Abstract

A multiple magmatic intrusions model has been proposed by Urbani et al. (2020) for the resurgence of the Los Potreros caldera floor, in the Los Humeros Volcanic Complex. This model predicts (1) the occurrence of few localized bulges in the otherwise not deformed caldera floor, and (2) that the faults corresponding to different bulges exhibit different spatial and temporal evolution. Already available field data from easily accessible outcrops and a simple morphological analysis show that these two conditions are not met at Los Potreros caldera. Also, a geothermal well (H4), located in the most recent supposed bulge for which Urbani et al. (2020) calculated an intrusion depth (Loma Blanca, intrusion depth of 425±170 m), doesn't show any thermal and lithological evidence of such a shallow cryptodome. Finally, already published stratigraphic data and radiometric dating apparently disprove the proposed correlation between extruded viscous lavas and faulting. Thus, even if recent shallow intrusions may exist in the area, Urbani et al. (2020) fails to provide any useful information on their occurrence, location, age, emplacement depth, role in the resurgence of the Los Potreros caldera floor, and influence on the structure of the Los Humeros geothermal field.

1 Introduction

Urbani et al. (2020) (henceforth U2020) made a contribution to the study of caldera resurgence based on field data and geothermal well logs from the Los Humeros Volcanic Complex (LHVC) and scaled analogue models. U2020 constrained the spatial–temporal evolution of post–caldera volcanism at LHVC and estimate the depth of the magmatic intrusions feeding the active geothermal system by integrating the fieldwork data, well logs and laboratory results.

The main conclusion of U2020 is that the resurgence of the Los Potreros caldera in the LHVC "*is due to multiple deformation sources*", "*linked to small magmatic intrusions located at relatively shallow depths (i.e. < 1 km)*". U2020 suggested that these intrusions should be located below three uplifted areas surrounding the Arroyo Grande, Los Humeros and Loma Blanca faults, respectively.

The analysis by U2020 suffers from poor field data (Section 2), geometric and structural inconsistencies between the LHVC post–caldera deformation and the analogue modelling (Section 3), lack of any substantial validation of the results with the available well logs (Section 4), and contradictions with the reference stratigraphy and radiometric ages recently published by some of the U2020 authors (Section 5). These problems, which largely undermine their conclusions, are discussed below.

2 Location and relative age of faulting

The occurrence and relative age of faulting is analysed by U2020 observing faults and hydrothermal alteration in the Holocene Cuicuiltic Member unit (Dávila–Harris and Carrasco–Núñez, 2014). The Cuicuiltic Member blankets the whole area, is very well exposed, has been dated at ca. 7 ka and is made of alternated fallout

deposits of different composition and colour (Dávila–Harris and Carrasco–Núñez, 2014). The Cuicuiltic Member has been considered an ideal marker layer for documenting Holocene faulting and stratigraphy in the caldera complex, because of the contrasting black and white colours of the alternated fallout deposits composing the unit (e.g. Dávila–Harris and Carrasco–Núñez, 2014; Norini et al., 2015, 2019; U2020). This unique feature makes the Cuicuiltic Member easily recognizable in the field, and any displacement along faults very sharp and pristine (Dávila–Harris and Carrasco–Núñez, 2014). Indeed, many easily accessible outcrops showing faults in the Cuicuiltic Member have been documented within the Los Potreros caldera by Dávila–Harris and Carrasco–Núñez (2014), Norini et al. (2015, 2019) and GEMex (2019) (Figs. 1 and 2).

U2020 proposed a new interpretation of some structures already identified in previous studies (e.g. Arellano et al., 2003; Norini et al., 2015, 2019). The reinterpretation of U2020 has been based on their field data, distinguishing between lineaments ("*morphological linear scarps with no measurable fault offsets and/or alteration at the outcrop scale*") and active and inactive faults ("*associated with measurable fault offsets and with active or fossil alteration*"), respectively. The reinterpreted structural features are the Las Papas, Las Viboras, Arroyo Grande and Maxtaloya faults (Fig. 1).

