Dear editor.

Thank you for your comments and remarks. We hereby address the each points that was present the annotated pdf file. We also did an overall check for the english, organisation and mistyping.

Detailed Answers to remarks and comments

Comment 1: "Do not indent paragraphs":
Done accordingly through the paper.

Comment 2: "lines 16-18 should be placed at the end of the Abstract, where general implications should be also mentioned".
Modified accordingly, with small modifications "Integrating both geochronology and morphometrical results into lithospheric-scale numerical models allows a better understanding of this intraplate-orogen evolution and dynamic. We assume that the main conclusions are true to the general case of intraplate deformation. That is to say, once the topography has been generated by a triggering process. Associated uplift is then enhanced by erosion and isostatic adjustment leading to a significant accumulation of mainly vertical deformation.".

Comment 3: "lines 19-22 to be placed after line 16"
Changed accordingly.

Comment 4, line 31: "of what"
Simplification done with "part" changed with "unexplained uplift".

Comment 5, line 31: "NOTE: dynamic topography refers to topography generated by movement caused by differentiaf buoyancy (convection) in the Earth's mantle."
Agree. We argue that this dynamic topography could be one satisfactory explanation for the uplift triggering phenomenon, however our study has no quantification to assert this hypothesis.

Comment 6: line 42: "Why focusing on the study area? Linkage between the previous lines is needed"
We added theses sentences in the text for clarity: "Intraplate deformations evidenced by seismic activity is sometimes explained by the transient phenomenon (e.g., glacial isostatic rebound, hydrological loading). However, to explain the persistence through time of intraplate deformation, and explain the high finite deformation we can observe in the topography in many parts of the world as for instance the Ural mountains in Russia, the Blue Mountains in Australia or the French Massif Cen-tral, one needs to invoke continuous processes at the geological time-scale. Located in the southwestern Eura-sian plate (fig. 1), the French Massif Central is an ideal case to study this processes because a high resolution DEM encompasses the whole region and widespread karstic areas are present along its southern and western edges, allowing the possibility to quantify landscape evolution rates thanks to TCN burial ages.".

Comment 7: line 58: "From line 58, this text should be included in a paragraph entiled "Geologial Backgorund". Reference to a regional figure is needed"
The sub-section has been created. Link toward geological information website (from the french geological survey (BRGM) is mentioned.

Comment 8: line 65 "age? Regional significance?", in reference to the Cevennes Fault system.
"The area is also affected by the major NE-SW trending Cevennes fault system, a lithospheric-scale fault, inherit-ed from the Variscan orogen. This fault system was reactivated several times (e.g. as a strike-slip fault during the Pyrenean orogen or as a normal fault during the Oligocene extension)." was added for concise information.

Comment 9: Suggested to delete lines 100 to 108
Changed as suggested

Comment 10: for line 265-267: "The first part should be put in the Materials and Methods section".
This section can be, indeed redundant with previous section. However, because of the complex and multidisciplinary approach, we think that a short reminder of the inquired hypothesis helps the reader when starting this section.

Comment 11: "The first part should be put in the Materials and Methods section" concerning the first lines of the section "Geomorphometrical approach".
We slightly changed the organisation of the section in order to 1) increase the clarity and 2) highlight the multi-disciplinary approach. The point being that both section "Determining incision rate" and "Geomorphometry signature"

are stand-alone sections. This choice is also motivated by the fact that given the size of the paper, such organization should result in easier reading. See the modified document for changes.

Comment 12: for conclusion reorganization "Present the main conclusions as bullet points" and "Which the main implications at broader scale: i.e. for intraplate deformation?".
We modified the conclusion accordingly, see modified document.

Line 11: "dynamic" changed for "dynamics"

Line 12-13: space added between number and units

Line 13: question mark linked with "(e.g. Geodesy and Seismology)". Changed to geodetic and seismologic data.

Line 14 – 16: "Because the Cévennes margin allows the use of karst sediments geochronology and morphometrical analysis, we study the vertical displacements of that region: the southern part of the French Massif-Central" changed for "We focus our study on the southern part of the Massif-Central, known as the Cévennes and Grands Causses, which is a key area to study the relationship between the recent geological deformation and landscape evolution. This can be done through the study of numerous karst systems with trapped sediments combined with the anal-ysis of a high-resolution DEM."

Line 17: "helped" changed with "integrated" with

Line 30: "dating technics" changed as suggested by "the geochronological results" and "obtain" changed as suggested by "derived"

Line 31-32: "due to the Massif Central Plio-Quaternary magmatism" changed with "as consequence of the Pliocene-Quaternary magmatism of the region" as suggested

Line 32: "Plio-Quaternary" suggested to be changed by "Pliocene-Quaternary". Changed for all the occurrences in the manuscript

Line 35: "Such" changed as suggested by "this"

Line 36: "yrs." Changed with "yr"

Lines 37-41: "On geological time-scales, transient phenomenon that are classically used to explain intraplate deformations (as seen through the seismic activity) can not be a satisfactory explanation though, this then raises the question of the origin of the high finite deformations observed in many parts of the world as for instance the Ural mountains in Russia, the Blue Mountains in Australia or the French Massif Central." changed with "Intraplate deformations evidenced by seismic activity is sometimes explained by the transient phenomenon (e.g., glacial isostatic rebound, hydrological loading). However, to explain the persistence through time of intraplate deformation, and explain the high finite deformation we can observe in the topography in many parts of the world as for instance the Ural mountains in Russia, the Blue Mountains in Australia or the French Massif Central, one needs to invoke continuous processes at the geological time-scale.".

Line 52: "mountains" is removed.

Line 53-54: "(Topographic font in figure 1 show first order topography and morphology)" has been removed.

Line 54: "figure 1" changed with "Figure 1" as suggested.

Line 58: "formations" and "area" changed as suggested by "rock units" and "in the study area" respectively.

Line 60: "lower" is highlighted. Changed to middle.

Line 61: "thick" changed with "of thickness" as suggested

Line 63: "as being at the origin of" changed as suggested with "for the origin".

Line 65: "between" added as suggested.

Line 68: "Eventually" changed with "Finally".

Line 73 and 74: Removed as suggested.

Line 78: References moved to the end of the sentence as suggested.

Line 82: “in debate” changed as suggested by “debated”

Line 83: One reference, with overview synthesis was added.

Line 90: subsection title changed to “Materials and methods” as suggested

Line 93: “of” added as suggested

Line 93 to 95: “We employ two methods, cosmogenic 10Be/26Al burial dating quartz cobbles that have been transported by rivers and paleomagnetic analyses along vertical profiles of endokarstic clay both of which have been deposited in multiple cave systems at the time cave entry was at river channel elevation” rephrased to “We employ two methods to infer allochthonous karstic infilling age and associated river down-cutting. First, we use quartz cobbles to measure concentration of cosmogenic 10Be and 26Al isotopes. The 10Be/26Al ratio provide burial ages of these karstic infilling. Second, paleomagnetic analyses of clay deposits provide paleo-polarities. In both cases, vertical profiles among tiered caves systems and horizontal galleries could provide local incision rate information.”

Line 95: “In parallel, by analyzing a high-resolution DEM (5m), we show that the region is affected by a regional tilting.” modified to “By analyzing a high-resolution DEM (5m), we show that the region is affected by a southeastward regional tilting”.

Line 108-109: Modified as suggested to “Our research approach provides an opportunity to discriminate between three possible explanations for the current terrain morphology.”

Line 109: “terrain morphology” proposed to be changed by morphotectonic signature.
We choose to stay with “terrain morphology” since part of it could be only related to to climatic fluctuations, without a tectonic control. Morphotectonic terms would be misleading, providing a strong *a priori* interpretation.

Line 199: Subsection title changed to “Local incision rate from burial ages (Rieutord Canyon)”

Line 215: Subsection title changed to “Local incision rate from paleomagnetic data (Southern Grands Causses)”

Line 264: subsection title changed to “Geomorphometrical signature”.
We consider that the term Geomorphometrical is more suited because it deals with morphological quantification

Line 268 “differential vertical movement” added for better clarity.

Line 269: “Fig. 9” is highlighted with “Fig. 9” as a comment. We are not sure of what we should do so we keep it as it is.

Line 271: “Other issue could be due to diffusion processes that could create apparent tilting.” changed to “We point out that surface slope increase through time (e.g. apparent tilting) could be due to diffusion processes and not related to differential vertical displacements”.

Line 274: “us” changed with use.

Line 312: Subsection “Numerical modelling” incorporated inside the “Discussion” subsection.

Determining the Plio-Quaternary uplift of the southern French massif-Central; a new insights for intraplate orogen dynamics.

Abstract.

The evolution of intra-plate orogens is still poorly understood. Yet, this is of major importance for understanding the Earth and plate dynamics, as well as the link between surface and deep geodynamic processes. The French Massif Central is an intraplate orogen with a mean elevation of 1000 m, with the highest peak elevations ranging from 1500 m to 1885 m. However, active deformation of the region is still debated due to scarce evidence either from geomorphological or ~~geophysical (i.e.~~ geodetic~~sy~~ and seismologic~~y)~~ data. We focus our study on ~~Because t~~ the southern part of the Massif-Central, known as the Cévennes and Grands Causses ~~margin~~, which is a key area to ~~try and link~~study the relationship between the recent geological deformation and ~~the recent~~ landscape evolution. This ~~ability is due to both~~can be done through~~,~~ the study ~~presence~~ of numerous karst systems with trapped sediments ~~and available~~combined with the analysis of a high-resolution DEM ~~allows the use of karst sediments geochronology and morphometrical analysis, we study the vertical displacements of that region: the southern part of the French Massif-Central. . Geochronology and morphometrical results, helped with lithospheric-scale numerical modelling, allow, then, a better understanding of this intraplate-orogen evolution and dynamic.~~

———Using the ability of the karst to durably record morphological evolution, we first quantify the incision rates. We then investigate tilting of geomorphological benchmarks by means of a high-resolution DEM. We finally use the newly quantified incision rates to constrain numerical models and compare the results with the geomorphometric study.

We show that absolute burial age ($^{10}Be/^{26}Al$ on quartz cobbles) and the paleomagnetic analysis of karstic clay deposits for multiple cave system over a large elevation range correlate consistently. This correlation indicates a regional incision rate of 83 $^{+17}/_{-5}$ m.Ma^{-1} during the last ca 4 Myrs (Pliocene-Quaternary). Moreover, we point out through the analysis of 55 morphological benchmarks that the studied region has undergone a regional southward tilting. This tilting is expected as being due to a differential vertical motion between the north and southern part of the studied area.

Numerical models show that erosion-induced isostatic rebound can explain up to two-thirds of the regional uplift deduced from ~~dating techniques~~the geochronological results and are consistent with the southward tilting ~~obtain~~derived from morphological analysis. We presume that the remaining unexplained uplift ~~part~~ is related to dynamic topography or thermal isostasy due to the Massif Central

Ppliocene-~~quaternary~~ Quaternary magmatism.

