

23 underlying strata and suggest extrusion was initially explosive, and erupted lava flows that feed
24 lobate lava fans. The lava flows are >9 km long and contain lava tubes that have rugged basal
25 contacts defined by $\sim 90 \pm 23$ m high erosional ramps. We suggest the lava flows eroded down into
26 and were emplaced within wet, unconsolidated, near-seafloor sediments. Extrusion dynamics were
27 likely controlled by low magma viscosities as a result of increased dissolved H₂O due to high
28 hydrostatic pressure, and soft, near-seabed sediments, which collectively are characteristic of deep-
29 water environments. We calculate that long run-out lava flows account for 50–97% of the total
30 erupted volume, with a surprisingly minor component (~ 3 –50%) being preserved in the main
31 volcanic edifice. Accurate estimates of erupted volumes therefore require knowledge of volcano
32 and lava basal surface morphology. We conclude that 3D seismic reflection data is a powerful tool
33 for constraining the geometry, volumes, and extrusion dynamics of ancient or active deep-water
34 volcanoes and lava flows.

38

39 **1. Introduction**

40 The external morphology of volcanoes and their eruptive products reflect, and provide insights
41 into, the processes controlling magma extrusion and volcano construction (e.g. Walker, 1993;
42 Planke et al., 2000; Grosse and Kervyn, 2018). By collecting high-resolution, quantitative data on
43 the morphology of modern volcanic edifices and surrounding lava flows from airborne/shuttle radar
44 topography or time-lapse multi-beam bathymetry, we can estimate erupted volumes, at least for

45 individual eruptive episodes (e.g. Holcomb et al., 1988; Walker, 1993; Goto and McPhie, 2004;
46 Cocchi et al., 2016; Somoza et al., 2017; Allen et al., 2018; Chadwick et al., 2018; Grosse and
47 Kervyn, 2018). Whilst remote sensing data capture the external morphology of volcanoes and lava
48 flows, both before, during, and after eruptions, they do not image their basal surface or internal
49 architecture. Without access to the full 3D structure of these extrusive systems, it is difficult to assess
50 the accuracy of estimated volumes of total erupted materials over multiple eruptive episodes, and to
51 thus test long-term volcano growth and lava emplacement models.

52 Several studies demonstrate that seismic reflection data can be used to map the external
53 morphology and internal architecture of buried volcanoes in 3D (e.g. Planke et al., 2000; Calvès et
54 al., 2011; Jackson, 2012; Magee et al., 2013; Arnulf et al., 2014; Reynolds et al., 2017; Arnulf et al.,
55 2018). To-date, most seismic-based studies have focused on volcanoes formed in sub-aerial or
56 shallow-marine environments (e.g. Planke et al., 2000; Jackson, 2012; Magee et al., 2013; Keen et
57 al., 2014; Reynolds et al., 2018), although seismic reflection surveys have been used to image the
58 shallowly buried flanks of deep-water volcanoes (e.g. Funck et al. 1996). The 3D geometry, internal
59 structure, and volume of deep-water volcanoes thus remain poorly documented. Without such
60 information on the structure of deep-water volcanoes, we cannot assess how they grow or what
61 hazard they may pose (e.g. tsunamis induced by flank collapse, seabed deformation and instability
62 induced by highly explosive eruptions).

63 We use high-resolution 3D seismic reflection data to examine the external morphology and
64 internal architecture of two, Late Miocene-Quaternary submarine volcanoes that were emplaced in
65 deep-water (>2.0 km) on highly stretched continental crust in the northern South China Sea (Fig. 1).
66 The volcanoes and associated lava flows are now buried by a ~55–330 m thick sedimentary

67 succession (Fig. 1). These two volcanoes are physically isolated and appear to have been fed by
68 independent, sub-volcanic intrusive bodies (i.e. sills; see below); we can thus confidently
69 characterize each individual volcano and its associated lava flows (Fig. 1b). By interpreting volcano
70 and lava flow 3D structure, distribution, and size, we aim to determine extrusion dynamics, calculate
71 accurate erupted volumes, and relate our findings to modern deep-water volcanoes studied using
72 bathymetry and remote sensing data. We show that the basal surfaces of these volcanic edifices and
73 lava flows are erosive, with 50–97% of the total erupted material hosted within the latter; i.e. the
74 volcano edifices only comprise a small portion of the total erupted volume. We suggest the high
75 hydrostatic pressure of the deep-water environment controlled melt H₂O content and internal lava
76 viscosity, effusion rate and, consequently, volcano and lava flow morphology and run-out distance.
77 Our results also show that erupted volumes calculated from airborne/shuttle radar topography or
78 time-lapse multi-beam bathymetry data, without knowledge of detailed geometry of the basal
79 surfaces of the lava flows and the volcanoes themselves, may be grossly underestimated, particularly
80 if extrusion was explosive and/or involved erosion of the seabed.

81

82 **2. Geological setting**

83 The study area is located south of Pearl River Mouth Basin, on the northern, highly stretched
84 continental crust of the South China Sea (Franke, 2013; Zhao et al., 2016) (Fig. 1a). The South
85 China Sea was an area of subduction in the late Mesozoic, before the onset of continental rifting
86 and subsequent seafloor spreading (~33-15 Myr) in the Cenozoic (e.g. Taylor and Hayes, 1983;
87 Briais et al., 1993; Franke et al., 2014; Li et al., 2014; Sun et al., 2014a; Ding and Li, 2016). A lack
88 of seaward-dipping reflections (SDRs) and low volumes of rift-related igneous rocks, suggest the

89 northern part of the South China Sea is a magma-poor margin (e.g. Clift et al., 2001; Yan et al.,
90 2006; Cameselle et al., 2017). Seafloor spreading ceased at ~15 Ma (Li et al., 2014), with post-rift
91 thermal cooling driving subsidence of the northern South China Sea margin since the Early Miocene
92 (Ru and Pigott, 1986; Yu, 1994). During this phase of thermal subsidence, the Dongsha Event (~5.3
93 Ma) occurred, which involved widespread uplift and normal faulting (e.g. Lüdmann et al., 2001).
94 Several mechanisms may have triggered the Dongsha Event, including the collision between Taiwan
95 and the East Asian continent (Lüdmann et al., 2001; Hall, 2002), isostatic rebound (Zhao et al.,
96 2012), post-rift magmatism (Franke, 2013), lithospheric bending (Wu et al., 2014), and/or
97 subduction of the South China Sea beneath the Philippine Sea plate (Xie et al., 2017).

98 Post-spreading magmatism in the South China Sea may reflect ascent of magma triggered by
99 subduction of the South China Sea along the Manila trench and collision with Taiwan Island
100 (Lüdmann et al., 2001), convective removal of continental lithosphere by warm asthenosphere
101 (Lester et al., 2014), or magma ascent from a high-velocity layer in the lower crust fed by the Hainan
102 mantle plume (Xia et al., 2016; Fan et al., 2017). Volcanoes generated by post-rift magmatism in
103 the early Miocene and Quaternary were emplaced both onshore and offshore (e.g. Zou et al., 1995;
104 Yan et al., 2006; Franke, 2013; Li et al., 2014; Sun et al., 2014b; Zhao et al., 2014, 2016; Fan et al.,
105 2017), with the latter typically extruded onto the continental slope in relatively shallow water depths
106 (<300 m; Yan et al., 2006; Zhao et al., 2016). Boreholes reveal these shallow-water volcanoes are
107 composed of basalt, dacite, and rhyolitic tuff (Li and Liang, 1994; Yan et al., 2006; Zhao et al.,
108 2016). In addition to the onshore and shallow-water volcanoes, several volcanoes were emplaced
109 further basinwards on the continental slope in deeper water, close to the Continent-Ocean Boundary
110 (COB; Fig. 1) (Clift et al., 2001; Wang et al., 2006; Cameselle et al., 2017). We examine two of

111 these deep-water volcanoes, which are situated in an area currently characterized by water depths
112 of 1850–2680 m and are now buried beneath sedimentary strata up to 330 m thick (Fig. 1).
113 Micropalaeontological data from the Pearl River Mouth Basin (Xu et al., 1995; Qin, 1996), and
114 microfauna data from ODP borehole sites 1146 and 1148, indicate the Middle Miocene (16.5 Ma)
115 to Recent, nanofossil-bearing clays overlying the volcanoes were deposited in a deep-water setting
116 (1.0–3.0 km; Wang et al., 2000).

