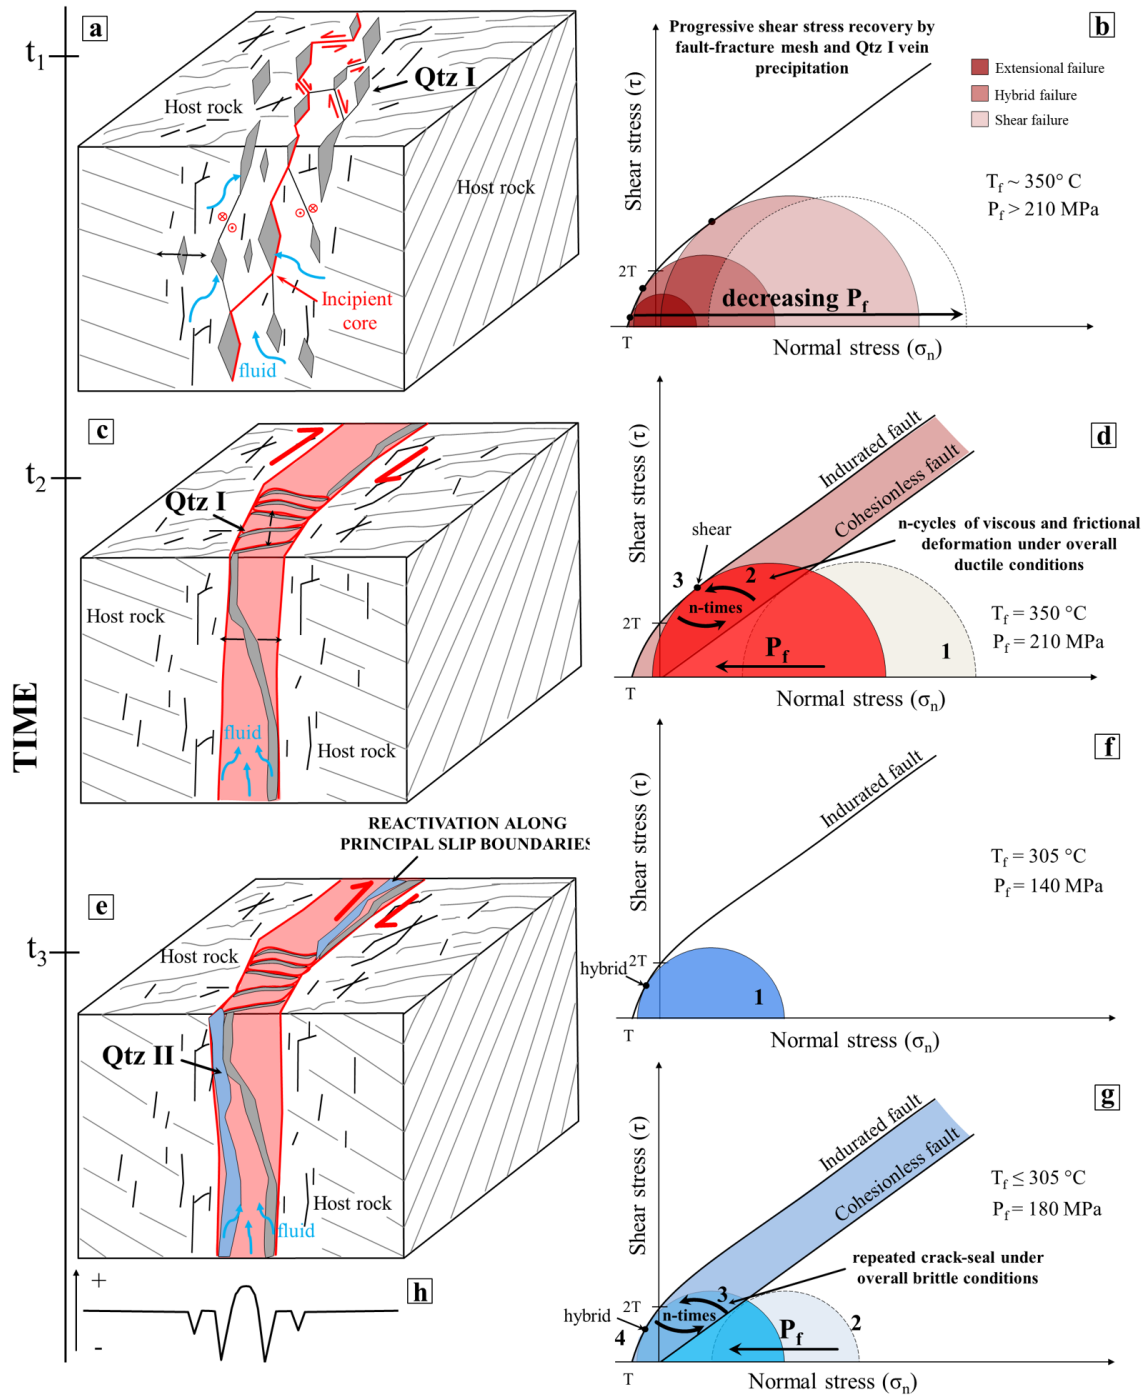

1021 Figure 11. Chlorite chemical composition diagram and mineral-pair geothermometry applied to the assemblages of the Qtz I- and Qtz II veins.
 1022 (a) Chlorite compositional diagram based on Hey (1954). Green, red, pink and light blue symbols indicate distinct chlorite textures in association
 1023 with Qtz I and Qtz II veins. (b) Chlorite-quartz formation temperature estimated using the method of Bourdelle and Cathelineau (2015). The
 1024 maximum temperature is from the Qtz I-chlorite pair from the fault core. (c) Estimated temperature of formation of sphalerite-stannite in
 1025 association with Qtz II vein (based on Shimizu & Shikazono (1985)). The region of the plot that was calibrated with this geothermometer lies
 1026 between the 250 and 450 °C isotherms.
 1027

1028

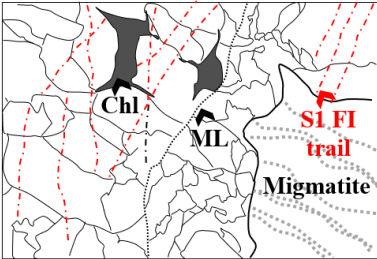

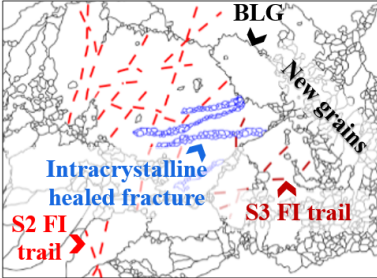

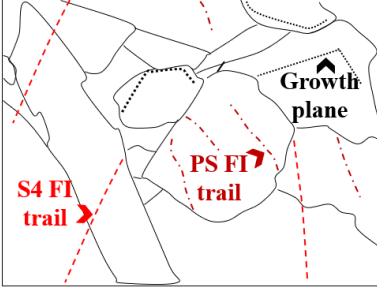

1029 Figure 12. P-T diagrams showing the ranges of PT trapping conditions of the analysed fluid inclusions: (a) secondary inclusions in Qtz I from
 1030 the fault damage zone; (b) secondary inclusions from Qtz I in the fault core; (c) pseudosecondary inclusions trapped in Qtz II in the fault core
 1031 and (d) secondary inclusions in the Qtz II. Thin dashed lines indicate maximum and minimum isochores of FIAs in each structural domain. The
 1032 coloured areas identify the probable PT trapping ranges defined by: i) the slope and position of the fluid inclusion isochores as determined by
 1033 the most representative salinity and homogenization temperature range (Supplementary Material for details); ii) mineral pairs geothermometry
 1034 and iii) hydrostatic and lithostatic fluid pressures computed assuming a regional geothermal gradient of c. 40 °C/km (assuming retrograde
 1035 conditions of 4 kbar and 650 °C, from Kärki and Paulamäki, 2006). The liquid-vapour equilibrium curve for the H₂O-NaCl modeled fluid is also
 1036 indicated.