Integrating both geochronology and morphometrical results into lithospheric-scale numerical model~~sing~~ allows a better understanding of this intraplate-orogen evolution and dynamic. We assume that the main conclusions are ~~extendable~~true to the general case of intraplate deformation. That is to say, once the topography has been generated by ~~such deformations are probably due to the interaction of~~ a triggering process, rock~~. Associated -~~uplift is then enhanced by erosion and isostatic adjustment leading to a significant accumulation of mainly vertical deformation.

1 Introduction and Tectonic Setting

1.1 Introduction

Since the past few decades, plate-boundary dynamic~~s~~ is to a first order, well understood. ~~Such~~This is not the case for intraplate regions, where short-term (10^3-10^5 yr~~s.~~) strain rates are low and the underlying dynamical processes are still in debate (e.g. Calais et al., 2010; Vernant et al., 2013; Calais et al., 2016; Taray**oun et al., 2017).** ~~On geological time-scales, transient phenomenon that are classically used to explain intraplate deformations (as seen through the seismic activity) can not be a satisfactory explanation though, this then raises the question of the origin of the high finite deformations observed in many parts of the world as for instance the Ural mountains in Russia, the Blue Mountains in Australia or the French Massif Central.~~ Intraplate deformations evidenced by seismic activity is sometimes explained by ~~T~~the transient phenomenon ~~used for explaining the~~(e.g., glacial isostatic rebound, hydrological loading). However, to explain the persistence through time of intraplate deformation, and explain the high finite deformation we can observe in the topography in many parts of the world as for instance the Ural mountains in Russia, the Blue Mountains in Australia or the French Massif Central, ~~intraplate deformations (as seen through the seismic activity) are, by definition not stable through time. O~~one needs to invoke ~~a~~ continuous ~~phenomenon~~processes ~~(~~at the geological time-scale. ~~) to explain the high finite deformation we can observe in the topography in many parts of the world as for instance the Ural mountains in Russia, the Blue Mountains in Australia or the French Massif Central~~

Located in the southwestern Eurasian plate (fig. 1), the French Massif Central is an ideal case ~~for~~to study~~ing intraplate orogen dynamic~~this processes because a high resolution DEM encompasses the whole region and~~, in its southern and western edges,~~ widespread karstic areas are present along its southern and western edges, allowing the possibility to quantify landscape evolution rate~~s~~ thanks to TCN burial ages

~~. In this study we focus on the Cevennes Mountains and the Grands Causses regions that form the southern part of the French Massif Central, located in the southwestern Eurasian plate (fig.1).~~

~~-~~The region is characterized by a mean elevation of 1000 m with summits higher than 1500 m. Such topography is likely to be the result of recent, active uplift and as the Cevennes mountains experiences an exceptionally high mean annual rainfall (the highest peak, Mount Aigoual, records the highest mean annual rainfall in France of 4015 mm) it raises the question of a possible link between erosion

and uplift as previously proposed for the Alps (Champagnac et al., 2007; Vernant et al., 2013; Nocquet et al., 2016). This region currently undergoes a small but discernible deformation, but no significant quantification can be deduced due to the scarcity in seismicity (Manchuel et al., 2018). In addition, GPS velocities are below the uncertainty threshold of GPS analyses (Nocquet et Calais, 2003; Nguyen et al., 2016).

In this study we focus on the Cevennes Mountains and the Grands Causses (fig.1) area, where ~~tiers~~ caves~~s~~ systems with trapped sediments are known over a widespread altitude range.

South and West of the crystalline Cevennes mountains, prominent limestone plateaus, named Grands Causses, rise to 1000m and are dissected by few canyons that are several hundreds of meter deep ~~(Topographic font in figure 1 show first order topography and morphology)~~. The initiation of incision, its duration and the geomorphic processes leading to the present-day landscape remain poorly constrained. A better understanding of the processes responsible for this singular landscape would bring valuable information on intraplate dynamics, especially where large relief exists.

1.2. Geological background

The oldest ~~formations~~rock units in the study area~~a~~ were formed during the Variscan orogeny (late Palaeozoic, ~300 Ma; Brichau et al., 2007) and constitute the crystalline basement of the Cevennes. Between 200 and 40 Ma (Mesozoic and ~~lower~~ middle Cenozoic), the region was mainly covered by the sea ensuring the development of an important detrital and carbonate sedimentary cover, which can reach several km of thickness in some locations (Sanchis and Séranne, 2000; Barbarand et al., 2001). During the Mesozoic era, an episode of regional uplift and subsequent erosion and alteration (called the Durancian event) is proposed ~~as being at~~for the origin of the flat, highly elevated surface that persists today across the landscape (Bruxelles, 2001; Husson, 2014).

The area is also affected by the major NE-SW trending Cevennes fault system~~.~~, a lithospheric-scale fault, inherited from the Variscan orogen. This~~;~~ fault system ~~that has been~~was reactivated ~~at~~ several ~~occasions~~times (e.g. as a ~~transform~~strike-slip fault during the Pyrenean orogen or as a normal fault during the O~~o~~ligocene extension). During the Pyrenean orogeny, between 85 to 25 Ma (Tricart, 1984; Sibuet et al., 2004), several faults and folds affected the geological formations south of the Cevennes fault, while very few deformations occurred f~~a~~urther north within the Cévennes and Grand Causses areas (Arthaud and Laurent, 1995). Finally~~Eventually~~, the Oligocene extension (~30 Ma) led to the counterclockwise rotation of the Corso-Sardinian block and the opening of the Gulf of Lion, re-activating some of the older compressive structures as normal faults. The main drainage divide between the Atlantic Ocean and the Mediterranean Sea is located in our study area and is inherited from this extensional episode (Séranne et al., 1995; Sanchis et al., 2000).

~~Superimposed at the inheritance from Durancian event, the last two major tectonic episodes which are the Pyrenean compression and the Oligocene extensionshaped the large-scale structural morphology of the region.~~ Afterwards during the Plio~~c~~ene-Quaternary period, only intense volcanic activity has affected the region, from the Massif Central to the Mediterranean shoreline. This activity is characteri~~z~~s~~s~~ed by several volcanic events that are well constrained in age (Dautria et al., 2010). The

last eruption occurred in the Chaîne des Puys during the Holocene (i.e. the past 10 kyrs (Nehlig et al., 2003; Miallier et al., 2004). Some authors proposed that this activity is related to a hotspot underneath the Massif Central ~~(Granet et al., 1995; Baruol and Granet, 2002)~~ leading to an observed positive heat-flow anomaly and a possible regional Pp~~l~~iocene-Quaternary uplift (Granet et al., 1995; Baruol and Granet, 2002). Geological mapping at different scale can be found at: http://infoterre.brgm.fr/.

~~———~~Despite this well described overall geological evolution the onset of active incision that has shaped the deep valleys and canyons (e. g. Tarn or Vis river, Fig 1) across the plateaus, and the mechanisms that controlled this incision are still ~~in~~ debated. One hypothesis proposes that canyon formation was driven by the Messinian salinity crisis with a drop of more than 1000m in Mediterranean Sea level (Moccochain., 2007). This, however, would then not explain the fact that the Atlantic watersheds show similar incision. Other studies suggested that the incision is controlled by the collapse of cave galleries that lead to fast canyon formation mostly during the late Quaternary, thus placing the onset of canyon formation only a few hundreds of thousands of years ago (Corbel, 1954). In contrast, it has also been proposed more recently (based on relative dating techniques and sedimentary evidence) that incision during the Quaternary was negligible (i.e. less than a few tens of meters), and that the regional morphological structures seen today occurred around 10 Ma (Séranne et al., 2002; Camus, 2003).

1.3~~2~~ Materials and methods~~Working hypothesis~~

~~———~~In this paper, we provide new quantitative constraints on both the timing of incision and the rate of river down-cutting in the central part of the Cévennes and of the Grands Causses that has resulted in the large relief between plateau and channel bed. -

We employ two methods~~,~~ ~~–~~ to infer allochthonous karstic infilling age and associated river down-cutting. First, we use~~d~~ quartz cobbles to measure concentration of ceosmogenic ^{10}Be and~~e~~/ ^{26}Al isotopes. The ^{10}Be/^{26}Al ratio provide burial ~~dating~~ages of these karstic infilling. Second, ~~clay deposits are that have been transported by rivers and psquartz cobble~~ used for paleomagnetic analyses of clay deposits provide~~, the objective being the obtention of~~ paleo-polarities. In both cases, vertical profiles among tiered~~s~~ caves systems and horizontal galleries could provide local incision rate information. ~~along vertical profiles of endokarstic clay both of which have been deposited in multiple cave systems at the time cave entry was at river channel elevation.~~ B~~In parallel, b~~y analyzing~~analysing~~ a high-resolution DEM (5m), we show that the region is affected by a southeastward ~~a~~ regional tilting. Our results allow to quantify the role of the Pliocene-Quaternary incision on the Cévennes landscape evolution and to constrain numerical modeling~~modelling~~ from which we derive the regional uplift rates and a tilt of geomorphological markers.

~~One important point of this study is the integration of multi-disciplinary approaches in order to constrain intraplate deformation. Such an approach is necessary to bring new insights into the lithosphere behaviour of slow dynamic regions. If the uplift is easily recognisable in the landscape (1000 m high plateaus), quantifying its timing and evolution rates is harder and can't be performed by classical technics (e.g. GPS). This is why we aim to quantify the incision rate over the longest~~

~~possible period thanks to the karstic immunity. Dealing with long-term incision rates (up to 5 Myrs) should permit to smooth possible climatic-driven incision rate variations (with time-span of several kyrs).~~

If incision is initiated by uplift centered~~centred~~ on the North of the area where elevations are maximum, it will lead to tilting of fossilized~~fossilised~~ topographic markers as strath terraces. Our research approach~~method of analyses~~ provides an opportunity to ~~select~~discriminate between three possible explanations for the current terrain morphology. The first is based on old uplift and old incision (Fig. 2.A). In this case, apparent incision rates would be very low. For instance, if incision commenced 10 Ma (Serrane et al., 2002), we would find surface tilting but cosmogenic burial dating with $^{10}Be/^{26}Al$ which cannot discern ages older than ~ 5Ma due to excessive decay of 26Al, would not be possible. The second possibility (Fig. 2.B) is that the uplift is old, and incision consequently follows but with a time lag. Here the incision rate would be rather fast, but no tilting is expected for the river-related markers because no differential uplift occurs after their formation. Finally, the third possibility (Fig 2.C) is that uplift and incision are concurrent and recent (i.e. within the time scale of cosmogenic burial dating) and thus we would expect burial ages < 5 Myrs relatively high incision rates, and tilting of morphological markers. These different proposals for the temporal evolution of the region will then be compared using numerical model~~l~~ing.