117

118 **3. Data and Methods**

119 We use a time-migrated 3D seismic reflection survey acquired in 2012 and covering an area of
120 ~350 km² (Fig. 1b). The seismic data are zero-phase processed and displayed with SEG (Society of
121 Exploration Geophysicists) normal polarity, whereby a downward increase in acoustic impedance
122 (a function of rock velocity and density) corresponds to a positive reflection event (red on seismic
123 profiles) (e.g. Brown, 2004). The inline and crossline spacing are 25 m, respectively. The seismic
124 data have a dominant frequency in the interval of interest (i.e. 0–400 ms two-way time (twt)) of ~40
125 Hz.

126 Stacking velocities are not available for the survey and no wells intersect the studied Late
127 Miocene-Quaternary buried deep-water volcanic features. We thus have no direct observations of
128 the composition or velocities of the seismically imaged volcanic materials. Depth-conversion of
129 volcano edifice and lava flow thickness measurements in milliseconds (twt) to meters is therefore
130 based on velocity estimates, which introduces some uncertainty into our erupted volume
131 calculations. To derive a reasonable velocity estimate, we use velocity data obtained from boreholes
132 (i.e. BY7-1 and U1431) (Li et al., 2015; Zhao et al., 2016) and OBS (Ocean Bottom Seismometer)

133 profiles (Yan et al., 2001; Wang et al., 2006; Chiu, 2010; Wei et al., 2011) in the South China Sea.
134 The boreholes, which are situated >300 km away from our study area, intersect buried basaltic
135 volcanoes with p-wave velocities of ~4.5 km/s (BY7-1; Zhao et al., 2016) and ~3.0–5.0 km/s (IODP
136 U1431; Li et al., 2015). OBS profiles reveal that submarine volcanoes located 140 km from the
137 study area (Fig. 1a) typically have p-wave velocities of >3.0 km/s, and occasionally up to ~5.5 km/s
138 (Yan et al., 2001; Wang et al., 2006; Chiu, 2010; Wei et al., 2011). These p-wave velocities of ~3.0–
139 5.5 km/s are consistent with p-wave velocity data for shallow-water, mafic volcanoes located
140 offshore western India (~3.3–5.5 km/s; Calvès et al., 2011), and southern Australia in the Bight
141 (~2.4–6.7 km/s, with an average velocity of 4.0 km/s; Magee et al. 2013) and Bass (~2.2–4.0 km/s
142 with an average of 3.0 km/s; Reynolds et al. 2018) basins. Based on these velocity data, we assume
143 the imaged volcanic deposits here have mafic compositions and p-wave velocities of 4.0 (± 1.0) km/s.
144 It is important to note that using a range of estimated velocities does not affect our calculation of
145 the *relative* amount of material contained within volcanic edifices versus the flanking lava flows.

146 We calculate a vertical resolution ($\lambda/4$) of ~10 m for the sedimentary strata overlying the volcanic
147 materials, given a dominant frequency of 40 Hz and assuming a seismic velocity of 2.2 km/s for the
148 nanofossil-bearing clay (based on seismic refraction profiles OBS1993, Yan et al., 2001; OBS2001,
149 Wang et al., 2006; OBS2006-3, Wei et al., 2011). The calculated vertical resolution for the volcanic
150 materials is 19–31 m, based on a dominant frequency of 40 Hz and estimated seismic velocities of
151 4.0 (± 1.0) km/s. The top and base of volcanic structures can be distinguished in seismic reflection
152 data when their thickness is greater than the estimated vertical resolution (i.e. 19–31 m) (Brown,
153 2004). Volcanic structures with thicknesses below the vertical resolution, but above the detection
154 limit (i.e. $\lambda/8 = 10\text{--}16$ m), are imaged as tuned reflection packages whereby reflections from their

155 top and base contacts interfere on their return to the surface and cannot be distinguished (Brown,
156 2004). The lava flows we image are typically >2 seismic reflection thick ($>41\pm 10$ m), suggesting
157 they too are thicker than the tuning thickness and are represented by discrete top and basal
158 reflections (Tables 1-3).

159 We used a regional 2D seismic profile and interpreted four seismic surfaces tied to ODP Site 1146,
160 which is located ~ 65 km west of the study area (Figs. 1a, 2), and two horizons locally mappable
161 around the volcanoes: T0 (~ 2.58 Ma), T1 (~ 5.3 Ma), TRa (~ 6.5 Ma), and TRb (~ 8.2 Ma), TM (top
162 of the volcanic material) and BM (base of the volcanic material). The youngest age of the volcanoes
163 and associated lava flows are determined using the first seismic reflection that onlaps or overlies
164 them (Fig. 3). After mapping TM and BM, we calculated the volumes of the volcanic features
165 (Tables 1-4), with errors largely arising from uncertainties in the velocities (4.0 ± 1.0 km/s) used to
166 undertake the depth conversion (see above).

167 Root mean square (RMS) amplitude extractions and slices through a variance volume were used
168 to constrain the geometry, scale, and distribution of the submarine volcanoes (Figs. 3-8). The RMS
169 amplitude attribute computes the square root of the sum of squared amplitudes, divided by the
170 number of samples within the specified window used; put simply, the RMS attribute measures the
171 reflectivity of a given thickness of seismic data (Fig. 4a) (Brown, 2004). The variance attribute is
172 free of interpreter bias because it is directly derived from the processed data (Fig. 5). Variance
173 measures the variability in shape between seismic traces; this can be done in a specified window
174 along a picked horizon or within a full 3D seismic volume. Variance is typically used to map
175 structural and stratigraphic discontinuities related to, for example, faults and channels (Brown,
176 2004).

177

178 **4. Seismic expression and interpretation of igneous features**

179

180 **4.1. Observations**

181 We identify three main types of seismic structures and associated facies related to these buried
182 deep-water volcanoes: (1) Seismic Facies 1 (SF1): two (V1 and V2) conical-shaped features up to
183 ~202 ms twt (~404±101 m) thick, which internally are weakly-to-moderately reflective or chaotic
184 with distinguished reflections downlapping onto BM, capped by a positive polarity, high-amplitude
185 reflection (TM) onlapped by overlying strata (Figs. 3a, 7); (2) Seismic Facies 2 (SF2): ribbon-like,
186 broadly strata-concordant, high-amplitude, positive polarity reflections, which emanate from the
187 conical structures (SF1) and extend up to ~9.2 km downslope (Figs. 3a-b, 6-7); and (3) Seismic
188 Facies 3 (SF3): saucer-shaped, strata-discordant, high-amplitude reflections situated beneath SF1
189 and SF2 (Fig. 6).

190

191 **4.2. Interpretations**

192 The conical shape of SF1 and downlap of its internal reflections (where developed) onto BM,
193 coupled with onlap of overlying reflections onto TM, suggest SF1 is an extrusive rather than
194 intrusive feature. SF1 is similar in terms of its conical shape, highly reflective top, and internally
195 chaotic reflections to mud volcanoes documented elsewhere in the northern South China Sea (Sun
196 et al., 2012; Yan et al., 2017). It is therefore plausible SF1 could represent a mud volcano that fed
197 long run-out mud flows (i.e. SF2). Alternatively, the highly reflective, ribbon-like geometry of SF2
198 is similar to that associated with shallow/free gas accumulations (Sun et al., 2012). We consider

199 these two interpretations unlikely because: (i) the limited supply and high viscosity of mud means
200 mud volcanoes are rarely associated with long run-out flows, although we note that one mud flow
201 in the Indus Fan was ~5.0 km long (Calvès et al. 2009); and (ii) the top of SF2 is defined by a
202 positive polarity reflection (downward increase in acoustic impedance), which is opposite to that
203 typically associated with shallow/free gas accumulations (e.g. Judd and Hovland, 2007; Sun et al.,
204 2012). Based on their geometric and geophysical characteristics, spatial relationships, and similarity
205 to structures observed on other rifted continental margins, we interpret these features as volcanic
206 edifices (SF1), genetically related lava flows (SF2), and saucer-shaped shallow sills (SF3) (e.g.
207 Berndt et al., 2000; Planke et al., 2000; Thomson and Hutton, 2004; Calvès et al., 2011; Jackson,
208 2012; Magee et al., 2013; Keen et al., 2014; Reynolds et al., 2018). We now focus on the detailed
209 external morphology and internal architecture of the two deep-water volcanoes that are shallowly
210 buried (<330 m) and thus well-imaged.