1037

1039 Figure 13. Conceptual model of the temporal and mechanical evolution of the BFZ300 fault zone (see text for more details). Grey lines: traces
1040 of metamorphic foliation. Black lines: fractures related to the BFZ300 structural development. (a) Initial embrittlement of the migmatitic
1041 basement occurred by fracture coalescence (red line) under (b) initial lower differential stress conditions and high fluid pressure and followed
1042 by a transient increase of differential stress. A first generation of quartz veins (Qtz I) precipitated inside the diffuse network of joints and
1043 hybrid/shear fractures which formed during this first deformation stage. (c) Progressive strain localization and fluid channeling within the fault
1044 core occurred by (d) episodically renewed fluid-pressure build-up driven by cycles of brittle and ductile deformation. (e-g) Progressive
1045 exhumation and cooling of the fault system occurred concomitant with several brittle reactivation episodes of the fault zone under hybrid
1046 conditions and fluid pressure lower than during the previous deformational stages. Lastly, a second generation of quartz veins (Qtz II) was
1047 emplaced, mainly along the principal slip boundaries of the fault core, following the Qtz I vein as shown by (h) the strength profile across the
1048 fault architecture, that suggests lower tensile strength values (and hence higher reactivation potential) along the Qtz I vein / host rock walls.

1049 Table 1: Schematic summary of main microstructures, fluid properties, and PT deformation conditions in the quartz veins of the BFZ300 fault.

<i>Structural zone and sample</i>	<i>Qtz type</i>	<i>Deformation type</i>	<i>Microstructures</i>	<i>Microthermometric properties</i>	<i>Fluid pressure (P_f) and mineral pair thermometry</i>
Damage zone (PH-21)	Qtz I	Brittle/Ductile		$T_{\text{mice}} \text{ S1: } -0.1 \text{ to } -5.9 \text{ } ^\circ\text{C}$ $T_{\text{htot}} \text{ S1: } 150\text{-}400 \text{ } ^\circ\text{C}$	$T_{\text{Chl-QtzI (DZ)}}: 175\text{-}240 \text{ } ^\circ\text{C}$ $P_f \text{ (S1): } 50\text{-}80 \text{ MPa}$
Fault core (TPH120-4A)	Qtz I	Cyclic Brittle/Ductile		$T_{\text{mice}} \text{ S2: } -0.4 \text{ to } -8.2 \text{ } ^\circ\text{C}$ $T_{\text{htot}} \text{ S2: } 130\text{-}410 \text{ } ^\circ\text{C}$	$T_{\text{Chl-QtzI (FC)}}: 350 \text{ } ^\circ\text{C}$ $P_f \text{ (S2): } 30\text{-}210 \text{ MPa}$
Fault core (TPH120-6) (TPH120-4)	Qtz II	Brittle		$T_{\text{mice}} \text{ PS: } -0.1 \text{ to } -13.6 \text{ } ^\circ\text{C}$ $T_{\text{htot}} \text{ PS: } 150\text{-}440 \text{ } ^\circ\text{C}$ $T_{\text{mice}} \text{ S4: } 0 \text{ to } -11 \text{ } ^\circ\text{C}$ $T_{\text{htot}} \text{ S4: } 130\text{-}430 \text{ } ^\circ\text{C}$	$T_{\text{Chl-QtzII}}: 160\text{-}220 \text{ } ^\circ\text{C}$ $T_{\text{Sph-Stann-Qtz II}}: 250\text{-}305 \text{ } ^\circ\text{C}$ $P_f \text{ (PS): } 50\text{-}140 \text{ MPa}$ $P_f \text{ (S4): } 40\text{-}180 \text{ MPa}$

1050
 1051 Note: microstructures are coupled with the corresponding FI types and PT constraints derived from the collected dataset. See text for more explanations.
 1052 Notice that we combine structural and geochemical data to constrain the relationships between stages of mineral-scale deformation and fluid circulation,
 1053 which in turn defines the relative chronology of stages of fluid flow during faulting.
 1054 ML: median line; Blg: bulging.

Note: * - located within cataclastic band and close to stylolite. ** - located along stylolite

Sphalerite and stannite compositions from locations indicated by ** have been used to calculate the temperatures of sphalerite-stannite equilibrium following the geothermometer of Shimizu and Shikazono (1985). See text for more explanations.