2. Determining the incision rates in the Cévennes and the Grand Causses Region

2.1. Principles and methods

2.1.1. Karst model

No evidence of important aggradation events has been reported in the literature for the studied area. Therefore, we base our analysis on a per descensum infill model of the karst networks whereby sediments are transported and then deposited within cave galleries close to base level. When cave-systems and entry passages are near the contemporaneous river channel elevation (including higher levels during floods), the deposition into caves of sediments, from clay to cobbles occurs, especially during flood events. Subsequent river incision into bedrock creates a relative base level drop (due to uplift or sea-level variations). The galleries associated with the former base-level are now elevated above the new river course and become disconnected from further deposition. Hence fossilised and trapped sediments throughout the cave network represent the cumulative result of incision. In this commonly used model (Granger et al., 1997; Audra et al., 2001; Stock et al., 2005; Harmand et al., 2017), the higher the gallery elevation (relative to the present-day base level) the older the deposits in that gallery. As a result, the objective here is to quantify a relative lowering of the base level in the karst systems, with the sediments closest to the base level being the youngest deposits, and note that we do not date the cave network creation which may very well pre-date river sediment deposition.

Within individual canyons, successions of gallery networks across the full elevation range from plateau top to modern river channel, were not always present and often sampling could not be conducted in a single vertical transect. Thus, we make the assumption of lateral altitudinal continuity i.e. that within a watershed, which may contain a number of canyons, the sediments found in galleries at the same elevation were deposited at the same time. Inside one gallery, we use the classical principle of stratigraphy sequence (i.e. the older deposits are below the younger ones). More informations and detailed relationships concerning the karstic development and geometric relationship between karstic network and morphological markers could be find in Camus (2003). In any cases, our aim is not to date the galleries formation, neither to explain the formation processes (e.g. past preferential alteration layer); but to use the time information brought by the sediment that have been trapped into the cave system. Therefore, we apply the common used model (example in Harmand et al., 2017) that had been proved by Granger et al., (1997, 2001). For cave topographic survey, we refer the reader to https://data.oreme.org/karst3d/karst3d_map that provides 3D survey.

2.1.2. Burial ages

Burial dating using Terrestrial cosmogenic nuclides (TCN) is nowadays a common tool to quantify incision rates in karstic environment (Granger and Muzikar, 2001; Stock et al., 2005; Moccochain., 2007; Tassy et al., 2013; Granger et al., 2015; Calvet et al., 2015; Genti, 2015; Olivetti et al., 2016; Harmand et al., 2017; Rovey II et al., 2017; Rolland et al., 2017; Sartégou, 2017; Sartégou et al., 2018). This method relies on the differential decay of TCN in detrital rocks that were previously exposed to cosmic radiation before being trapped in the cave system. With this in mind, the ^{10}Be and ^{26}Al nuclide pair is classically used as (i) both nuclides are produced in the same mineral (i.e. quartz), (ii) their relative production ratio is relatively well constrained (we use ~~here~~ a standard ^{26}Al/^{10}Be pre-burial ratio of 6.75, see Balco et al., 2008) and (iii) their respective half-lives (about 1.39 Myr and 0.70 Myr for ^{10}Be and ^{26}Al, respectively) are well suited to karstic and landscape evolution study, with a useful time range of ~100 ky to ~5 Myr.

To quantify the incision rate of the limestone plateau of the Cevennes area, we analysed quartz cobbles infilling from four caves of the Rieutord canyon (Fig. 1), this canyon is well suited for such study because horizontal cave levels are tiers over 200 m above the current river-level and are directly connected to the canyon, leading to a straight relationship between river elevation and the four cave infilling that we have sampled (Cuillère cave, Route cave, Camp-de-Guerre cave and Dugou cave). Furthermore, cobbles source is well known and identified: the upstream part of the Rieutord river, some tens of kilometers~~es~~ northward, providing a unique sediment origin composed of granite and metamorphic rocks embedding numerous quartz veins. All samples (Example Fig. 3) were collected far enough away (>20m) from the cave entrance and deep enough below the surface (>30m) to avoid secondary in-situ cosmogenic production of ^{10}Be and ^{26}Al in the buried sediments.

The quartz cobbles were first crushed and purified for their quartz fraction by means of sequential

acid attack with Aqua-Regia (HNO_3 +3HCl) and diluted Hydrofluoric acid (HF). Samples were then prepared according to ANSTO's protocol (see Child et al. 2000) and ~300µg of a ^{9}Be carrier solution was added to the purified quartz powder before total dissolution. AMS measurements were performed on the 6MV SIRIUS AMS instrument at ANSTO and results were normalised to KN-5-2 (for Be, see Nishiizumi et al., 2007) and KN-4-2 (for Al) standards. Uncertainties for the final ^{10}Be and ^{26}Al concentrations include AMS statistics, 2% (Be) and 3% (Al) standard reproducibility, 1% uncertainty in the Be carrier solution concentration and 4% uncertainty in the natural Al measurement made by ICP-OES, in quadrature. Sample-specific details and results are found in table 1.

2.1.3. Paleomagnetic analysis

———In parallel with burial dating, we analyzed the paleomagnetic polarities within endokarstic clay deposits within two main cave systems: the *Grotte-Exsurgence du Garrel* and the *Aven de la Leicasse* (Fig. 1). These two cave systems allowed us collecting samples along a more continuous range of elevations than the one provided by the Rieutord samples (for burial age determination) and also extending the spatial coverage to the Southern Grands Causses region. Thanks to the geometry of these two cave systems, we sampled a 400m downward base level variation. The sampling was done along vertical profiles from a few ten of centimeters to 2 meters high by means of Plexiglas cubes with a 2 cm edge length (Fig. 4) used as a pastry cutter. We weren't able to analyse clay samples from Rieutord canyon because no reliable clay infilling was found in the Rieutord caves.

Demagnetisation was performed with an applied alternative field up to 150mT using a 2G-760 cryogenic magnetometer, equipped with the 2G-600 degausser system controller. Before this analysis, each sample remained at least 48h in a null magnetic field, preventing a possible low coercivity viscosity overprinting the detrital remanent magnetisation (DRM) (Hill, 1999; Stock et al., 2005; Hajna et al., 2010). If the hypothesis of instantaneous locked in DRM seems reasonable compared with the studied time span, it is important to keep in mind that the details of DRM processes (as for instance the locked in time) is not well understood (Tauxe et al., 2006; Spassov et Valet, 2012) and could possibly lead to small variations (few percents) in the following computed incision rates.

Because fine clay particles are expected being easily reworked in the cave, careful attention was paid to the site selection and current active galleries were avoided. Clays deposits had to show well laminated and horizontal layering in order to prevent analysis of in-situ produced clays (from decalcification) or downward drainage by an underneath diversion gallery that could strongly affect the obtained inclination (and also the declination to a minor extent). Note that for paleo-polarities study alone, small inclination or declination variations won't result in false polarities

2.2 Quantifying the average incision rates

2.2.1. ~~Rieutord~~Local incision rate from burial ages (Rieutord Canyon)

———The relationship between burial ages and incision is shown in Figure 5. For the four caves, we

observed a good relationship between burial ages and finite incision, except for the Camp-de-Guerre cave (CDG) site, the higher the cave is, the older the burial ages are. Burial ages for the Cuillère cave, Dugou cave, Camp-de-Guerre cave and Route cave are 2.16 ± 0.15, 0.95 ± 0.14, 0.63 ± 0.1 and 0.21 ± 0.1 Myrs respectively. This is consistent with the supposed cave evolution and first-order constant incision of the Rieutord canyon. CDG age has to be considered with caution. The CDG cave entrance located in a usually dry thalweg can act as a sinkhole or an overflowing spring depending on the intensity of the rainfall. The sample was collected in a gallery showing evidence of active flooding ~10 m above the Rieutord riverbed, therefore the older than expected age, given the elevation of the cave, is probably due to cobbles that came from upper galleries during flood events. Forcing the linear regression to go through the origin, leads to an incision rate of 83 ± 35 $m.Ma^{-1}$. These results show that at least half of the 300 m deep Rieutord Canyon is a Quaternary incision. Extrapolating the obtained rate yields an age of 4.4 ± 1.9 Ma for the beginning of the canyon incision, which suggests that the current landscape has been shaped during the Pliocene-Quartenary period. To extend our spatial coverage and bring stronger confidence into our results, we combine Rieutord burial ages with paleomagnetic data from watersheds located on the other side of the Herault watershed.

2.2.2. Local~~South Grands Causses~~ incision rate from paleomagnetic data (Southern Grands Causses)

A total of 100 clay-infilling samples distributed over of 13 sites (i.e. profiles) ~~were~~was studied. The lowest sample elevation above sea level (a.s.l.) is in the Garrel (ca 190 m) and the highest in the Leicasse (ca 580 m a.s.l.). In the Leicasse cave system, we sampled 8 profiles totalizing 60 samples. Profiles elevations are located between ca 200 m and ca 400 m above the base level (a.b.l.), which corresponds to the elevation of the Buèges river spring at 170 m a.s.l.

In the Garrel cave system, we sampled 5 profiles totalizing 40 samples that range between 20 m and 80 m a.b.l. defined by the Garrel spring at 180 m a.s.l. Given the very marginal difference in elevation between the local base levels from these two caves, we assume that they have the same local base level. At each studied site~~s~~, if all the profile samples have the same polarity, the site is granted with the same polarity, either normal or reverse. If not (i.e. the profile displays normal and reverse polarities), we consider it as a transitional site. Figure 6 shows the results plotted with respect to the paleomagnetic scale (x axis) for the past 7 Ma, and their elevation above the base level (y axis). The measured paleomagnetic polarities on each site~~s~~ is plotted several times for given incision rates supposed to be constant through times (this allows determining different age models and analyze their correlation with the distribution of paleomagnetic data, see below). First, we note a good agreement between samples located at the same elevation elevation and being part of the same stratigraphic layer (Camus, 2003). This syngenetic deposition allows, as best explanation to prevent from a possible partial endokarstic reworking. Second, the different elevations of the galleries where we collected the samples allow proposing that the Leicasse deposits encompass at least three chrons,

while the Garrel deposits encompass only one. Third, a transitional signal comprised between a reversal signal (lower samples) and a normal signal (upper ones) is observed at Les Gours sur Pattes (LGP) sampling site (Fig. 7). This provides a strong constraint on the age of the sediment emplacement in the Leicasse with respect to the magnetostratigraphic timescale (Fig. 6).

Compared to the Leicasse cave system, the elevation/polarity results for the Garrel are less constrained. Only one site shows a reverse polarity at 90 m a.b.l., and the transitional polarity found at 40 m a.b.l. is unclear (tab, suppl mat.). The rest of the polarities (72 samples) are all normal. Given that a U-Th ages younger than 90 kyrs was obtained for two speleothems (Camus, 2003) covering our samples collected at 40 m a.b.l. (Fig. 6), we consider that the emplacement of the clays deposits occurred during the most recent normal period and are therefore younger than 0.78 Ma (Figure 6). The transition between the highest normal sample and the reversed one is located somewhere between 78 m and 93 m a.b.l. suggesting a maximum base level lowering rate of 109 ± 9 $m.Ma^{-1}$.

To go further in the interpretation of our data, and better constraint the incision rate, we performed a correlation analysis between observed and modelled polarities for a 0 to 200 $m.Ma^{-1}$ incision-rate range (linear rate, each 1 m.Ma-1). Modelled polarities are found using the intersection between sample elevation and incision-rate line.