211

212 **4.3. Volcano edifice 1 (V1) and associated lava flows**

213 V1 is a prominent, ~202 ms twt high (404 ± 101 m) and ~3.0 km diameter conical volcanic edifice
214 covering ~7.2 km², with a volume of $\sim 0.94 \pm 0.24$ km³ and an average flank dip of $\sim 15.0^\circ \pm 3.6^\circ$ (Figs.
215 3-4; Table 1). V1 is overlapped by overlying reflections, with the oldest onlapping reflection
216 correlating to TRa (~6.5 Ma); this suggests V1 was emplaced in the latest Miocene (>6.5 Ma) (Fig.
217 3a). V1 is underlain by a downward-tapering, >1.1 km deep, up to 2.0 km wide, sub-vertical zone
218 of chaotic reflections (Fig. 3a). We attribute the poor imaging within this chaotic sub-vertical zone
219 to: (1) the presence of sub-vertical feeder intrusions that disrupt background reflections and scatter
220 energy (cf. Thomson, 2007); (2) increased fluid flow and hydrothermal alteration in fractured and

221 deformed host rock adjacent to the magma plumbing system; and/or (3) scattering of energy
222 travelling through the volcano, leading to ‘wash-out’ of the underlying data (i.e. a geophysical
223 artefact; Magee et al. 2013). This reduction in imaging beneath the volcanoes partly obscures their
224 basal surface, but where visible it is clear BM undulates and truncates underlying stratal reflections
225 (Fig. 3b).

226 Volcano V1 is surrounded by an asymmetric apron of moderate-to-high amplitude reflections
227 extending up to 1.5 km from the main edifice. The apron is up to ~ 115 ms twt thick ($\sim 230 \pm 58$ m),
228 and has a dip of $< 0.5^\circ$ (Figs. 4a-b; Table 2). A package of moderate-to-very high-amplitude
229 reflections extending a further c. 1.5 km down-dip of this apron contains very high-amplitude,
230 channel-like geometries (marked C1-C3 in (Fig. 4a), which terminate down-dip into or are flanked
231 at prominent bends by, moderate-amplitude, fan-like geometries (marked F1-F4 in Fig. 4a). We
232 interpret these two features as lava flow channels and fans, respectively (Fig. 3-4). The lava flow
233 channels are sinuous, < 340 m wide, and usually bisect the lava fans (Figs 4a-b). Lava flow-related
234 features (i.e. apron, channels, and fans) emanating from V1 cover an area of ~ 14 km² (Tables 3-4),
235 have an average thickness of ~ 33 ms twt ($\sim 66 \pm 17$ m), and a volume of $\sim 0.92 \pm 0.23$ km³; this volume
236 is nearly equal to that of V1 ($\sim 0.94 \pm 0.24$ km³) and thus represents $\sim 50\%$ of the total erupted volume
237 ($\sim 1.86 \pm 0.47$ km³).

238

239 **4. 4. Volcano edifice 2 (V2) and associated lava flows**

240 V2 covers ~ 0.44 km² and is elliptical in plan-view, with long and short axes of ~ 1.2 km and ~ 0.6
241 km, respectively (Figs. 5, 7). The volcano is ~ 100 ms twt high ($\sim 200 \pm 50$ m), with an irregular base,
242 has flank dips of $\sim 27.8^\circ \pm 5.9^\circ$, and a volume of 0.03 ± 0.01 km³ (Figs. 5, 7; Table 1). The top of V2

243 is of moderate amplitude and is irregular, with the oldest onlapping reflections correlating to
244 Reflector T1 (~5.3 Ma) suggesting V2 is latest Miocene-earliest Pliocene (>5.3 Ma), but probably
245 younger than V1 (>6.5 Ma) (Fig. 7). Reflections within V2 are chaotic and, similar to V1, V2 is
246 underlain by a vertical zone of disturbance (Fig. 7). V2 lacks a lava apron, instead being directly
247 flanked by relatively straight, >9.2 km long lava flow channels extending beyond the seismic survey
248 boundary on its south-eastern side (C4-C7) (Fig. 5a). Lava flow C6 is unusual in that underlying
249 strata are truncated at the base of the flow, defining ‘ramps’ that are up to ~32.5 ms twt high (~65±16
250 m) and dip towards V2 at ~25.5°±5.8° (Fig. 8). Beyond the main ramp at the base of lava flow C6
251 (Fig. 5b), the lava flow thickens to ~130 ms twt (~260±65 m), where it is defined by stacked, high-
252 amplitude reflections that have a lobate geometry in plan-view (F5) (Figs. 5, 7, 8c-d). At its distal
253 end, the pinch out of F5 occurs where it abuts a basal ramp that is ~90±23 m tall and that dips
254 ~9.3°±2.3° (Figs. 8c-d). F5 is capped by a younger lava fan (F6) (Figs. 8c-d). The V2-sourced lava
255 flows (C4-C7 and F5) cover ~11.5 km²; ~4.20 km² of this comprises lava flow channels and ~7.32
256 km² lava fan. Given the average thickness of the lava flow channels (~61±16 m) and fans (~109±27
257 m), we estimate the total volume of V2-sourced lava flows to be ~1.05±0.27 km³; this volume
258 estimate is ~35 times greater than that of the main V2 edifice (0.03±0.01 km³), representing ~97%
259 of the total erupted volume.

260

261 **4.5. Shallow sills and associated lava flows**

262 South of V2, we map two areally extensive, partly merged lava flows emanating from the upper
263 tips of inclined sheets fringing saucer-shaped sills (i.e. S1 and S2) (Figs. 1b, 5-6). A narrow, vertical,
264 seismically chaotic/blanking zone occurs directly below the saucer-shaped sills (Fig. 6). Several

265 linear structures, rooted at the junction between sills, and feeding the overlying lava fan (F6), are
266 also observed (Fig. 6). F6 covers an area of $\sim 49 \text{ km}^2$, with a diameter of $\sim 7.9 \text{ km}$ and thickness of
267 $55 \pm 14 \text{ m}$ (Table 4). F6 is directly onlapped by surface T0 ($\sim 2.58 \text{ Ma}$), suggesting it was emplaced
268 in the latest Pliocene ($> 2.58 \text{ Ma}$) (Fig. 6). Similar to other lava fans, F6 is characterized by a single,
269 positive, high-amplitude seismic event (Fig. 6). F6 extends beyond the seismic coverage and is much
270 bigger than other lava fans imaged in the study area (Figs. 5-6; Table 4).

271

272 **5. Discussion**

273 **5.1. Water depths during volcano emplacement**

274 The different burial depths and onlap relationships of the volcano edifices and lava flows studied
275 here suggest three phases of volcanism: i.e. $\sim 6.5 \text{ Ma}$ for V1, $\sim 5.3 \text{ Ma}$ for V2, and $\sim 2.58 \text{ Ma}$ for
276 S1/S2 (Figs. 2-3, 6-7). According to the relative sea-level change curve of the Pearl River Mouth
277 Basin acquired from nannofossils (Xu et al., 1995; Qin, 1996) and the dating of volcanic phases, the
278 water depths during V1 and V2 emplacement were likely $\sim 75 \text{ m}$ and $\sim 150 \text{ m}$ shallower than the
279 present depths of $\sim 2.25 \text{ km}$ and $\sim 2.14 \text{ km}$, respectively. The water depth during the emplacement of
280 F6, fed by S1/S2, was probably $\sim 150 \text{ m}$ greater than the present depth of $\sim 2.32 \text{ km}$ (Xu et al., 1995;
281 Qin, 1996). To be conservative, we estimate that volcanism in the study area occurred in water
282 depths of a little over 2.0 km .

283

284 **5.2. Origin of post-spreading volcanism in the SCS**

285 The volcanoes documented here ($\sim 6.3\text{--}2.58 \text{ Ma}$) have similar ages with those documented at
286 Hainan Island (e.g. Tu et al., 1991; Shi et al., 2011) and southwestern SCS (e.g. Li et al., 2013) (Fig.

287 1a). However, these volcanoes are substantially younger than those previously observed in the
288 central SCS (~13.8–7.0 Ma; Expedition 349 Scientists, 2014; Li et al., 2015) and on the middle-
289 lower slope of the northern SCS (~23.8-17.0 Ma; Yan et al., 2006; Zhao et al., 2016; Fan et al.,
290 2017). We note that the small-scale, buried, post-spreading volcanic features studied here have not
291 been identified by lower-resolution techniques (e.g. gravity, magnetism, OBS and 2D seismic data).
292 These young volcanic features may be widespread and diagnostic of post-spreading magmatism
293 across the northern SCS (e.g. Briaies et al., 1993; Yan et al., 2006).

