Abstract. The prediction of physicochemical rock properties in subsurface models regularly suffers from uncertainty observed at the sub-meter scale. Although at this scale – which is commonly termed the lithofacies scale – the physicochemical variability plays a critical role for various types of subsurface utilization, its dependence on syn- and post-depositional processes is still subject to investigation.

The impact of syn- and post-depositional geological processes, including depositional dynamics, diagenetical compaction and chemical mass transfer, onto the spatial distribution of physicochemical properties in siliciclastic media at the lithofacies scale is investigated in this study. We propose a new workflow using two cubic rock samples where eight representative geochemical, thermophysical, elastic and hydraulic properties are measured on the cubes' faces and on samples taken from the inside. The scalar fields of the properties are then constructed by means of spatial interpolation. The rock cubes represent the structurally most homogeneous and most heterogeneous lithofacies types observed in a Permian lacustrine delta formation that deposited in an intermontane basin. The spatio-temporal controlling factors are identified by exploratory data analysis and geostatistical modeling in combination with thin section and environmental scanning electron microscopy analyses.

Sedimentary structures are well preserved in the spatial patterns of the negatively correlated permeability and mass fraction of Fe_2O_3 . The Fe-rich mud fraction, which builds large amounts of the inter-granular rock matrix and of the pseudomatrix, has a degrading effect onto the hydraulic properties. This relationship is underlined by a zonal anisotropy that is connected to the observed stratification. Feldspar alteration produced secondary pore space that is filled with authigenic products including illite, kaolinite and opaque phases. The local enrichment of clay minerals implies a non-pervasive alteration process that is expressed by network-like

spatial patterns of the positively correlated mass fractions of Al_2O_3 and K_2O . Those patterns are spatially decoupled from primary sedimentary structures. The elastic properties, namely P- and S-wave velocity, indicate a weak anisotropy that is not strictly oriented perpendicularly to the sedimentary structures.

The multifarious patterns observed in this study emphasize the importance of high-resolution sampling in order to properly model the variability present in a lithofacies-scale system. Following this, the physicochemical variability observed at the lithofacies scale might nearly cover the global variability in a formation. Hence, if the local variability is not considered in full-field projects – where the sampling density is usually low – statistical correlations and thus conclusions about causal relationships among physicochemical properties might be feigned inadvertently.

1 Introduction

The utilization of the subsurface in disciplines such as petroleum reservoir engineering, geothermal heat extraction, mining, carbon-capture and storage or nuclear waste disposal requires highly accurate spatial predictions of relevant physical or geochemical properties in order to assess the economic feasibility of a target region (Landa and Strebel, 2002; Heap et al., 2017; Kushnir et al., 2018; Rodrigo-Illarri et al., 2017). Although most of these types of utilization take place at full-field scales, geological variability present at the sub-meter scale may play an important role during the development process. The scale we are speaking of is commonly termed the lithofacies scale (Miall, 1985). Geological heterogeneities at the lithofacies scale might constitute undesirable features in the subsurface such as flow-barriers in reservoirs (Landa and Strebel, 2002; Ringrose et al., 1993; Medici

et al., 2016, 2019), pathways in radionuclide repository sites (Kiryukhin et al., 2008) and in contaminated sites (Tellam and Barker, 2006) or geochemical anomalies in mining areas (Wang and Zuo, 2018). Hence, the controlling factors of sub-meter variability should be understood and at least roughly quantified before starting the development in the subsurface region.

In sedimentary bodies, the spatial distribution of the properties is mainly controlled by depositional and diagenetical processes (McKinley et al., 2011, 2013). The spatial characteristics of physicochemical properties in sedimentary rock media are complex due to strongly intersecting and interacting processes during sediment transport, deposition and diagenesis (McKinley et al., 2011). Multiple studies aimed to quantify the variability at the lithofacies scale, most of which concentrated on reservoir properties such as permeability and porosity in 2-D space (McKinley et al., 2011; Hornung et al., 2019). A 2-D analysis suits well for identifying non-visible patterns related to micro-bedding structures at multiple scales even in very homogeneous sandstones (McKinley et al., 2004). That perspective, however, involves simplifications of the physicochemical variability in 3-D space since specific rock properties such as permeability are dependent on the Cartesian direction. Also, consideration of geostatistical parameters such as variographic direction, range, sill and nugget revealed differences in 3-D compared to 2-D space (Landa and Strebel, 2002; Hurst and Rosvoll, 1991).