We obtained 10 possible incision rates with the same best correlation factor (Fig. 8) spanning from 43 to 111 $m.Ma^{-1}$ (mean of 87 ± 24 $m.Ma^{-1}$). Taking into account the transitional signal of the LGP site in the Leicasse cave yields a linear incision rate of 83 $^{+17}/_{-5}$ $m.Ma^{-1}$. Proposed uncertainties are based on previous and next transition-related estimated incision rate.

Using a similar approach for the Rieutord crystalline samples, that is to say we compute, for the same incision-rate space, the distance in a least square sens between the modeled age and the measured ones in order to check the cost function shape and acuteness. With this method, we determined a linear incision rate of 85 ± 11 $m.Ma^{-1}$ (Fig 8). Those two results, based on independent computations, suggest the same first-order incision rate for the last 4 Ma of 84 $^{+21}/_{-12}$ $m.Ma^{-1}$. Given that the Rieutord, Garrel and Buèges rivers are all tributaries of the Hérault river, we propose that this rate represents the incision rate for the Hérault river watershed, inducing approximately 300-350 m of finite incision over the Pliocene-Quaternary period.

If the landscape is at first order in an equilibrium state, that is to say, if we preclude our incision rates being a regressive erosional signal, the incision needs to be balanced by an equivalent amount of uplift. If the uplift rate is roughly correlated to the regional topography, lowest uplift rates would be expected in the south of our sampling sites inducing regional tilting of morphological benchmarks. In the next part, we search for such evidences that would suggest differential uplift.

2.3 Geomorphometrical approachsignature

3.1 Tested hypothesis and methods

According to the Massif-Central centered uplift hypothesis, morphological markers such as strath terraces, fluvio-karstic surfaces or abandoned meanders should display a southward tilting due to differential uplift between the northern and the southern part of the region.

———To investigate these ~~different~~differential vertical movement signals, we used the morphological markers available ~~for~~in the study area (Fig. 9). We used a 5 m resolution DEM analysis to identify the markers corresponding to surfaces with slope < 2°. This cut-off slope angle prevents to identify surface related to local deformation such as for example landslide or sinkhole. We point out that ~~increasing in one~~ surface slope increase through time (e.g. apparent tilting) could be due to~~Other issue could be due to~~ diffusion processes ~~that could create apparent tilting~~ and not ~~because~~related ~~of~~to differential vertical displacements. However that problem is address by 1) the automatic selection and correction and the final manual check for residue random distribution (see below).The local river slope is on the order of 0.1° so the 2° cut-off angle is far from precluding to identify tilted markers. We also use a criterion based on an altitudinal range for a surface. This altitudinal span is set individually for each surface based on elevation, slope and curves map analysis, and encompass from few meters to tens of meters depending on the size of the marker. We checked 80% of the identified surfaces in the field in order to avoid misinterpretation. Some pictures are provided in supplementary material. The dip direction and angle of the surface in computed in a two steps approach. First, we fit a plan using extracted points from the DEM inside the delimited surface. Second, based on this plan we remove the DEM points with residuals 3 times larger than the standard error and compute more accurate plan parameters (second fitting). This outlier suppression removes any inaccurate DEM points and correct for inaccurate surface delimitation (e.g. integration of a part of the edge of a strath terrace, diffusion processes marks, etc.).

Because no obvious initially horizontal markers are known, we propose to correct the marker current slope by the initial one to quantify the tilt since the marker emplacement. To do so we follow the method used by Champagnac et al. (2008) for the Forealps. We identify the drain related to the marker formation and compute its current local slope and direction. This method assumes that landscapes are at the equilibrium state and that the river slope remained constant since the marker formation. This assumption seems reasonable given the major river profiles and because most of the markers used are far from the watershed high altitude areas precluding a recessive erosional signal. Finally, we removed the local river plan from the DEM extracted surface.

3.2. Morphometrical results

Following this methodology, we obtained 61 surfaces. We then applied three quality criterions to ensure the robustness of our results: 1) The minimal surface considered is 2500 m^2 based on a comparison between the 5m resolution DEM and a RTK GPS survey over 3 strath terraces (Hérault river); 2) Final plans with dip angles larger than 2° are removed; 3) The residuals for each geomorphological marker must be randomly distributed without marker edge signal, or clear secondary structuration. Only 38 markers meet those 3 quality criterions.

If the identified and corrected markers haved indeed registered ana differential uplift between the north and the south, we expected the following signals:

- The dipping direction of the tilted markers should be parallel to the main gradient of the topography, i.e. between 150°E and 180°E for our studied region. This expectation is the most important one, regarding uncertainties on the uplift rate and lithospheric elastic parameters.

- A latitudinal tilting trend, i.e. an increase of the tilt angle along the topography gradient. Indeed, null or small tilts are expected near the shoreline and within the maximum uplift area of the Cevennes/Massif Central, while the maximum tilt is expected at a mid-distance between these two regions, i.e. about 50 km inland from the shoreline.

- A positive altitudinal tilting trend (an increase in dip angle with altitude). This trend would be representative of the accumulation of finite tilt. However, it supposes a linear relationship between the altitude and the age of the marker formation. If at first order, this straightforward hypothesis seems reasonable for river-controlled markers (e.g. strath terraces), other surfaces are hardly expected to follow such an easy relationship.

Among the three expected signal, southward dipping is robustly recorded with a mean tilt angle of 0.60 ± 0.40 ° with an azimuth of N128 ± 36°E (Fig. 10). Latitudinal trend and altitudinal trend are less robustly reached but that is not surprising because of the strong susceptibility to local phenomenon or even so lack of robust age constraint.

43 DiscussionNumerical modelling

Both geomorphological and geochronological evidence suggest a Pliocene-Quaternary uplift of the Cevennes area. The origin of such uplift could be associated with several processes: erosion-induced isostatic rebound, dynamic topography due to mantle convection, thermal isostasy, residual flexural response due to the Gulf of Lion formation, etc. For the Alps and Pyrenees mountains, isostatic adjustment due to erosion and glacial unloading has been recently quantified (Champagnac et al., 2007, Vernant et al., 2013; Genti et al, 2016, Chery et al. 2016). Because the erosion rates measured in the Cevennes are similar to those of the Eastern Pyrenees (Calvet et al., 2015, Sartégou et al., 2018a), we investigate by numerical modelling how an erosion-induced isostatic rebound could impact the southern Massif Central morphology and deformation.

We define a representative cross-section parallel to the main topographic gradient (i.e. NNW-SSE) and close to the field investigation areas (Figure 11). We study the lithospheric elastic response to erosion with the 2D finite element model ADELI (Hassani et Chery, 1996; Chéry et al. 2016). The model is composed of a plate accounting for the elasticity of both crust and uppermost mantle. Although the lithosphere rigidity of the European plate in southern Massif central is not precisely known, vertical gradient temperatures provided by borehole measurements are consistent with heat

flow values ranging from 60 to 70 mW.m^2 (Lucazeau et Vasseur, 1989). Therefore, we investigate plate thickness ranging from 10 to 50 km as done by Stewart et Watts (1997) for studying the vertical motion of the alpine forelands. We choose values for Young's and Poisson parameters of respectively 10^{11} Pa and 0.25, both commonly used values for lithospheric modelling (e.g. Kooi et Cloething, 1992; Champagnac et al. 2007, Chéry et al., 2001). This leads to long-term rigidity of the lithosphere model ranging from 10^{21} to 10^{25} N.m. Since the effect of mantle viscosity on elastic rebound is assumed to be negligible at the time scale of our models (1 to 2 Myrs), we neglect the visco-elastic behaviour of the mantle. Therefore, the base of the model is supported by an hydrostatic pressure boundary condition balancing the weight of the lithosphere (Fig. 11). Horizontal displacements on vertical sides are set to zero since geodetic measurements show no significant displacements (Nocquet et Calais, 2003; Nguyen et al., 2016). The main parameters controlling our model are the erosion (or sedimentation) triggering isostatic rebound and the elastic thickness. The erosion profile (Fig. 11) is based on topography, our newly proposed incision rate and other studies (Olivetti et al., 2016 for onshore denudation and Lofi et al., 2003; Leroux et al., 2014 for offshore sedimentation). This profile is a simplification of the one that can be expected from Olivetti et al. (2006) and do not aim at matching precisely the published data because of, first, the explored time-span (~ 1 Myrs) is not covered by thermochronological data (> 10Myrs) or cosmogenic denudation rate (10s-100s kyrs). Second, we base our erosion rate as being linked with local (10s km^2) slopes, that are higher near the drainage divide. We, by this aim can invoke any kind of erosion processes (e.g. landslides). Third, the model suppose a cylindrical structure and then, high-frequency lateral variations in term or actual denudation rate or proxy (slope, elevation, etc.) must be averaged. Concerning this erosion profile, parametric study (highest erosion rate ranging from 1 to 1000 m.Myrs^{-1}) give no difference in the interpretation and, for few percent variations, only few percent variations in the modeled uplift-rate.

The flexural rigidity controls the intensity and wavelength of the flexural response and ranges from 10^{21} to 10^{25} N.m. It can be expressed as a variation in elastic thickness (Te) ranging from 4.4 to 96 km (Fig. 12). We also test a possible Te variation between inland and offshore areas. For the following discussion, we use an elastic thickness of 15km corresponding to a value of D of 3.75 x10^{23} N.m^{-1}. In this case, the inland and offshore parts are largely decoupled and the large sedimentation rate in the Gulf of Lion does not induce a flexural response on the Cévennes and Grands Causses areas. With a maximum erosion rate of 80 m.Ma^{-1} (Fig 11), the models display uplift rates of 50 m.Ma^{-1} over more than 100 km. As previously explained, the finite incision is permitted by an equal amount of uplift considering that the incision is not due to regressive erosion. If all tested models show uplift, the modelled amplitudes are smaller than the expected ones. To obtain the same uplift rate than the incision rates, the applied erosion rate over the model must be increased. However, we assume that the landscape is at equilibrium, so, if the erosion rate is increased, it will be higher than the incision rate leading to the decay of relief over the area. No evidence of such evolution is found over the region and, if further studies need to be done to quantify the actual erosion rate, we mostly think that a second process is acting, inducing the rest of the uplift that can't be obtained by the erosion–induced

isostatic adjustment. Finally, models predict a seaward tilt of the surface at the regional-scale (Fig. 13), in agreement with the observed tilting of morphological markers.

~~4. Discussion~~

———We assume that the sediments collected in the karst were deposited per descensum, i.e. we do not know if the galleries existed a long time before or were formed just before the emplacement of the sediments, but the more elevated the sediments are, the older their deposit is. If there is no evidence of an important aggradation episode leading to more a complex evolution as proposed for the Ardèche canyon (Moccochain et al., 2007; Tassy et al., 2013), we point out that small aggradation or null erosion period could, however, be possible. Some processes could explain such relative stability: e.g. variation in erosion (due to climatic fluctuation) or impact of eustatic variations (in river profile, flexural response, etc.). Such transient variations have been shown for the Alps (Saillard et al., 2014; Rolland et al., 2017) and are proposed as being related to climato-eustatic variations and therefore should last 10 to 100 kyrs at most.