294 Given that the volcanoes documented here were emplaced after SCS rifting (>32 Ma ago; e.g.
295 Taylor and Hayes, 1983; Franke et al., 2014; Li et al., 2015) and spreading (>15 Ma ago; Li et al.,
296 2014), it is clear they have a different origin than the breakup-related volcanoes described elsewhere
297 (e.g. Yan et al., 2006; Expedition 349 Scientists, 2014; Li et al., 2015; Zhao et al., 2016; Fan et al.,
298 2017). The post-spreading age of volcanism may suggest that mantle melting (Clift et al., 2001) and
299 convective removal of continental lithosphere by warm asthenosphere (Lester et al., 2014),
300 processes typically associated with rifting and breakup, were not responsible for the generation of
301 this phase of igneous activity. Magmatism gets younger south-eastwards, from ~23.8–17.0 Ma on
302 the proximal continental slope (Yan et al., 2006; Zhao et al., 2016; Fan et al., 2017) to ~6.30–2.58
303 Ma in the deeper water study area. This observation is seemingly in agreement with the results of
304 teleseismic imaging, which shows southeastward migration of the eastern branch of the Hainan
305 mantle plume (Xia et al., 2016). This suggests that plume melt (Xia et al., 2016; Fan et al., 2017)
306 may have supplied magma to these volcanoes. However, where the Hainan mantle plume was
307 located or even whether the Hainan mantle plume occurred or not are still controversial at present
308 (e.g. Wheeler and White, 2000; He and Wen, 2011; Zhang and Li, 2018). Another possibility for

309 the origin of the magma feeding these volcanoes is related to the Dongsha Event, which may have
310 triggered mantle upwelling as well as transtensional faulting (Lüdmann et al., 1999). The Dongsha
311 Event peaked at ~5.3 Ma and 2.58 Ma (Lüdmann et al., 2001) and was broadly synchronous with
312 the main period of eruptive magmatism documented here. Faults generated during the Dongsha
313 Event may have provided high-permeability zones that promoted the vertical migration of magma
314 that fed the eruptive centers.

315

316 **5.3. Volcano construction**

317 Both V1 and V2 are underlain by sub-vertical, pipe-like zones of chaotic reflections, which we
318 suggest demarcate the limits of their magma plumbing systems. The basal surfaces of V1 and V2
319 truncate underlying strata (Figs. 3a, 7). Apparent erosion of the sub-volcanic substrate may indicate
320 the initial eruptions were explosive. Alternatively, subsidence of the volcano load into underlying,
321 wet, unconsolidated sediments may have caused the strata to locally compact and thereby change
322 the reflection configuration, making it appear that they are truncated.

323 Internal reflections that lie sub-parallel to the flanks of V1 and V2 suggest the volcanoes grew by
324 increasing both edifice height and diameter by the accretion of volcanic material (Magee et al. 2013).
325 Flank dips of ~15°–28° likely indicate that the volcanic material building the edifices constitutes
326 coherent lava flows and/or a dome structure, rather than a pyroclastic cone of tephra (Francis and
327 Thorpe, 1974; Griffiths and Fink, 1992). Construction via emplacement of coherent lava flows is
328 consistent with the presence of internal reflections in V1 and V2; i.e. boundaries between blocky
329 lava flows would be irregular and scatter seismic energy, meaning they would not likely be imaged.

330

331 **5.4. Lava flow extrusion dynamics**

332 In addition to the formation of volcanic edifices, both V1 and V2, as well as S1 and S2, are
333 associated with extensive lava flows. In particular, we show V1 and V2 are flanked either by an
334 asymmetric lava apron, which is broader on their downslope (SE) side, or lava flow channels that
335 flowed south-eastwards for up to >9 km (Figs. 3a, 4a-b, 5a). At sub-aerial volcanoes (e.g. Walker,
336 1993; Cashman et al., 1999), high eruption rates and low magma viscosities are the dominant causes
337 of long run-out lava flows. Extensive lava flows have also been observed at other deep-water
338 volcanoes (e.g. Chadwick et al., 2018; Embley and Rubin, 2018; Ikegami et al., 2018) where greater
339 dissolved H₂O contents in melt imply lower melt viscosity while the lavas were mobile. These low
340 viscosity, highly mobile lavas could potentially have longer run-out distances. Higher ambient
341 pressure can also affect bulk lava rheology, e.g. decreased vesicularity and crystal content. Lower
342 gas fractions will also suppress magma decompression and ascent prior to eruption, and, thereby,
343 effusion rates and extrusion dynamics (Bridges, 1997; Gregg and Fornari, 1998). For example, upon
344 eruption of a 1200°–1100°C basalt (MORB composition) at a confining pressure of 20 MPa (i.e. a
345 hydrostatic-equivalent water depth of 2 km), the melt can contain up to 1.4 wt% H₂O at equilibrium
346 volatile solubility (Newman and Lowenstern, 2002). Using the viscosity model of Giordano et al.
347 (2008) and 1.4 wt% H₂O, the resulting lava viscosity of 9–38 Pa s is significantly lower than a dry
348 (e.g. 0.1 wt% H₂O) sub-aerial basalt, having a viscosity range of 41–248 Pa s. Higher H₂O content
349 in lavas erupted in deep-water, compared to those extruded in sub-aerial settings, will mean: (1)
350 there are fewer bubbles from suppressed degassing or brittle fragmentation to hinder flow (Gregg
351 and Fornari, 1998); (2) crystallization may be inhibited, reducing the effect of crystal interactions
352 on viscosity; and (3) the glass transition temperature is suppressed (Giordano et al. 2008), allowing

353 lavas to flow further as the interiors cool.

354 From our seismic reflection data it is also clear that channelization in lava tubes, in addition to
355 the water content effects described above, also facilitated long distance lava transport. We suggest
356 these tubes formed by rapid cooling and thickening of a surficial crust that insulated and focused
357 lava flow through a core channel (e.g. Cashman et al., 1999). Based on the long run-out lava
358 distances, we consider our initial assumption that the imaged volcanic features have a mafic
359 composition is likely. Overall, whilst we do not know the composition of the lavas imaged in our
360 seismic reflection data, pressure-related changes in lava rheology and channelization of any lava
361 type (i.e. mafic to silicic) will allow it to flow hotter for longer. Given the downslope topographic
362 control during eruption, a combination of rheology changes and channelization allowed lavas to
363 flow for >9 km from associated volcanic edifices.

364 The overall geometry and internal architecture of the imaged lava flows indicate substrate
365 rheology also controlled emplacement dynamics. Our 3D seismic reflection data show that relatively
366 long run-out lava flows (>9 km) erupted from deep-water volcanoes have a rugged basal surface
367 that is locally defined by erosional basal 'ramps'. Truncation of underlying strata suggests the lavas
368 were able to erode down into the seabed, perhaps because the pre-eruption substrate was cold, wet,
369 and unconsolidated. We suggest erosion of the lava substrate was promoted by: (1) the dense
370 (bubble-poor) lava sinking down into or 'dredging' the soft sediments (Duffield et al., 1986; Ikegami
371 et al. 2018); (2) thermal erosion (Griffiths, 2000); and/or (3) more "turbulent" flow dynamics of
372 channelized lava, consistent with the inferred low viscosities (<10 Pa s).

373 Lava flows eventually ceased in distal areas due to gradual cooling and crystallization (Cashman
374 et al., 1999). We suggest that, in the case of the straight lava flows (C5 and C6), lava transported

375 within the axial tube temporarily accumulated at the end of the flow. Lava entering the tube from
376 the ongoing volcanic eruption caused an increase in pressure, with the cooled and crystallized
377 material at the flow toe forming a transient barrier. Eventually, pressure build-up was sufficient to
378 rupture this frontal barrier, leading to emplacement of a downdip fan (F5; Fig. 5a, 7-8) (Griffiths,
379 2000). However, in the case of fans (e.g. F1-4) fed by sinuous channels (Figs. 4a-b), we suggest
380 these were emplaced in a process similar to that documented by Miles and Cartwright (2010), with
381 lobate lava flows fed and bisected by a 'lava tube' through magma inflation and increases in eruption
382 rate. At the end of sinuous lava flow channels (e.g. C1), the main channel bifurcated to form a lobate
383 fan (F3, Figs. 4a-b), which was also probably caused by flow branching triggered by magma cooling
384 (Griffiths, 2000).