With a proper knowledge of the statistical and causal relationships among physicochemical rock properties at different scales, prognostic property models can be significantly enhanced by the integration of small-scale uncertainty into upscaling or conditional simulation algorithms (Lake and Srinivasan, 2004; Verly, 1993). Especially, since multivariate geostatistics can account for inter-relationships between rock properties, those relationships can be used as trends or drifts in geostatistical predictions in order to optimize their accuracy in space and time (Hudson and Wackernagel, 1994).

In order to quantify the spatial variability and the multidimensional relationships among physicochemical properties at the 3-D lithofacies scale, the quasi-continuous scalar fields of two rock cubes are modeled by means of spatial interpolation, which is constrained by laboratory measurements. The rock cubes have volumes of 0.0156 m^3 and 0.008 m^3 and have been sampled from a Permian lacustrine-deltaic sandstone formation that deposited in the intermontane Saar-Nahe basin during the Cisuralian series.

The lithological characteristics of the sandstones are analyzed and both isotropic and anisotropic properties, including bulk rock geochemistry, thermophysical, hydraulic and elastic rock properties, are measured on the cubes' faces. In addition, the intrinsic gas permeability under infinite pressure gradient, the effective porosity, the elemental composition, the thermal conductivity, the thermal diffusivity together with the P- and S-wave velocity are measured on 108 rock cylinders taken from the inside of the cubes represen-

tative for each Cartesian direction in order to account for anisotropic patterns.

The measurements are used to interpolate the full 3-D field of each property. Prior to interpolation, the discrete measurements are statistically analyzed for correlation and formal relationships. Interpolations are conducted using deterministic and stochastic methods including the inverse distance weighting (IDW) and simple kriging (SK) interpolation. The models are evaluated through cross-validation and the observed spatial patterns are categorized. The interpolation results providing the lowest cross-validation error are statistically analyzed again and compared with the aforementioned statistical patterns. Eventually, the geological processes, which produced the observed patterns, are interpreted and discussed with the help of qualitative thin section and environmental scanning electron microscope (ESEM) analyses.

The research outputs of this study lie between the scale of a core plug measurement and a wireline log/pumping test (Medici et al., 2018). Hence, we aim to contribute towards estimating the uncertainty that must be accounted for when performing up- or down-scaling between those two scales of investigation (Zheng et al., 2000; Jackson et al., 2003; Corbett et al., 2012; Hamdi et al., 2014).

2 Methodology

2.1 Sedimentological characterization and rock sampling

In order to cover multiple varieties of sedimentary lithofacies types, a quarry in Obersulzbach (Rhineland-Palatinate, Germany) in the Saar-Nahe basin was selected for the investigations (Fig. 1). The quarry belongs to the lacustrine-deltaic Disibodenberg Formation that is assigned to the Innervariscan Rotliegend Group and comprises four lithofacies types. This formation is deeply buried (1,995 to 2,380 m b.g.s.) in the northern Upper Rhine Graben in southwestern Germany (Becker et al., 2012) and constitutes a potential target unit for hydrothermal exploitation (Aretz et al., 2015). The maximum past overburden of the field site can be estimated to be between 1,950 m and 2,400 m as indicated by shale-compaction analyses, which were performed by Henk (1992). The outcrop has been chosen in order to estimate the variability of physicochemical properties that could be expected in this formation as an uncertainty factor if it gets targeted in a deep geothermal project.