Based on our sampling resolution, we cannot evidence such transient periods and we must use an average base level lowering rate in the karst, which we correlate to the incision of the main rivers. The TCN-based incision rate derived from the Rieutord samples (83 ± 35 m.Ma^{-1}) is consistent with the one derived from the Garrel (U-Th ages: 85.83 m.Ma^{-1} according to the sole U/Th exploitable result (Camus, 2003)) and from the Garrel-Leicasse combination (Paleomagnetic approach: 84 $^{+21}/_{-12}$m.Ma^{-1}). This mean incision rate of ca. 85 m.Ma^{-1} lasting at least 4 Ma, highlights the importance of the Pliocene-Quaternary period into the Cévennes and Grand Causses morphogenesis. Furthermore, the 300 to 400 m of incision precludes a relative base level controlled by a sea-level drop. Indeed, documented sea level variations are less than 100 m (Haq, 1988, Miller et al., 2005). Furthermore, the Herault river does not show any significant knickpoints or evidence of unsteadiness in its profile as expected if the incision was due to eustatic variations. Therefore, we propose that the incision rate of ~85 m.Ma^{-1} is due to a Pplio~~quaternary~~ Quaternary uplift of the Cévennes and Grands Causses region.

———Other river-valley processes could lead to a local apparent high incision rate as for instance major landslide or alluvial fan (Ouimet et al., 2008). This hypothesis of an epigenetic formation of the Rieutord is irrelevant because of i) none of the possible causes had been found in the Rieutord canyon and ii) the consistency of the TCN-based incision rate and the paleomagnetic-based incision rate for two other cave-systems. Indeed, the use of two independent approaches and three locations is a good argument in favour of the robustness of our proposed mean 85 m.Ma^{-1} incision rate. Yet, using more data, particularly burial dating colocalized with clays samples and adding sampling sites would give a stronger statistical validation. In the Lodève basin (Point 4, fig. 1), inverted reliefs allow another independent way to quantify minimal incision rate. K/Ar and paleomagnetic dated basaltic flows

spanning from 1 to 2 Myrs old that were deposited at the bottom of the former valley (Dautria et al., 2010) are now located at ca 150 m above the current riverbed leading to an average incision rate of 77 ± 10 m.Myr^{-1}, in agreement with karst-inferred incision rates.

Furthermore, preliminary results from canyons on the other side of the Grands Causses (Tarn and Jonte) based on in-situ terrestrial cosmogenic dating suggest similar incision rates (Sartegou et al., 2018b) and confirm a regional base level lowering of the Cévennes and Grands Causses region during the Pliocene-Quaternary. This is consistent with the similarities of landscapes and lithologies observed both on the Atlantic and Mediterranean watersheds (e.g. Tarn river).

———Once the regional pattern of the Pliocene-Quaternary incision established for the Cévennes-Grands Causses area, the next question is how this river downcutting is related to the regional uplift? First order equilibrium shape and absence of major knick points in the main river profiles preclude the hypothesis of regressive erosion. Hence, back to the three conceptual models presented in part 1 (Fig.2), we can discard, at first order, the models A (Old uplift-recent incision) and B (Old uplift-old incision) because obtain incision rate show recent incision and surface tilting tend to prove a current uplift. Therefore, the incision rate has to be balanced to the first order by the uplift rate. We add that eustatic variations are of too low magnitude (100-120 m) and can't explain such total incision (up to 400m). Furthermore, no obvious evidence of active tectonic is reported for the area raising the question of the processes responsible for this regional uplift. Very few denudation rates are reported for our study area (Schaller et al., 2001; Molliex et al., 2016; Olivetti et al., 2017), and converting canyon incision rates into denudation and erosion rates is not straightforward, especially given the large karst developed in the area. Using a first order erosion/sedimentation profile following the main topography gradient direction we have modelled the erosion-induced isostatic rebound. If this process could create between half and two third of the Pliocene-Quaternary uplift, a previously existent topography is needed to trigger erosion so it cannot explain neither the onset of the canyon-carving nor the full uplift rates. Other, processes have to be explored such as dynamic topography or thermal anomaly beneath the Massif-Central, the magmatism responsible for the important increase in volcanic activity since ~ 6 Myrs (Michon et Merle, 2001; Nehlig et al., 2003) could play a major role, notably in the initiation of Pliocene-Quaternary uplift. Further studies should aim to address the problem of uplift onset, giving more clues concerning the stable continental area but owing the data we presently have, discussing such onset is out of the scope of the paper.

55. Conclusion

Main results of this study are the following three points:

1- Mean incision rate of the Cevennes area is 83 $^{+17}/_{-5}$ m.Ma^{-1} during the last 4 Ma.

2- This incision is due to regional uplift with higher vertical velocities northward.

3- This uplift is partly due (½ to 2/3) to isostatic adjustment induced by erosion.

Furthermore, our study highlights the importance of multidisciplinary approach especially in the study of low-deformation rate areas.

To the contrary of previous studies that focused on one cave, we have shown that combining karst burial ages and paleomagnetic analysis of clay deposits in several caves over a large elevation range can bring good constraints on incision rates. This multi-cave system approach diminishes the intrinsic limits of the two single methods: low sampling density (and analysis cost) for the TCN ages and difficulty to set the position of paleomagnetic results. Our estimated paleo base level ages are Pliocene-Quaternary (ca. last 4 Ma) and allow to derive a mean incision rate of 83 $^{+17}/_{-5}$ m.Ma^{-1} for the Cevennes area.

The landscape, and especially the river profiles suggest a first-order equilibrium allowing considering the incision rate as an uplift rate.

~~We propose that related erosional isostatic adjustment is of major importance for the understanding of the southern French Massif-Central landscape evolution and explain a large part of the uplift. However, it is not the only process involved and we hypothesize that is could be especially combined with dynamic topography related to the Massif Central magmatism. Both mechanisms imply an uplift centered on the Massif Central and a radial tilt of the geomorphological surfaces.~~ We have shown using a geomorphological analysis that at least south of the Cévennes, several surfaces are tilted toward the SSE. This kind of study had been performed before on large structures (Champagnac et al., 2007) or endokarstic markers (Granger et Stock, 2004) but it is the first time that it is performed at such scale with small markers. Numerical modeling~~modelling~~ yields the same pattern of SSE dipping, allowing more confidence in the geomorphometric results.

Our multi-disciplinary approach brings the first absolute dating of the Cévennes landscapes and suggests that the present-day morphology is partly inherited from the Pp~~p~~lio-~~quaternary~~ Quaternary erosion-induced isostatic rebound.

We propose that related erosional isostatic adjustment is of major importance for the understanding of the southern French Massif-Central landscape evolution and explains a large part of the uplift.

At larger scale, we assume that the main conclusion ~~draw from this area~~of our study can be extrapolated to the majority of the intraplate orogens. That is to say, once the forces responsible for the initial uplift (e.g. plate tectonics, dynamic topography) fade out, the uplift continue thanks to erosion-induced isostatic adjustment.~~That is to say, on need a deep-seated phenomenon as dynamic topography, to trigger an uplift. This uplift is secondly enhanced by erosion and related isostatic adjustment.~~

~~A strong uplift impact is assumed to be due to magmatic-related dynamic topography that could explain another part of the uplift as well as the onset of such uplift that has afterward been accelerated by the erosion-induced isostatic rebound. These results enlighten the importance of surface processes into lithospheric-scale dynamic and vertical deformations in intra-plate domains.~~

~~———~~An analysis at the scale of the Massif Central is now needed before nailing down our interpretations of the Massif-Central dynamic. ~~, but such study will more likely highlight the importance of erosion processes to explain uplift of intraplate orogens, and will show that another process is needed for the Massif Central, which will most likely be dynamic topography related to magmatism.~~

Code and data availability

Surface analysis was performed using QGIS version 2.18, MAtlab® code and IGN DEM (RGE Alti®) 5m). Modeling was performed using ADELI code (Hassani et Chery, 1996; Chéry et al., 2016). Data for TCN and paleomagnetic analysis are provided in the manuscript itself or in supplementary material. Additional informations for geologic background are available at http://infoterre.brgm.fr/ (French Geological Survey data visualizer).

Author contributions

OM, PV and GC did the sampling. GC and DF performed the TCN analysis. PC and OM did the magnetic measurements and interpretations. OM did the surface identification and analysis. OM, PV and JC performed the numerical model. OM, OV, JFR, GC, PC, JC and DF interpreted and wrote the article.

Competing interests

The authors declare that they have no conflict of interest.

Acknowlegdments

We are grateful to ANSTO for providing facilities for chemical extraction for the TCN analysis. We thanks the reviewers for useful remarks and comments that we think help to increase the level of the paper.