385

386 **5.5. Volume balance of volcano edifice and lava flow**

387 Inaccurate constraints on total erupted volumes limits our understanding of volcano construction,
388 lava propagation, eruption rates, eruption durations, magma storage conditions, melting processes,
389 and risk assessment of volcanism in deep-water settings (Carey et al., 2018). High-resolution 3D
390 seismic reflection data allow us to calculate the volumes of material contained within volcano
391 edifices and in flanking lava flows, if they are thick enough to be imaged. In this study, we show
392 that most (i.e. 50-97%) of the erupted material was transported away from the imaged edifices. An
393 important result of our work is that flanking lava flows, and to a lesser extent the volcanic edifices,
394 have rugged and discordant bases (Fig. 7); accurately calculating the volume of deep-water
395 volcanoes and lava flows therefore requires an understanding of their pre-eruption basal morphology.
396 Erupted volume estimates based solely on remote sensing of the post-eruption seabed may be thus

397 incorrect (e.g. Robinson and Eakins, 2006). Although we show the accuracy of total erupted volume
398 estimates can be improved by constraining basal volcano and lava morphologies, seismic images
399 capturing the geological record of deep-water volcanoes cannot determine how much, if any, clastic
400 volcanic material was transported away from the eruption site as pumice rafts or through ocean
401 current clast suspension and subsequent transport (e.g. Jutzeler et al., 2014; Carey et al. 2018).
402 Nevertheless, 3D seismic imaging can significantly improve quantitative volume estimates of recent
403 and ancient volcanic edifices and lava flows, either outcropping on the seafloor or buried by
404 sedimentary successions.

405

406 **6. Conclusions**

407 High-resolution 3-D seismic data from the South China Sea allow us to image and map the
408 internal structure, calculate the volume of erupted material, and to better understand the extrusion
409 dynamics of buried deep-water volcanoes; such insights cannot readily be gained from analysis of
410 remote sensing data (e.g. airborne/shuttle radar topography). Volcanism occurred ~6.3–2.58 Ma,
411 after seafloor spreading had ceased in the area, and may be related to the Dongsha Event and/or a
412 hypothesized Hainan mantle plume. High hydrostatic pressure, an inclined seabed (~1°), and low-
413 strength, very fine-grained, near-seabed sediments, combined with formation of lava tubes and
414 extrusion of low-viscosity magmas, are likely responsible for observed long-distance lava run-outs
415 (>9 km) in this deep-water environment. We show the imaged volcanic edifices and associated lava
416 flows have rugged, erosional bases, meaning traditional remote sensing-based volume calculations
417 of deep-water volcanic features, which typically assume smooth bases, are underestimated. We
418 calculate a large amount (as high as ~97%) of the erupted materials were transported away from the

419 volcano edifices as lava flows, suggesting that volume of deep-water volcanic edifices may not
420 faithfully archive eruption size or magma production. Considering deep-water conditions (e.g. high
421 hydrostatic pressure and unconsolidated sediments) in the study area are common elsewhere, the
422 conclusions derived from this study can likely be used in other deep-water sedimentary basins and
423 perhaps sedimentary mid-ocean ridges. Our study highlights that 3D seismic reflection data can
424 contribute to understanding volcano morphology in 3D and accurately estimating the volumes of
425 erupted materials.

666

667

668 **Tables**

669

670 Table 1: Dimensions of volcano edifices. ^adiameter and dip are average values.

Volcano edifice	^a Diameter (m)	Height (m)	Area (km ²)	Volume (km ³)	^a Dip (°)
Volcano edifice 1 (V1)	3018	404±101	7.15	0.940±0.235	15.0±3.6
Volcano edifice 1 (V2)	714	200±50	0.44	0.030±0.008	27.8±5.9

671

672 Table 2: Dimensions of lava flow apron. ^aDiameter is calculated from the area as a circle. V =

673 Volcano edifice.

Lava flow apron	Diameter (m)	Area (km ²)	Thickness (m)	Volume (km ³)	Feeder	Shape
Lava flow apron	3182 ^a	7.95	80±20	0.637±0.159	V1	Ring

674

675 Table 3: Dimensions of lava flow channels (C). Please note that all the lengths of lava flow

676 channels are measured along their axes. ^aMaximum lengths (including the inferred part of lava

677 flow channels); ^bMinimum length (C3 extends beyond the 3D survey); ^cThickneses cannot be

678 measured, because of lava flow channels (C1 and C2) are only identified on the plan-view map

679 (RMS and variance slice map); ^dArea and volume don't include the inferred part of C5.

Lava flow channels		Length (km)	Width (m)	Thickness (m)	Area (km ²)	Volume (km ³)
Volcano edifices 1-related	C1	2.86 ^a	55-273	unknown ^c	0.31 ^a	unknown ^c
	C2	3.66 ^a	94-340	unknown ^c	0.56 ^a	unknown ^c
	C3	4.60 ^b	163-340	52±13	0.84 ^a	0.044±0.011
Volcano edifices 2-related	C4	2.80	172-229	61±15	0.54	0.032±0.008
	C5	9.15 ^a	185-267	64±16	1.52 ^d	0.097±0.024 ^d
	C6	6.39	203-285	60±15	1.47	0.088±0.022
	C7	1.93	236-427	57±14	0.67	0.037±0.009

680

681 Table 4: Dimensions of lava flow fans. ^aDiameter is calculated from the area as a circle.

682 ^bMinimum areas and volumes, because of limited data coverage. C = Lava flow channel; S = Sill.

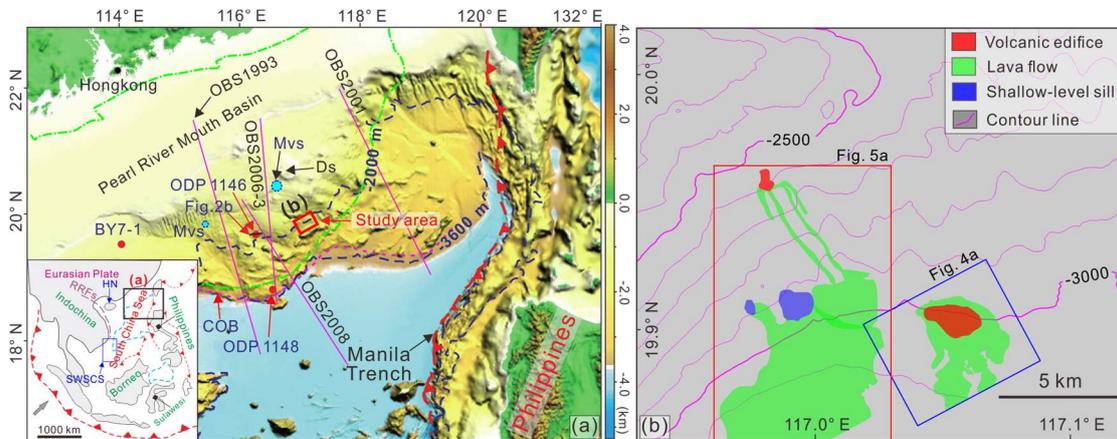

Lava flow fans	Diameter (m)	Area (km ²)	Thickness (m)	Volume (km ³)	Feeder	Shape
Lava flow fan 1 (F1)	944 ^a	0.70	41±10	0.028±0.007	C1	Lobate
Lava flow fan 2 (F2)	1050 ^a	0.87	41±10	0.035±0.009	C1	Lobate
Lava flow fan 3 (F3)	997 ^a	0.78 ^b	41±10	0.031±0.008 ^b	C1	Lobate
Lava flow fan 4 (F4)	2171 ^a	3.70 ^b	41±10	0.148±0.037 ^b	C2	Lobate
Lava flow fan 5 (F5)	3054 ^a	7.32	109±27	0.791±0.198	C5/C6	Lobate
Lava flow fan 6 (F6)	7906 ^a	49.07 ^b	55±14	2.650±0.662 ^b	S1/S2	Lobate