Two rock cubes of $0.2 \times 0.2 \times 0.2 \text{ m}$ (OSB2_c) and $0.25 \times 0.25 \times 0.25 \text{ m}$ (OSB1_c) were extracted from the outcrop wall using a rock chainsaw. According to the outcrop's coordinate system, one edge of the cuboid runs east-west (x), one north-south (y) and one in altitude (z) direction. The irregular cuboids were reworked to regular cubes with a stationary rock saw. We selected two types of lithofacies (Fig. 1e) – both sandstones – one representing a heterogeneous,

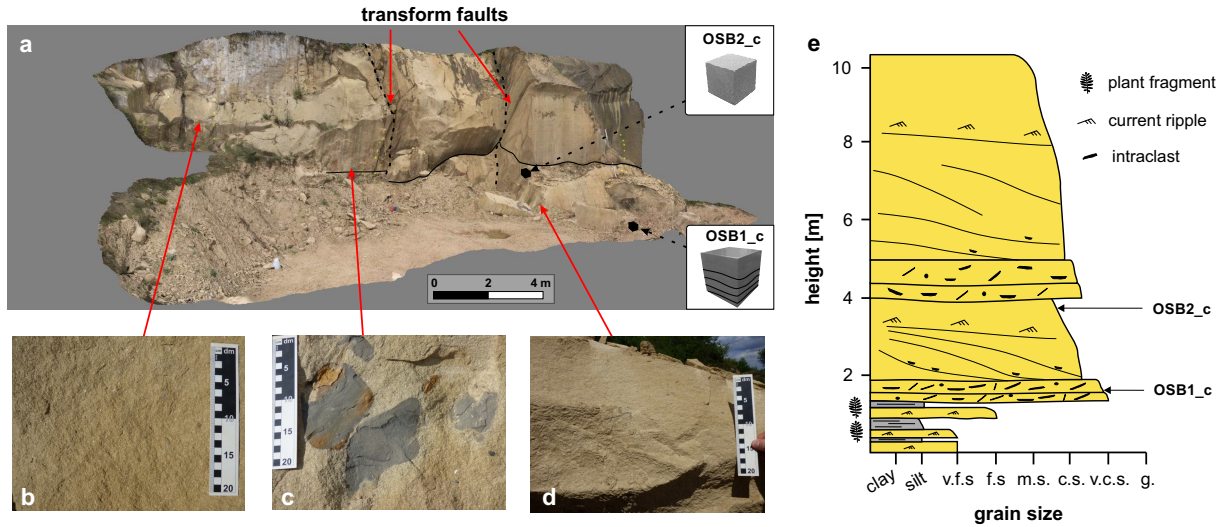

Figure 1. (a) The investigated sandstone quarry in Obersulzbach, Germany. The outcrop is compartmentalized in the central part by two transform faults, which belong to the Lauter fault zone (Stollhofen, 1998). The strike-slip faults provide offsets of a few meters. (b) Massive sandstone (c) Pelitic rip-up clasts embedded in a massive rock matrix (d) Ripple-cross bedded sandstone (e) Cumulative sedimentary log of the outcrop architecture. The sampling positions of OSB1_c and OSB2_c are marked. v.f.s. = very fine sand; f.s. = fine sand; m.s. = medium sand; c.s. = coarse sand; v.c.s. = very coarse sand; g. = granule.

compartmentalized variety (OSB1_c) and the other one a homogeneous variety (OSB2_c). The cubes were both extracted from a distributary mouth bar building a foreset in a fluvatile-dominated lacustrine delta. OSB1_c (Fig. 2) was taken from the high-energetic basal part whereas OSB2_c was taken from the lower-energetic top. The sedimentological characteristics including grain size, sorting, angularity, sedimentary structures and mineral content were determined by visual inspection, thin section and ESEM analyses. Two different types of zonal anisotropy and spatial patterns were expected to be found with the aforementioned sampling strategy. In other studies such as McKinley et al. (2011) measurements were directly conducted in the field. This approach, however, does often provide a drawback in accuracy and precision, especially in permeability measurements. In order to address this issue, we performed analyses on the faces of the cubes under laboratory conditions. In the next step, the cubes were cut to rock slabs, from which cylinder samples were extracted. Totally, 108 rock cylinders – 79 from OSB1_c and 29 from OSB2_c – were extracted from the rock cubes. It was ensured that at least five samples were produced representative for each Cartesian direction. Applying the formula for calculating a cylinder's volume V_c with