U2020 concluded that the Las Papas and Las Viboras are "*morphological scarps*" and "*lineaments*" not related with faulting. For the Las Papas lineament, U2020 stated that "*unaltered and undeformed deposits of the Cuicuiltic Member crop out along the E–W Las Papas lineament*" and that it "*is probably due to differential erosion of the softer layers of the pyroclastic deposits*". Even if the Las Papas and Las Viboras structures are several km long, the statements by U2020 have only been based on a single outcrop on the Las Papas trace (their LH–08, while their LH–07 outcrop is out of the fault trace, see fig. 3C). Several easily accessible outcrops had been previously found along the Las Papas and Las Viboras faults, as well as along many other faults deforming the area surrounding these two main volcanotectonic structures (Fig. 1) (e.g. Dávila–Harris and Carrasco–Núñez, 2014; Norini et al., 2015, 2019; GEMex, 2019). In all these outcrops, the faults invariably displace the Holocene Cuicuiltic Member and the underlying lava and pyroclastic units (for example see outcrops LH2017_32, LH64, LH62, LH66, LH23 in figs. 1 and 2). This means that the U2020 conclusion that the Las Papas and Las Viboras are not faults is obviously wrong, as shown by many already available data, and as also easily verifiable with a short field survey (Figs. 1 and 2) (e.g. Dávila–Harris and Carrasco–Núñez, 2014; Norini et al., 2015, 2019; GEMex, 2019). The U2020 description of their LH–08 outcrop can be explained by erosive retreat of the fault scarp, a very common process in dip–slip faults, especially in poorly consolidated sediments (e.g. Keller and Pinter, 2002; Burbank and Anderson, 2011). These observations show that previous works correctly concluded that Las Papas and Las Viboras are faults and have been active in the Holocene (e.g. Cedillo, 1997; Arellano et al., 2003; Dávila–Harris and Carrasco–Núñez, 2014; Norini et al., 2015, 2019; Carrasco–Núñez et al., 2017; GEMex, 2019).

U2020 inferred that the Arroyo Grande and Maxtaloya scarps have been generated by nowadays inactive faults. U2020 stated that these faults have been active "*prior to the deposition of the Cuicuiltic Member*". The statement by U2020 arose from the analysis of two outcrops (their LH–09, see fig. 3C, and the H6 well pad), where "*strongly altered and faulted … lavas and ignimbrites*" are "*covered by the unaltered Cuicuiltic Member*". As well known, active/fossil alteration doesn't always allow identifying faults or the age of faulting, because it depends also on their depth, life span of the hydrothermal system, spatial relationships, and fluid paths along primary permeability and faults zones (Bonali et al., 2016; Giordano et al., 2016). Easily accessible outcrops of the Arroyo Grande and Maxtaloya faults show displacements of the Cuicuiltic Member, clearly indicating that the conclusions of U2020 about the age of these two structures and the correlation between faulting and hydrothermal alteration are wrong (for example see outcrops PDL52, LH20, PDL08 in figs. 1 and 2) (Norini et al., 2015, 2019; GEMex, 2019). Faults displacing the Cuicuiltic Member are clearly exposed along

87 the Maxtaloya fault in the H6 geothermal well pad (corresponding to the PDL08 outcrop of figs. 1 and 2H).
88 The Maxtaloya fault trace is also coincident with a sharp thermal anomaly identified by Norini et al. (2015).
89 U2020 didn't mention this thermal anomaly, which further undermines their hypothesis and conclusions,
90 when they used the thermal remote sensing results of Norini et al. (2015) (Section 5.3 in U2020). Well
91 documented Holocene faulting (e.g. figs. 1 and 2) indicates that the Arroyo Grande and Maxtaloya faults have
92 been active after the deposition of the Cuicuiltic Member. Also, a sharp thermal anomaly suggests that the
93 Maxtaloya fault plays nowadays an important role in the ascent of hot geothermal fluids (Norini et al., 2015,
94 2019; Carrasco–Núñez et al., 2017; GEMex, 2019).

95

96 **3 Identification and geometry of uplifted areas**
97 U2020 identified three "*main uplifted areas*" surrounding the surface expressions of the Loma Blanca, Arroyo
98 Grande and Los Humeros faults. The supposed uplifted area around the Loma Blanca fault has also been
99 named by U2020 "*Loma Blanca bulge*". Regrettably, U2020 didn't provide any information on how these
100 uplifted areas have been identified and delimited. Among the three supposed uplifted areas, only the bulge
101 corresponding to the Loma Blanca fault has been briefly described: "*The fault system is on top of an elongated*
102 *crest (within an apical depression) of a morphological bulge, 1 km in width and 30 m in height*". Conversely,
103 no description or morphological data about the Arroyo Grande and Los Humeros uplifted areas have been
104 provided in U2020.