683

684

685 **Figures**

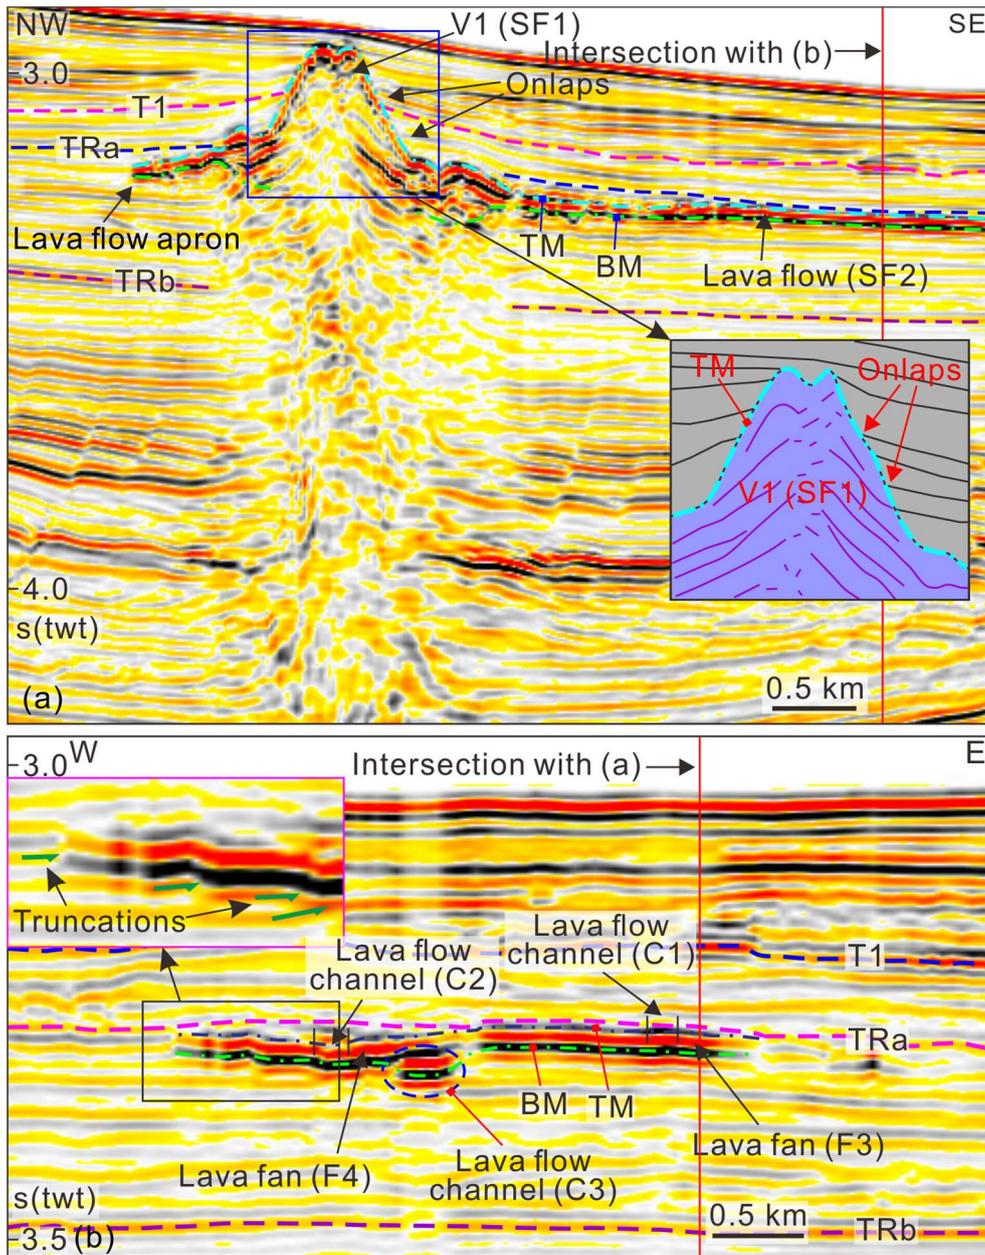

686

687

688 Figure 1: Geological setting of the study area. (a) Inset: regional setting of the South China Sea that
689 is bounded by the Red River Strike-slip faults (RRFs) to the west and by the subduction trench
690 (Manila Trench) to the east. Hainan Island (HN; Tu et al., 1991; Shi et al., 2011) and southwestern
691 South China Sea (SWSCS; Li et al., 2013) in which the magmatism has the similar ages with the
692 studied volcanoes are labelled in blue. In Figure (a): The study area (marked with red square) is
693 located to the south of Dongsha Islands (labeled Ds). The green dashed line outlines the boundary
694 of Pearl River Mouth Basin. Locations of boreholes (Red dots; Exploration well BY7-1 and ODP
695 sites 1146 and 1148), crustal structure profiles (Purple solid lines; OBS1993 (Yan et al., 2001),
696 OBS2001 (Wang et al., 2006), OBS2006-3 (Wei et al., 2011), and OBS2008 (Chiu, 2010)) and mud
697 volcanoes (Mvs) (Light blue dots; Sun et al., 2012; Yan et al., 2017) are labeled. Ds = Dongsha
698 Islands; COB = Continent ocean boundary (Adopted from Sibuet et al., 2016).The base map is
699 modified from Yang et al. (2015); (b) Seabed morphologies of the study area. Distributions of
700 volcano edifices (red), sills (blue), lava flows (green) and locations of Figures 4a and 5a are labeled.
701 The contour lines are in 100 ms (two way travel time).

702

712

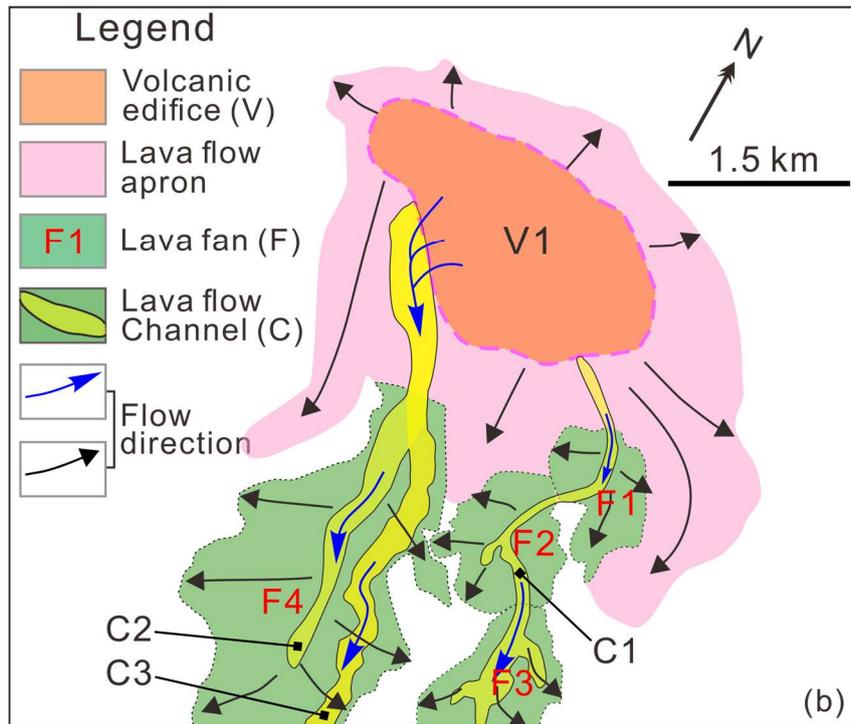

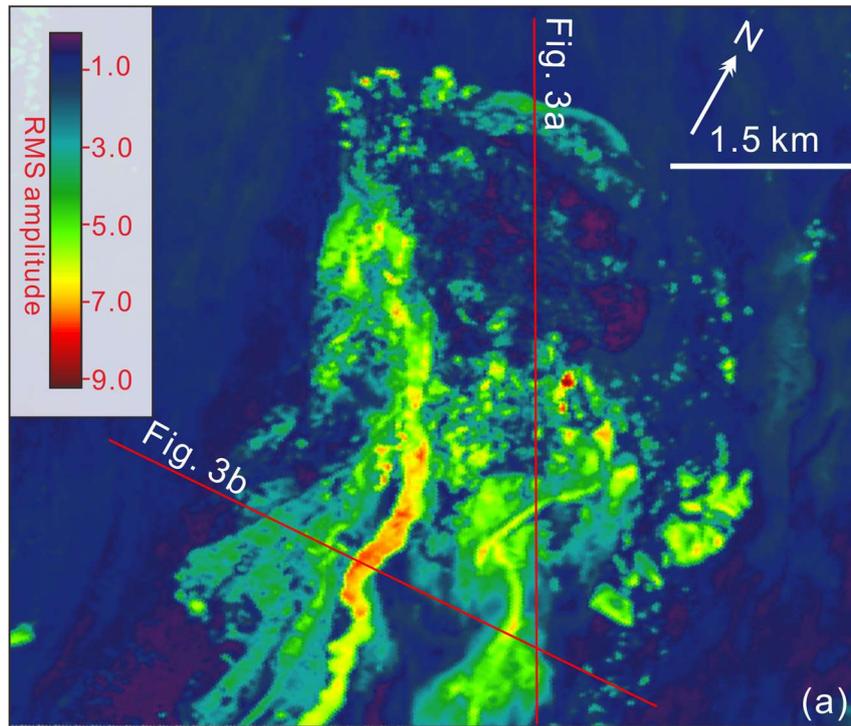

713 Figure 3: Seismic characteristics of deep-water volcano (V1) and associated lava flow channels/fans.

714 (a) Seismic profile crosscuts the volcano edifice and associated lava flow; (b) Seismic profile

715 crosscuts the lava flow (enhanced seismic anomalies). TM = top of volcano/lava flow; BM = base

716 of volcano/lava flow. See locations of seismic profiles in Figure 4.