$$V_c = h \times \pi \times r^2, \quad (1)$$

where h is the height of the cylinder and r the radius, the relative volume covered by the rock cylinders in the rock cubes was calculated to be 25.4% for OSB1_c and 18.2% for OSB2_c, respectively. Eventually, target meshes are needed to interpolate the full 3-D scalar fields. Therefore,

both cubes were modeled in 3-D using a regular grid consisting of 27,000 hexahedral, orthogonal cells. The elementary cell of OSB1_c has a volume of $5.7 \times 10^{-7} \text{ m}^3$ whereas OSB2_c's elementary cells have a volume of $3 \times 10^{-7} \text{ m}^3$.

2.2 Laboratory experiments

First, a local metric coordinate system was defined, where each edge of the cube represents an axis in the Cartesian coordinate system in order to reference each measurement to a point in space. The sampling points were set in a raster of 9×9 points on each face for OSB1_c and 5×5 for each face of OSB2_c. All measurements were conducted in the laboratory of the Institute of Applied Geosciences in Darmstadt, Germany. After drying the rock cubes at 60°C , non-invasive measurements were conducted on each face of the cube. On the cubes' faces the P- and S-wave velocity and elemental mass fractions were determined (Fig. 3).

After the extraction, the rock cylinders were oven-dried at 105°C and measured in order to determine the intrinsic gas permeability, effective porosity, P- and S-wave velocity, elemental mass fractions, thermal conductivity as well as the thermal diffusivity in unsaturated conditions. Those properties can be considered key properties of the rock matrix in porous aquifers with regard to hydrothermal systems (Agermar et al., 2014) since they constitute input variables for the governing equations for heat transfer and fluid flow in the subsurface (Carslaw and Jaeger, 1959).

The permeability was measured with the Hassler cell permeameter, which is described in Filomena et al. (2014). The Hassler cell is a gas-driven permeameter, which measures the

Figure 2. Lateral faces of OSB1_c displayed in the form of an open cube (from left to right: XZ Front, YZ Front, XZ Back and YZ Back). The internal bounding surfaces are indicated by the dashed lines.

Figure 3. (a) Sampling locations for the non-invasive measurements including P- and S-wave velocity and X-ray fluorescence exemplary displayed for the face XZ Back of OSB1_c (b) Schematic of the extraction strategy for sampling the rock cylinders.

permeability of a cylinder-shaped rock sample under steady-state gas flow. This technique allows for the estimation of the intrinsic gas permeability, which is the permeability at an infinite pressure gradient. The permeameter was set to accept a measurement if fifteen consecutive readings did not deviate by more than 5%. The measurement error, however, can exceed that value especially in low-permeable lithologies. Effective porosity measurements were conducted using an envelope density analyzer (GeoPyc 1360). The accuracy is given by the manufacturer to be within $\pm 0.55\%$ (Micromeritics, 1998). Thermal properties under unsaturated conditions, namely the thermal conductivity and thermal diffusivity, were determined with a thermal conductivity scanner (TCS) according to the work of Popov et al. (1999). The measurement error is quantified to be $\leq 3\%$ for thermal conductivity and $\leq 8\%$ for thermal diffusivity (Popov et al., 1999). The elastic properties of P- and S-wave velocity in the rock media were measured with the sonic wave generator UKS-D (Geotron) by sending a sonic wave pulse from a pulse-providing test head (UPG-S) to a receiver (UPG-E). The wave velocity is a function of travel length and time together with the density of the material. The initial occurrence of the P- or S-wave must be picked manually after visual inspection by the operator. Thus no measurement error can be provided since user bias cannot be assessed quantitatively. Bulk elemental analysis using the Bruker S1 TITAN handheld portable X-ray fluorescent (pXRF) analyzer was used to find correlations between the elemental composition and the