105 Simple topographic profiles of the caldera floor clearly show that these "*uplifted areas*" (or "*bulges*") have
106 been arbitrarily defined, without any specific and reproducible criterion (Fig. 3). The identification of apical
107 depressions by U2020 seems to be equally arbitrary. The "*uplifted areas*" include asymmetric reliefs and
108 depressed sectors, and have boundaries not necessarily corresponding to slope changes useful for their
109 delimitation (Fig. 3). The "*Loma Blanca bulge*" defined by U2020 comprises a sector of a westward tilted and
110 faulted surface, already described by Norini et al. (2019). The western boundary of the supposed "*bulge*" is
111 in the middle of the tilted surface, while the eastern one, corresponding to an already mapped normal fault,
112 is nearly at the same elevation of the summit of the "*bulge*" (Figs. 1 and 3A–3C) (Carrasco–Núñez et al., 2017;
113 Norini et al., 2019). Similarly, the eastern and western boundaries of the Arroyo Grande and Los Humeros
114 "*uplifted areas*" have been located by U2020 in the middle of tilted or flat surfaces, without any discernible
115 criterion (Fig. 3).

116 The U2020 model predicts the formation of an apical depression on top of a bulge induced by a shallow
117 magmatic intrusion. As clearly shown in the cross–sections of their figure 10, U2020 depicted apical
118 depressions on top of the three "*uplifted areas*" of Loma Blanca, Arroyo Grande and Los Humeros.
119 Unfortunately, topography doesn't show any well–defined apical depression in the Arroyo Grande and Los
120 Humeros areas (Fig. 3A–B). In fact, U2020 haven't even attempted to provide any description of those apical
121 depressions. Thus, the Arroyo Grande and Los Humeros apical depressions drawn in their figure 10 don't
122 have any relation with the topography and the structure of the caldera floor (e.g. Figs. 1 and 3 of the present
123 comment and fig. 4 of U2020).

124 Along with wrong interpretation of faults in the field and questionable delimitation of "*uplifted areas*" and
125 "*apical depressions*", U2020 also fails providing any kind of significant/independent validation of their
126 multiple magmatic intrusion model. For example, the U2020 analogue modelling predicts the development
127 of reverse faults at the base of the "*bulges*" induced by the emplacement of shallow cryptodomes (e.g. fig. 7
128 in U2020). U2020 didn't provide any field data or other evidence (morphostructural interpretation,
129 geophysics, well logs, etc.) locating these reverse faults, which are a fundamental feature of their model. As

130   noted above, the "*Loma Blanca bulge*" is delimited to the east by a normal fault already mapped by previous
131   authors (Carrasco–Núñez et al., 2017; Norini et al., 2019). This means that the modelling results cannot be
132   independently validated, as also discussed in the next section.
133

134   **4 Validation of the proposed model with well logs**
135   One of the most significant findings of U2020 is that the uplift in the "*Loma Blanca bulge*" has been generated
136   by a magmatic intrusion located at 425 ± 170 m of depth. U2020 also stated that this is the heat source of
137   the local geothermal anomaly. Such a shallow depth is within the range of geothermal wells drilled in the
138   area. Thus, the analysis of well logs might provide an opportunity to test the U2020 hypothesis and
139   calculation of intrusion depth. In fact, a simple validation attempt of the U2020 model in the "*Loma Blanca*
140   *bulge*" consists in the comparison of the temperature and lithological H4 well logs with the predicted
141   intrusion depth. This well is located on the top of the "*bulge*", just to the west of its "*apical depression*" (Fig.
142   3C–3D). Thus, the well logs should show a significant temperature change and intrusive/sub–volcanic
143   lithologies at the magma emplacement depth calculated by U2020.