717

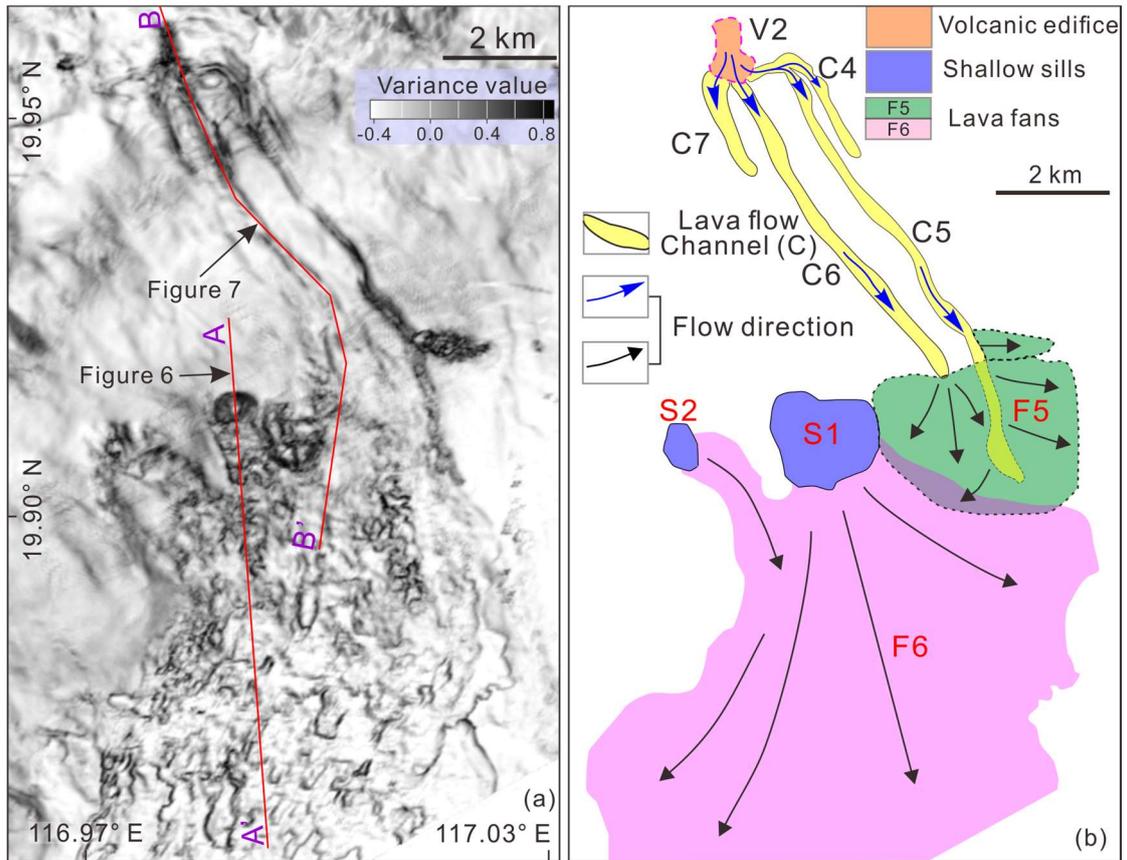

719

720 Figure 4: (a) and (b) RMS amplitude map (± 30 ms along the surface BM) and its interpretations.

721 Volcanic apron, lava flow channels/fans are labeled. See map location in Figure 1b. Red lines in (a)

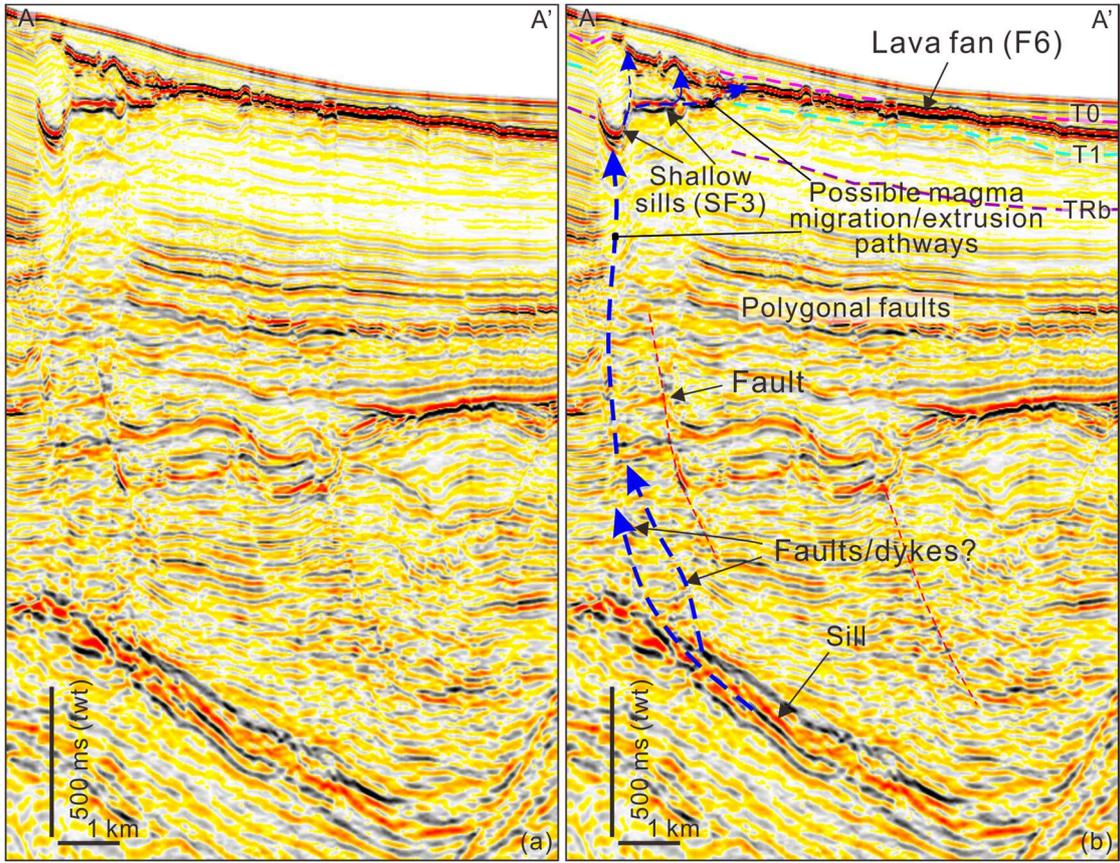

722 show locations of seismic profiles in Figure 3.

724

725 Figure 5: (a) Variance slice (extracted from the surface BM) and (b) its interpretations. Lava flows
 726 are clearly identified by their texture and marked in (b). C = lava flow channel; S = shallow sill; F
 727 = lava fan. Red lines A-A' and B-B' in (a) are seismic profiles shown in Figures 6 and 7.