petrophysical properties. The measurement device works on the basis of energy dispersive X-ray fluorescence (EDXRF) and estimates the elemental mass fractions of a sample. This device produces an ionizing X-ray beam of 1.2 cm diameter and quantifies the elemental composition based on the energy emitted by the ionized elements in the targeted area. The portable device can measure the fraction of elements with an ordinal number ≥ 12 and ≤ 235 if the threshold value, defined by the measurement error for the specific element in the sample, is exceeded. For this study, the device was operated in GeoChem, DualMining mode allowing for the detection of the major oxides SiO_2 , Al_2O_3 , Fe_2O_3 and K_2O as well as a wide range of other elements. The device has been calibrated with international standards. We used the previously mentioned major oxides for analyses since those can provide insight into the iron oxide and clay mineral distribution, which can significantly impact the petrophysical properties. More details on the measurement devices can be found in the works of Hornung and Aigner (2002), Sass and Götz (2012), Filomena et al. (2014) and Aretz et al. (2015).

2.3 Data analysis and spatial modeling

2.3.1 Variography

The experimental semivariogram represents the cumulative dissimilarity of a discrete set of point-pairs x with n_c as the

count of point-pairs within the distance classes h of identical distance increments (Eq. 2).

$$\gamma(h) = \frac{1}{2n_c} \sum_{\alpha=1}^{n_c} (z(x_\alpha + h) - z(x_\alpha))^2 \quad (2)$$

The continuous counterpart, represented by the variogram model, is an approximation to the experimental semivariogram assuming $z(x)$ to be a stationary random field (Wackernagel, 2003). A variogram model γ_{theo} is represented by a covariance function c with the relationship $\gamma_{theo}(h) = c(0) - c(h)$, where c is a positive definite, even function. Six covariance models are mostly used to fit the experimental semivariogram, namely the spherical, gaussian, exponential, power, kardinal sine and the linear model (Armstrong, 1998; Ringrose and Bentley, 2015). In this study, we only observe spherical relationships with nugget effect. This model is calculated as

$$c_{sph}(h) = \begin{cases} n + b \cdot \left(1 - \frac{3|h|}{2a} + \frac{|h|^3}{2a^3}\right) & \text{for } 0 \leq |h| < a \\ n & \text{for } |h| \geq a, \end{cases} \quad (3)$$

with the variables nugget (n), range (a) and sill (b). Semivariograms can be used to quantify the spatial or time correlation of a random property (Ringrose and Bentley, 2015; Gu et al., 2017; Rühaak et al., 2015). Further on, the differences in range and sill in dissimilar directional semivariograms can quantify the zonal and geometric anisotropy of a property (Ringrose and Bentley, 2015). The resulting covariance function is an input variable for stochastic interpolation algorithms.

2.3.2 Rock property interpolation

Spatial inter- and extrapolation can be generated with deterministic and stochastic techniques. All interpolations are based on the assumption that a point x_k with a known value $z(x_k)$ has a weight on a discrete point x_0 in space with an unknown value $z(x_0)$. The global known points, however, can be reduced to a local neighborhood of x_0 .

For deterministic interpolation the p-value inverse distance weighting (IDW) (Shepard, 1968) interpolation is used. The IDW interpolation generally calculates an unknown value $z(x_0)$ at point x_0 by weighting the distance of that point to each known value point (x_k) in space. The underlying formula for IDW is

$$z(x_0) = \frac{\sum_{k=1}^n z(x_k)/d_k^p}{\sum_{k=1}^n 1/d_k^p}, \quad (4)$$

where d is the Euclidean distance between the point with the known value x_k and the point with the unknown value x_0 ,

and p is an exponent factor to bias the weights non-linearly. The p-value is mostly used for smoothing the results by controlling the distance-decay effect (Lu and Wong, 2008). IDW is a reliable and widely applied method to interpolate static rock properties in one to three-dimensional space (Rühaak, 2006).