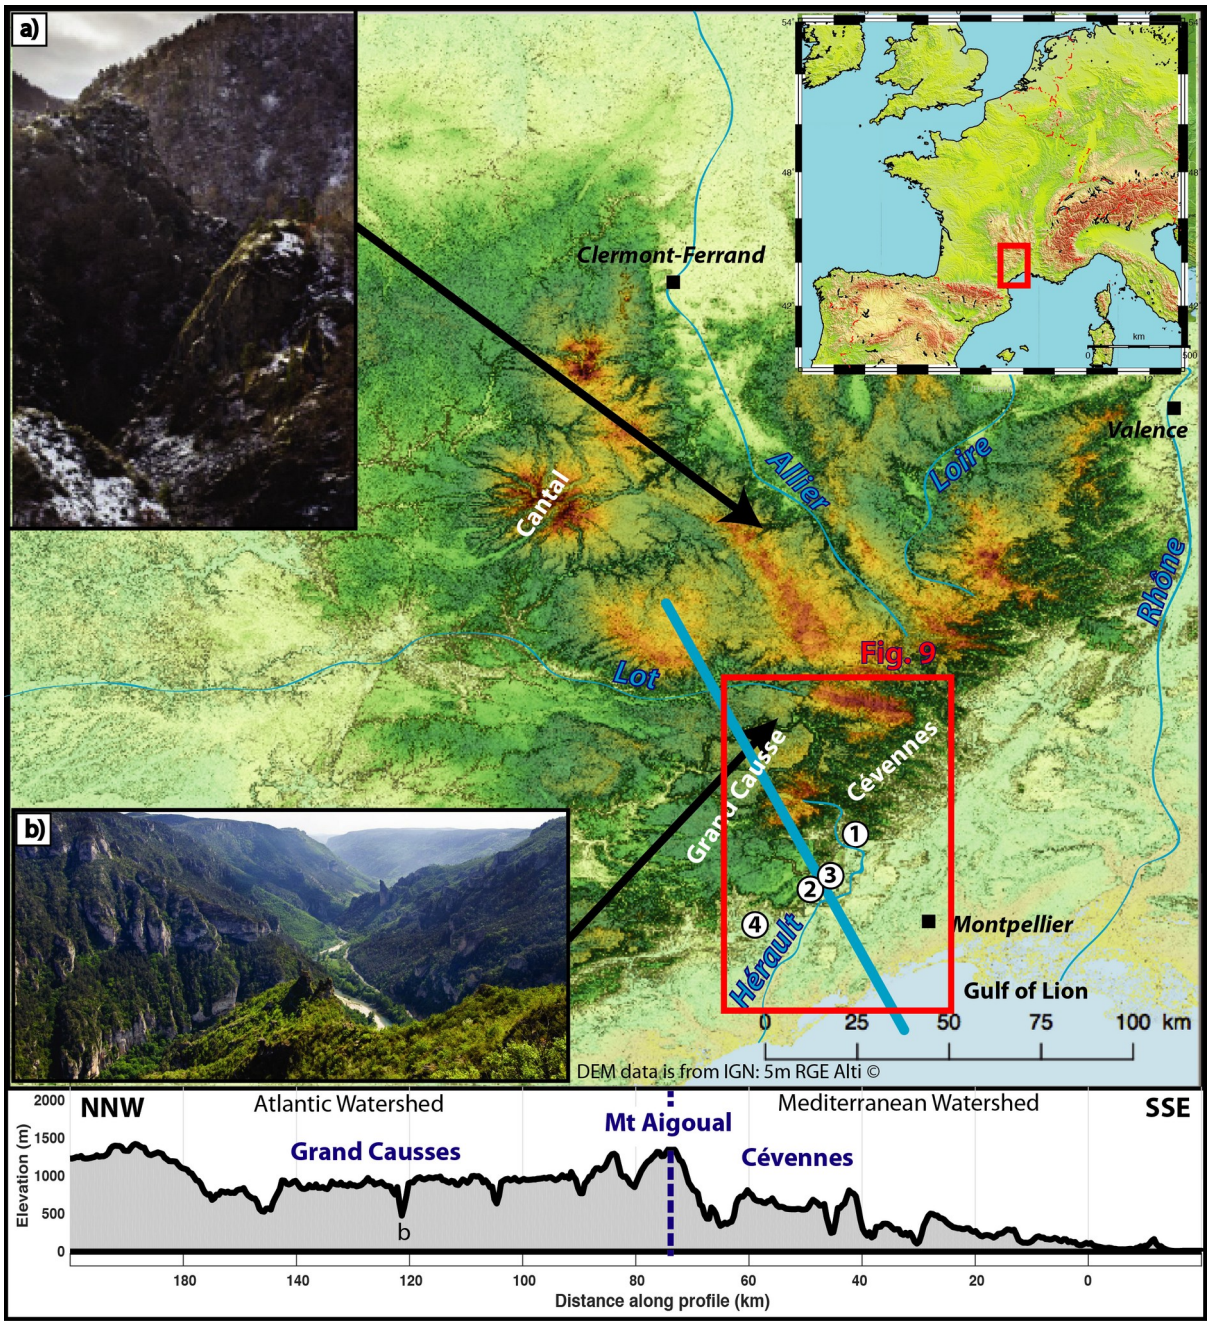

Figure 1: 30 m resolution DEM of the French Massif-Central and slope shadowed. Examples of finite incision typical of the French Massif-Central in a) crystalline area (Seuge Canyon) and b) limestone plateau (Tarn Canyon) Location of the restricted studied area in red box (fig. 9) and numerated site 1) is the Rieutord Canyon (43,958°N; 3.709°E) where TCN measurements have been done, 2) and 3) are the Leicasse Cave System (43,819°N; 3.56°E),and the Garrel Cave system (43,835°N; 3.616°E) respectively, where paleomagnetic analysis have been done and 4) is the Lodève basin (43,669°N; 3.382°E) with dated basaltic flows. Bottom panel is an example of typical topographic profile used for numerical model set up.
Note the south-western area with large plateau dissected by canyon, and the rugged area with steep valley called the Cevenne. They are typical regional limestone and crystalline morphology respectively.

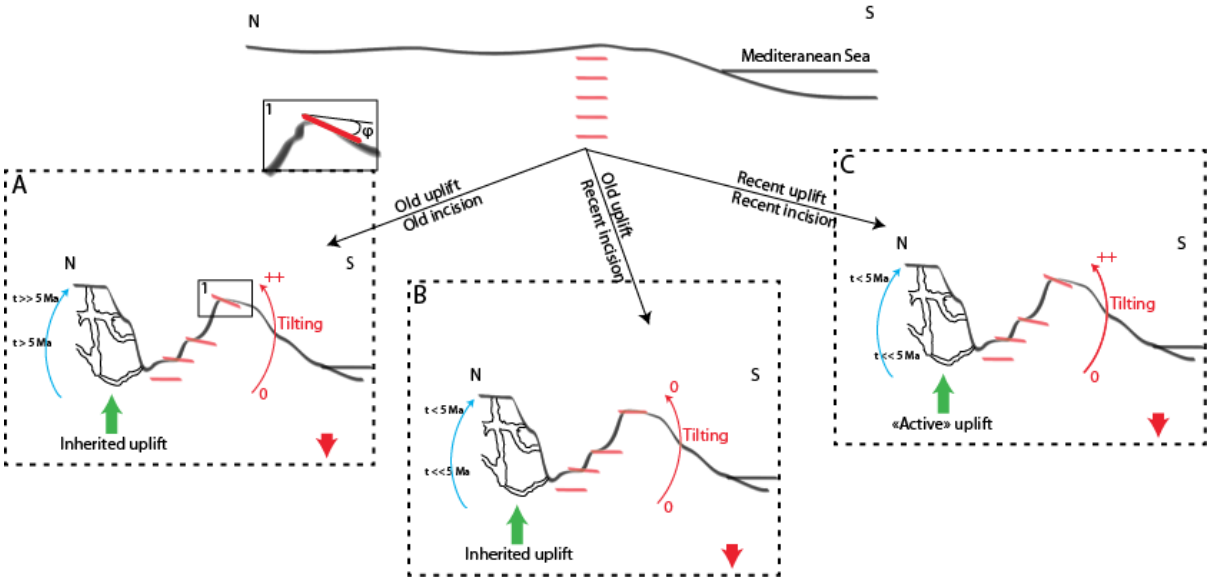

Figure 2: conceptual models for landscape evolution. Top panel is the initial stage (prior to uplift). Each panel represent a possible scenario explaining current morphology: A) Old uplift and old incision, B) Old uplift and recent incision and C) both recent uplift and incision. Blue arrow and associated ages show expected result (or absence of) for burial dating. Red level represents morphological markers that are fossilised when reaching the surface, accumulating afterward (or not) the differential uplift by finite tilting.

Figure 3: Example of quartz cobbles sampled for burial dating. Location: Cuillère Cave

Figure 4: Example of clay sampling for the paleomagnetic study. Location at the entrance shaft (Highest elevation of every samples (~580 m a.s.l.), Leicasse Cave system)

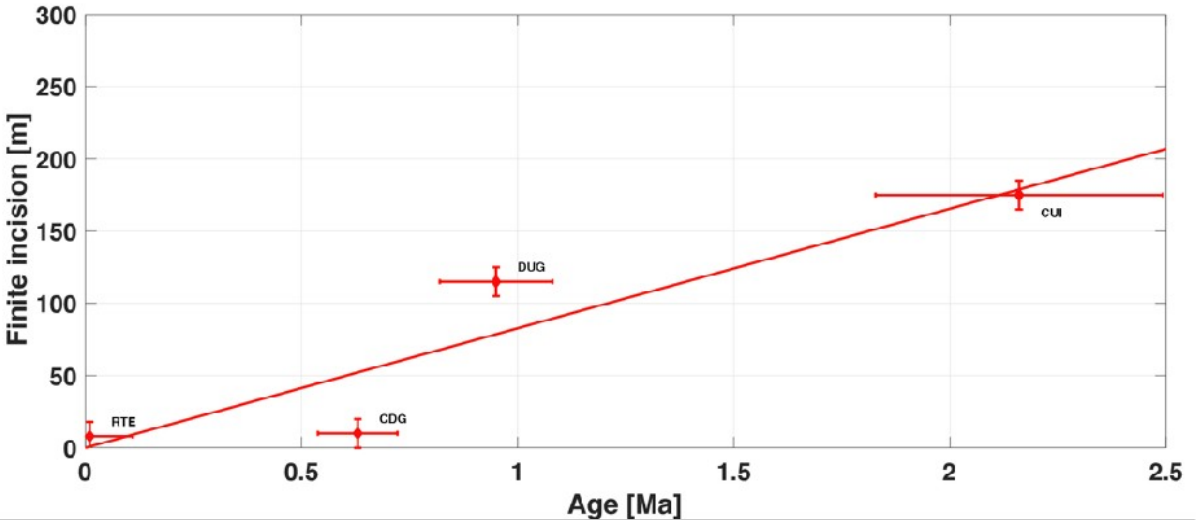

Figure 5: Relation finite incision-burial age for the Rieutord canyon. Finite incision is the elevation of the sampling site relatively to the current riverbed. RTE for Route Cave, CDG for Camp de Guerre Cave, DUG for Dugou Cave and CUI for Cuillère Cave

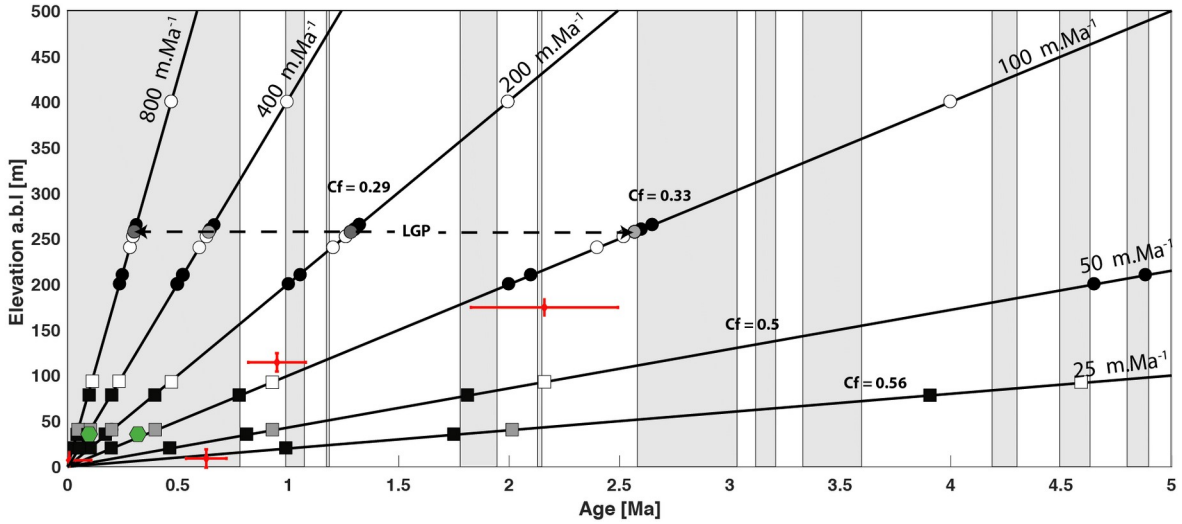

Figure 6. Constraining the incision rate in the Cevennes margin, using paleomagnetic polarities from clay deposits (black, grey and white symbols) and burial ages (red crosses): Circles are from the Leicasse cave with LGP being *les gours sur pattes profile (see text)*, squares are from the Garrel cave. Black, grey and white symbols correspond to normal, transitional and reverse polarities, respectively. Black linear straight lines define possible incision rates that are supposed stable thought time. (numbers in white rectangles define the Cf values are Ccorrelation factor between the measured paleomagnetic polarities and the predicted paleomagnetic scale (see also Figure 8). Green hexagons show the U/Th ages obtained in the Garrel by Camus (2003).