728

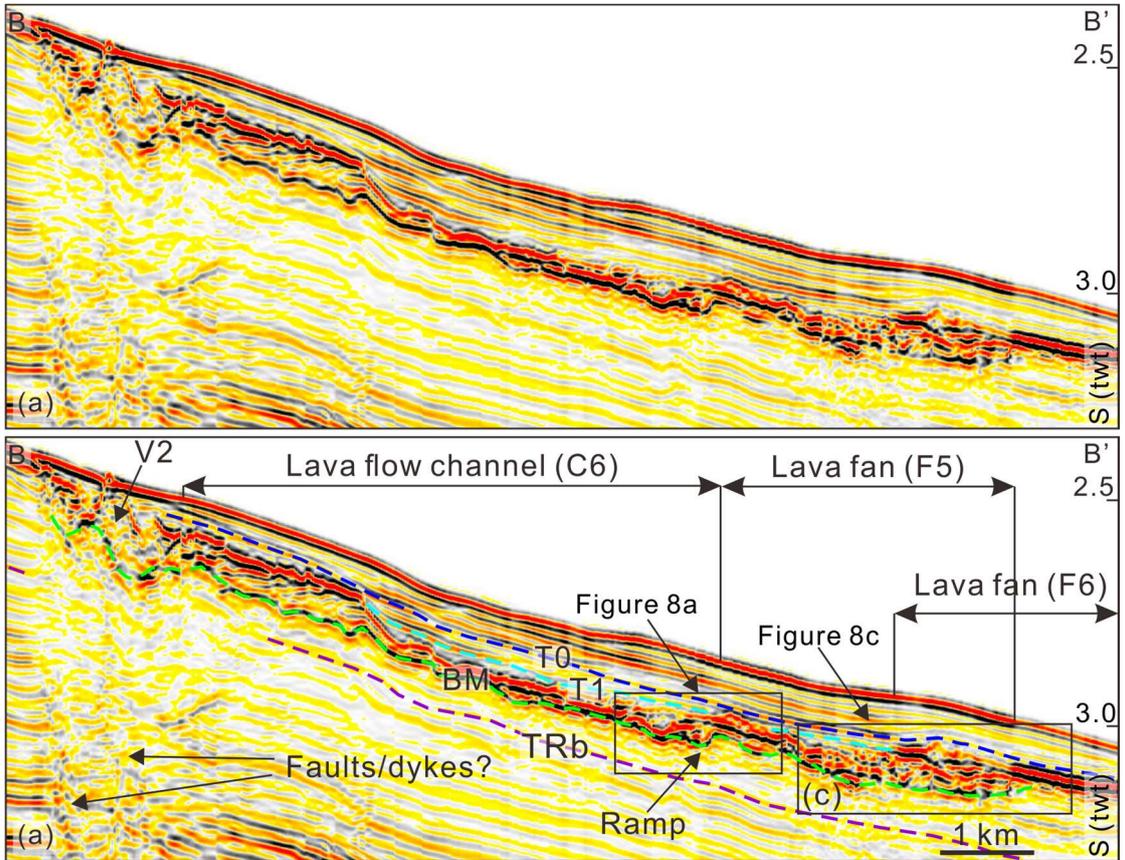

730

731 Figure 6: (a) Seismic profile and (b) its interpretation show magma plumbing system from deep-

732 seated sill, shallow sill (S1) and lava fan (F6). See location of seismic profile A-A' in Figure 5a.

733

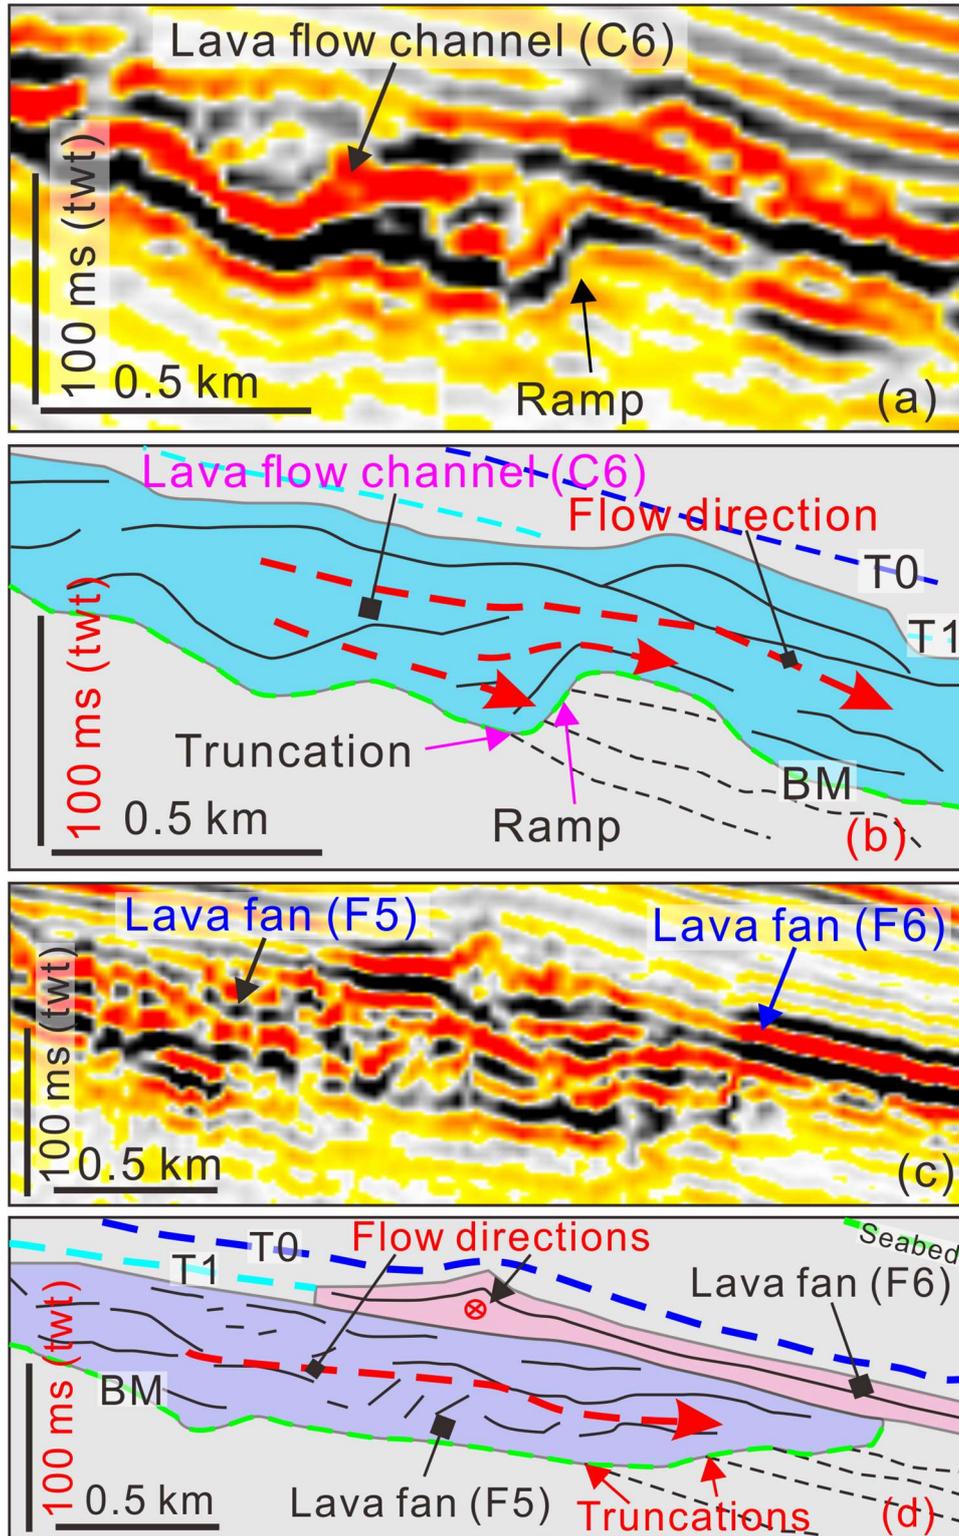

735

736 Figure 7: (a) Seismic profile crosscuts V2 and along lava flow channel (C6) and Lava fans (F5 and

737 F6). The V2 has a sharp boundary to the upslope. Lava fan 6 (F6) is directly overlying the Lava fan

738 5 (F5). BM = base of volcano/lava flow; See location of seismic profile B-B' in Figure 5a.

739

740

741 Figure 8: (a) and (b) Enlargement of the end of lava flow channel (ramp structure) and its line

742 drawings; (c) and (d) Enlargement and its line drawings of the lava fans (F5 and F6). BM = base of

743 volcano/lava flow. See locations in Figure 7.