144   According to data published by Arellano et al. (2003) and U2020, the H4 stratigraphic log doesn't show any
145   evidence of intrusive bodies from the surface down to 1900 m of depth, nor a sharp increase of the
146   temperature and geothermal gradient, which remains constant (about 20°C/100 m) (fig. 3D). Also, the
147   temperature profiles measured in several wells of the field, as displayed in the fig. 17 of Arellano et al. (2003),
148   don't show any strong temperature inversion or sharp changes in the geothermal gradient possibly
149   correlated to recent intrusive bodies at very shallow depth ("*< 1 km*"). On the contrary, these data indicate a
150   deeper origin of the heat source (or sources), with some variation of the geothermal gradient due to faults
151   and or permeability changes.
152

153   **5 Stratigraphy and radiometric ages**
154   One of the results presented in U2020 is that "*…the recent (post–caldera collapse) uplift in the Los Potreros*
155   *caldera moved progressively northwards … along the Los Humeros and Loma Blanca scarps*". Based on the
156   proposed U2020 uplift model, it means that shallow intrusions of small magmatic bodies and, consequently,
157   the volcanic feeding system moved progressively northwards. This statement presents some discrepancies
158   with the stratigraphy, geology and radiometric ages recently published by some of the U2020 authors
159   (Carrasco–Núñez et al., 2017, 2018; Juárez–Arriaga et al., 2018), as summarised by the following points:

160   a)   An obsidian dome (Qr1 Rhyolite of Carrasco–Núñez et al., 2017) has been dated using the U/Th
161   method at 44.8±1.7 ka by Carrasco–Núñez et al. (2017, 2018). Its location corresponds to the obsidian
162   dome cropping out along the Los Humeros fault described in U2020 and connected with the syn– to
163   post–Cuicuiltic Member eruption (7.3–3.8 ka) (Fig. 4). In U2020 there is no description of two
164   generations of obsidian domes along Los Humeros fault, nor any explanation to invalidate the
165   previous radiometric dating. Therefore, the U2020 attribution of this obsidian dome to the 7.3–3.8
166   ka volcanic activity phase appears unjustified and, consequently, weakens their model;

167   b)   The most recent volcanic activity of LHVC (post–Cuicuiltic Member) is clustered in two main ages,
168   around 3.8 and 2.8 ka, as indicated by recent radiometric and paleomagnetic data (Carrasco–Núñez
169   et al., 2017; Juárez–Arriaga et al., 2018) (Fig. 4). According to these ages and the LHVC geological map
170   (Carrasco–Núñez et al., 2017), the vents feeding the post–Cuicuiltic Member volcanic activity are
171   mainly located close to the southern and south–western sectors of the Los Humeros caldera rim.

172   These data suggest that the shallow feeding system of the post–Cuicuiltic Member activity is mainly
173   located in the southern and south–western sectors of the LHVC, some kilometres far from the
174   supposed bulged areas. Also, the ages and locations of the volcanic vents do not show any
175   progressive northward shift, but a scattered activity along the Los Humeros caldera rim.
176

177 **6 Conclusion**
178 We identified several problems in the U2020 study, showing that their model does not conform to most of
179 the, if not all, geological constraints from the Los Potreros caldera. The boundary conditions of a model and
180 the validation of the modelling results should always be based on the geological constraints that the natural
181 prototype imposes. Conversely, the multiple magmatic intrusion model is imposed by U2020 to the natural
182 prototype regardless of several evidences of no fit between them. This mismatch between nature and model
183 includes the age and location of faulting, identification and delimitation of uplifted areas and apical
184 depressions, temperature and lithological well logs, and stratigraphic and radiometric data. The forced
185 application of a predetermined model to a natural prototype raises questions about the real purpose of this
186 kind of studies. Such modelling could even be counterproductive for scientific knowledge if applied to case
187 studies for which there are few geological constraints (for example in remote areas), and therefore an
188 independent validation of the results is more difficult or impossible. Fortunately, previous recent studies
189 provided enough independent data to validate new models applied to the LHVC. The occurrence of multiple
190 magmatic intrusions at different depths in the Los Potreros caldera is not questioned in our comment, but
191 we think that the U2020 study fails to identify the deformation source (or sources) driving caldera resurgence
192 and representing the heat source of the geothermal field. As a result, their calculations and conclusions are
193 unlikely to have any relevance to volcanotectonic or geothermal processes in the LHVC.