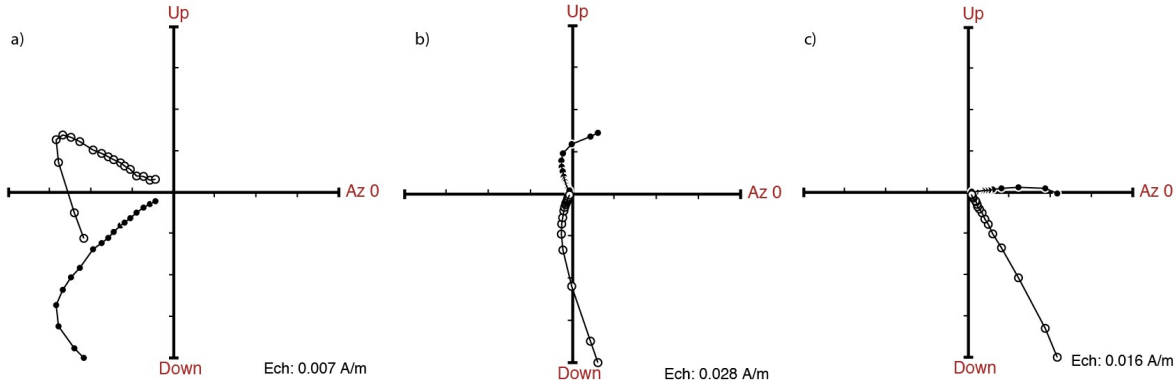

Figure 7: Zijderveld Diagram for three samples from the Gours-sur-Pattes (Leicasse) site. Stratigraphical order is from a) (the older, base of the profile) to c) (the younger, top of the profile.

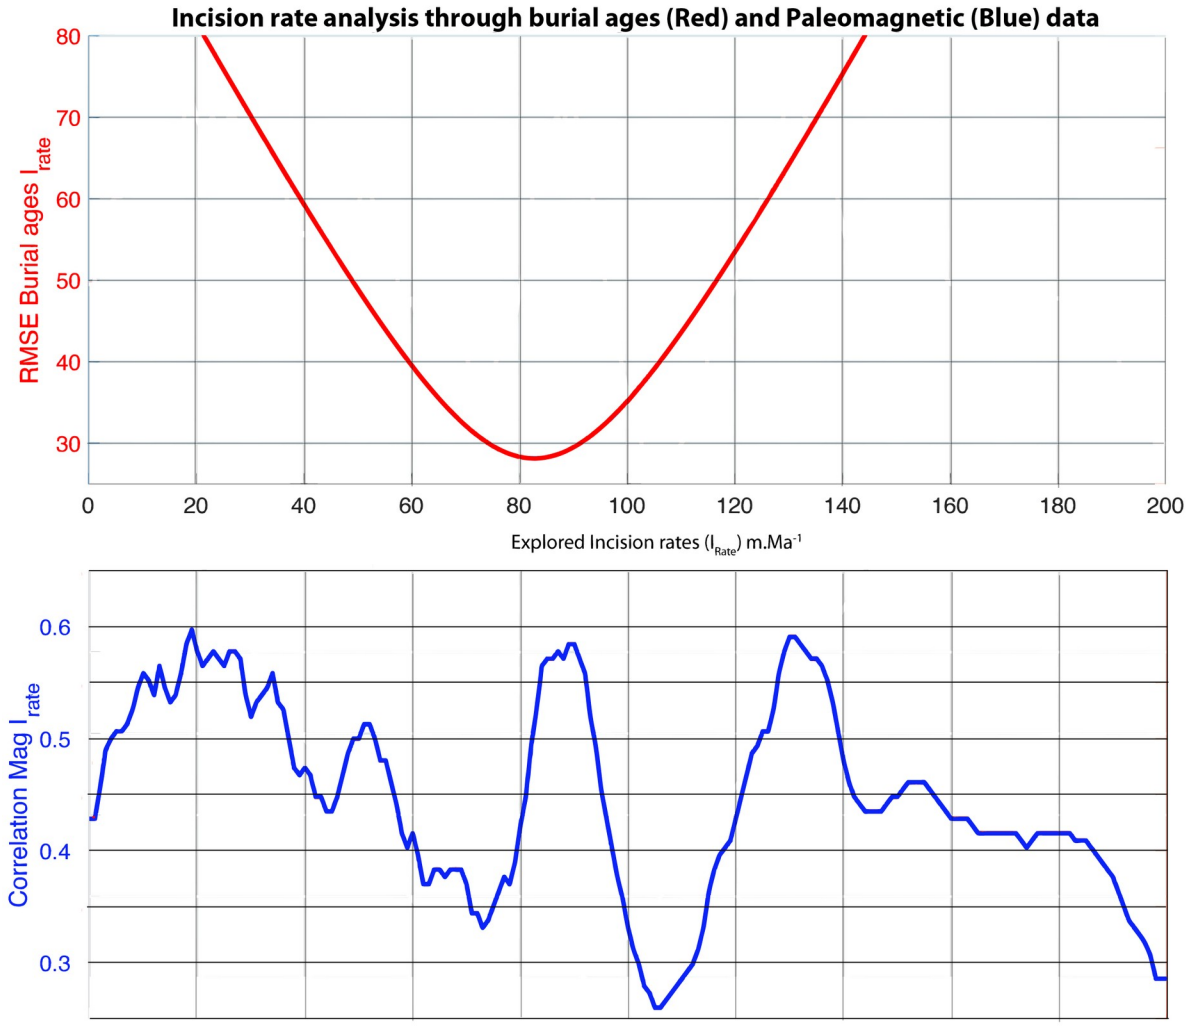

Figure 8: Best incision rate based on paleomagnetic data (blue) and burial ages (red). The blue curve is the normalised smoothed (10 m/Ma sliding window for better visualisation) correlation between theoretical and observed polarities. The highest correlation corresponds to the best incision rates. The red curve is the RMSE for the linear regression through the burial ages data set shown on Fig. 4.

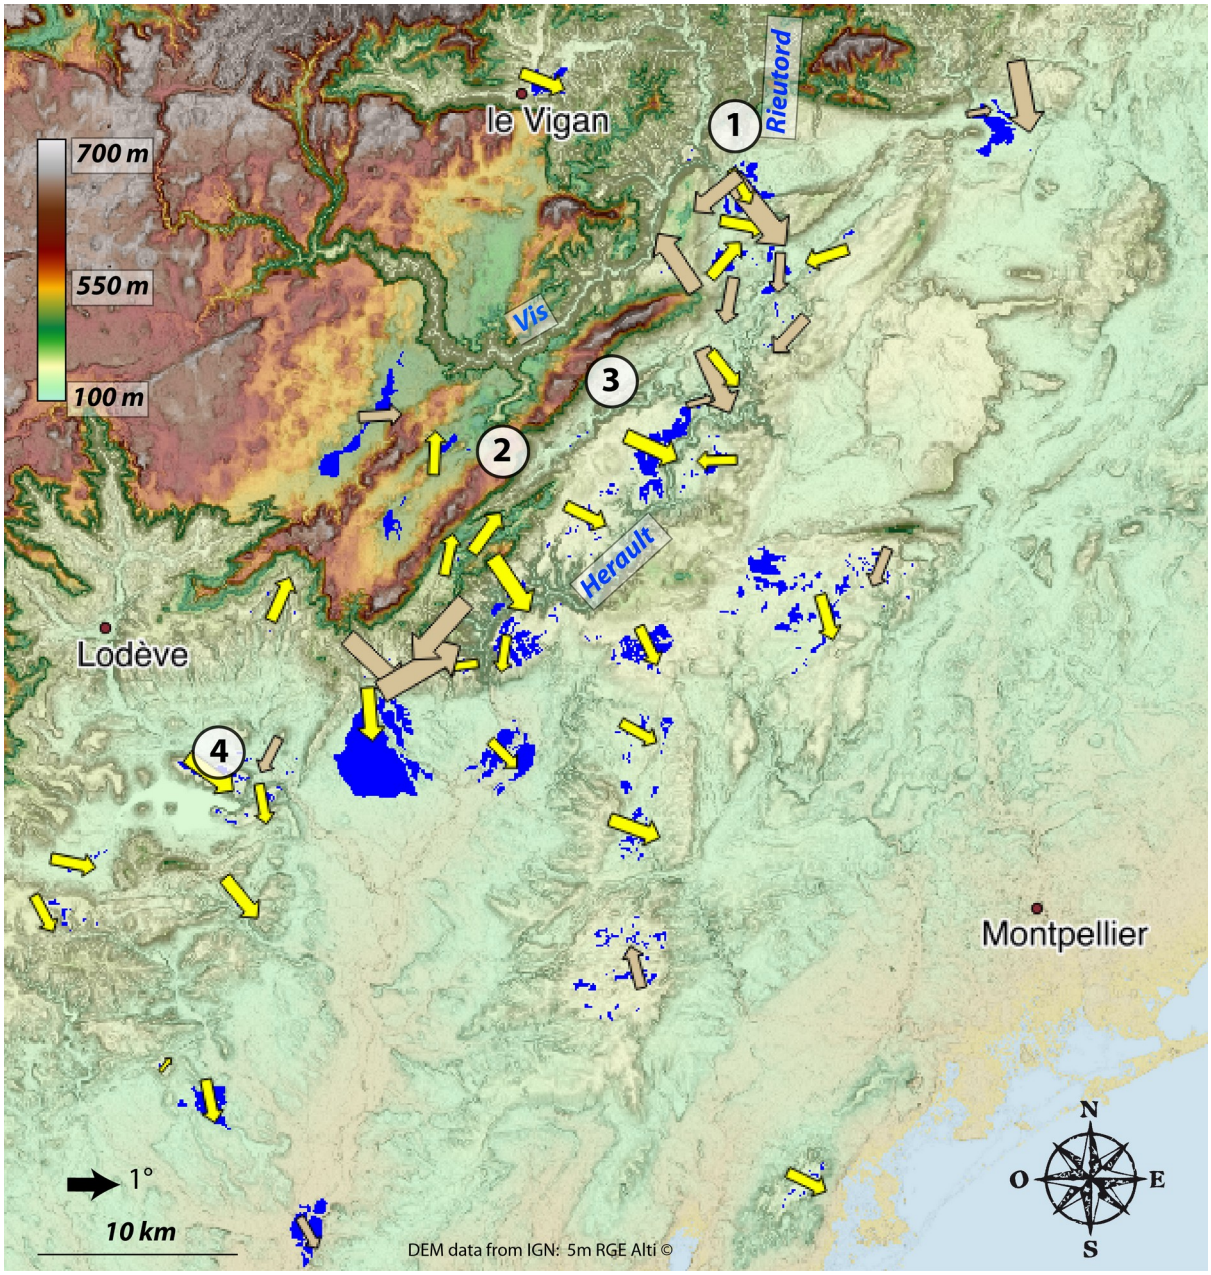

Figure 9: Tilting map of geomorphological benchmark (blue areas). Fond-map is 30 m resolution DEM with slope shadow. Arrows are orientating according to the marker downward dip and sized according to the corrected tilting angle (the bigger, the more the tilting). Yellow and brown arrows are for robust and rejected surfaces respectively. Several arrows are hidden because of their small size and too high proximity with bigger ones. Numerated site 1) is the Rieutord Canyon, 2) is the Leicasse Cave System, 3) is the Garrel Cave system and 4) is the Lodève basin with dated basaltic flows. See Fig. 1 for geographical coordinates.

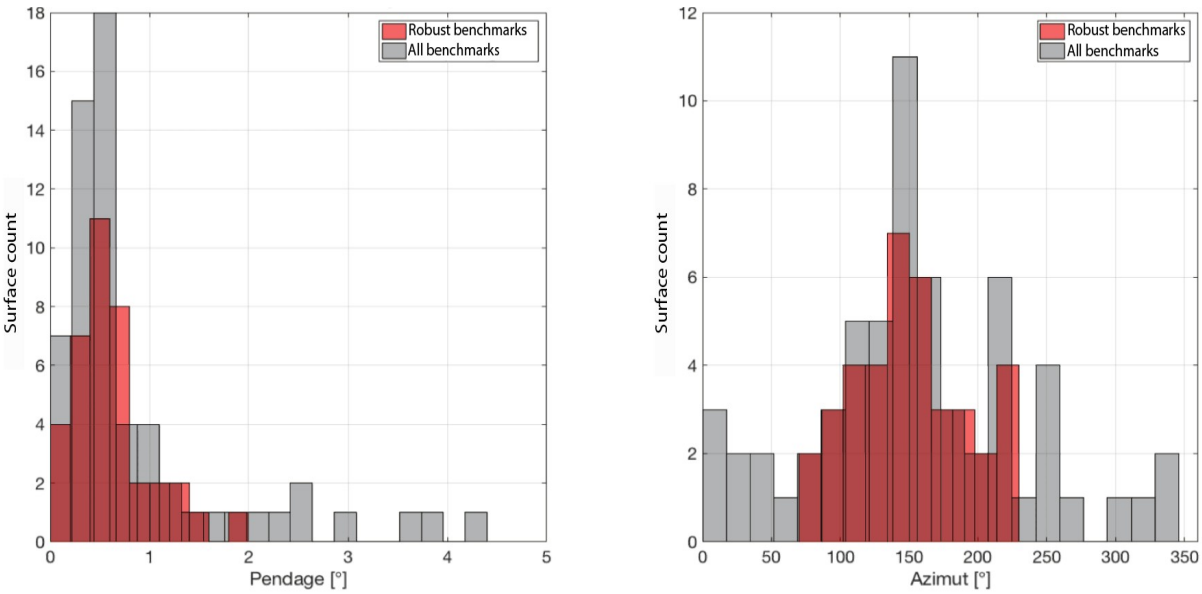

Figure 10: Tilting and azimuth distribution. Left panel is density distribution for surface maximum tilting in degree. Right panel is azimuth of maximum dipping relative to the north. For each histogram, red and grey populations are for robust and primary detected markers.

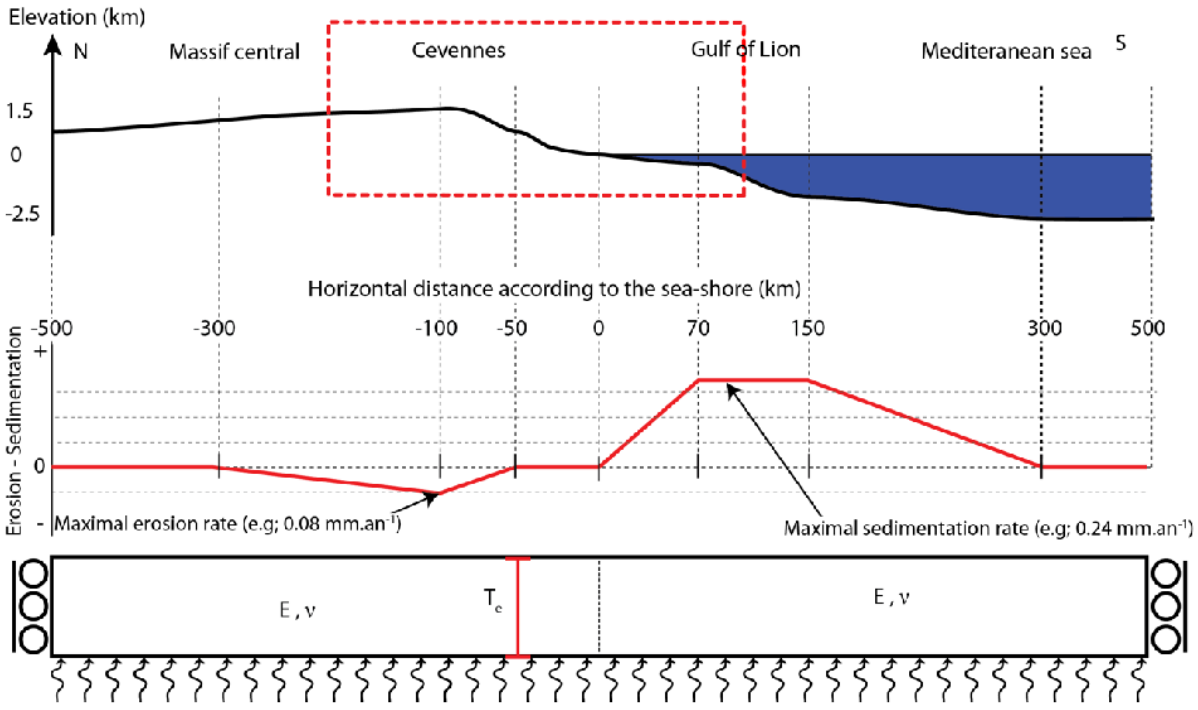

Figure 11: Top panel: schematic topographic profile. The red box delimites the area shown fig. 1 and 9. Middle panel, surface processes profile, negative values are for erosion and positive values for sedimentation. Bottom panel: model set-up with two compartments (one for the Cevennes area and the second on for the gulf of lion). The base of the model is compensated in pressure and the right and left limits are fixed at zero horizontal velocities and free vertical ones. Te is the equivalent elastic thickness (in km), E (Pa) and ν are the Young modulus and the Poisson coefficient respectively whom values are independent in each compartment.

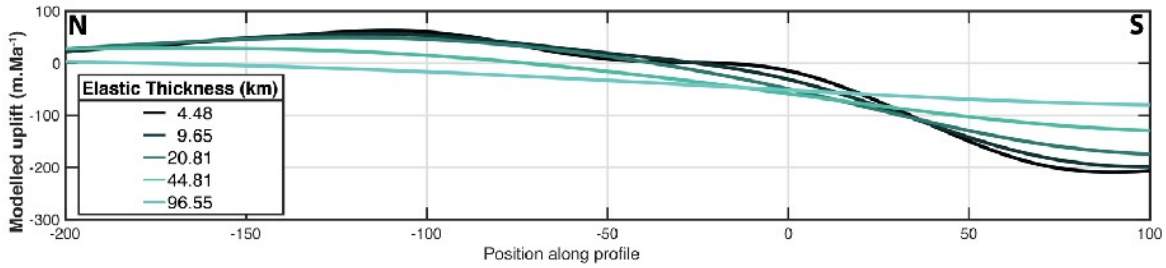

Figure 12: Modelled uplift according to different Te. Most probable Te are between 10 and 30 km.

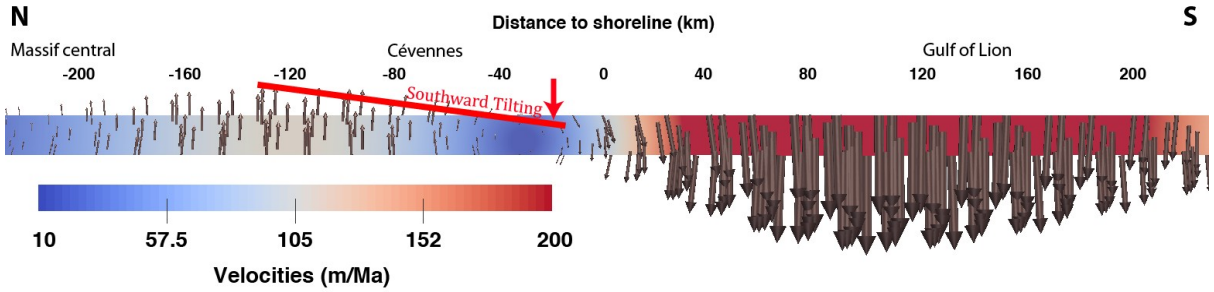

Figure 13: Modelling result for Te= 15km. Erosion-sedimentation rate profile is the same as in fig. 6. Velocity field is shown using arrow for scale and orientation and ~~colour~~color code for value. Black values on top are distance relative to the sea-shore (positive value landward and negative values seaward). Red line represents the southward modelled tilting due to differential uplift.

Cave	Lat	Lon	Elevation	height (a.b.l)	^{10}Be conc (atom/g)	σ ^{10}Be (atom/g)	^{26}Al conc (atom/g)	σ ^{26}Al (atom/g)	26Al/10Be (and error)	Burial age (Ma)	Burial age error (Ma)

Table 1: Samples analytical results and parameters. Cave code are: RTE for the “de la route” Cave, CDG for the “Camp de Guerre” cave, DUG for the “Dugou” Cave and CUI for the “Cuillère” Cave. Main parameters are the geographical coordinate (Lat, Lon in decimals degree), the elevation (a.s.l), the height (a.b.l., computed relatively to the surface river elevation. The concentration (atoms/g quartz) of 10Be and 26Al in collected sand samples are all AMS 10Be/Be and 26Al/Al isotopic ratios corrected for full procedural chemistry blanks and normalised to KN-5-4 and KN -4-2, respectively.The error () is for total analytical error in final average 10Be and 26Al concentrations based on statistical counting error s in final 10Be/Be (26Al/Al) ratios measured by AMS in quadrature with a 1% error in 9Be spike concentration (or a 4% error in 27Al assay in quartz) and a

920 2% (or 3%) reproducibility error based on repeat of AMS standards. Burial age (minimum) assuming no post-
921 burial production by muons at given depth (all deeper than 30m) in cave below surface and assuming initial
922 26Al/10Be ratio is given by the production ratio of 6.75. The burial age error determined by using a +/-1σ
923 range in the measured 26Al/10Be ratio