For stochastic interpolation simple kriging (SK) is used. Kriging in general is a popular technique to interpolate geological properties in space (Goovaerts, 1997; Rühaak, 2015; Malvić et al., 2019). Through kriging, the value $z(x_0)$ at an unknown point x_0 is calculated by weighting the neighboring known values and building a linear combination of those via the formula

$$z(x_0) = \sum_{k=1}^n w_k \cdot z(x_k), \quad (5)$$

where w_k is the weight of the known point x_k with the value $z(x_k)$. SK requires knowledge of the stationary mean μ (Deutsch and Journel, 1998), which modifies Eq. 5 into

$$z(x_0)_{SK} = \sum_{k=1}^n w_k \cdot z(x_k) + \left(1 - \sum_{k=1}^n w_k\right) \cdot \mu. \quad (6)$$

To obtain the simple kriging weights, a set of n equations has to be solved. This set of equations can be written as

$$\begin{pmatrix} c(x_1 - x_1) & \cdots & c(x_1 - x_n) \\ \vdots & \ddots & \vdots \\ c(x_n - x_1) & \cdots & c(x_n - x_n) \end{pmatrix} \begin{pmatrix} w_1 \\ \vdots \\ w_n \end{pmatrix} = \begin{pmatrix} c(x_1 - x_0) \\ \vdots \\ c(x_n - x_0) \end{pmatrix} \quad (7)$$

with c as covariance function and x_n as point with known value (Wackernagel, 2003). The quality of kriging interpolation is dependent on the variogram model, the defined neighborhood, the sampling density and the goodness-of-fit to the experimental values.

2.4 Cross-validation

Cross-validation can be used to assess the quality of a model. During cross-validation, p randomly selected samples are removed from the input data set of size n with $0 < p < n$ and the interpolation is performed without those samples (Celisse, 2014). The measures of goodness-of-fit being used in this study include the root-mean-square error (RMSE)

$$RMSE = \sqrt{\frac{1}{n} \sum_{k=1}^n (\hat{z}(x_k) - z(x_k))^2} \quad (8)$$

and the mean-absolute error (MAE)

$$MAE = \frac{1}{n} \sum_{k=1}^n |\hat{z}(x_k) - z(x_k)| \quad (9)$$

with $\hat{z}(x_k)$ as estimated value at point x_k . Those parameters allow for the quantitative assessment of an interpolation's quality. They might be prone to bias if the sampling density in the target domain is extremely scarce.

2.4.1 Anisotropy

Anisotropy describes the dependence of a physical property on a direction. Rock properties such as stiffness, permeability or thermal conductivity are anisotropic in most cases. Hence, measurements of those properties might show differing magnitudes in different directions if the medium is polar anisotropic. The intrinsic permeability, for example, provides typical ranges for the ratio between the vertical (k_v) and horizontal permeability (k_h) of 10^{-5} to 1 (Ringrose and Bentley, 2015). Anisotropy in geological media is generated by preferred orientation of mineral grains or cracks as well as by the intrinsic anisotropy of single crystals (Thomsen, 1986).

Following, we will exemplarily describe the anisotropy of elasticity and we will provide measures for anisotropy quantification under the simplifying assumption of transversal isotropy. The elastic modulus tensor can be expressed as a 4th-rank tensor

$$\mathbf{C} = \begin{pmatrix} C_{11} & C_{11} - 2C_{66} & C_{13} & 0 & 0 & 0 \\ C_{11} - 2C_{66} & C_{11} & C_{13} & 0 & 0 & 0 \\ C_{13} & C_{13} & C_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & C_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & C_{66} \end{pmatrix} \quad (10)$$

where C_{ij} represents an elasticity modulus and the indices are related to the directional P- and S-wave velocity, under the assumption that z is the symmetry axis. The velocities can be calculated by

$$v_p^z = \sqrt{\frac{C_{33}}{\rho}} \quad (11)$$

$$v_s^z = \sqrt{\frac{C_{66}}{\rho}} \quad (12)$$

where v_p is the P-wave velocity and v_s is the S-wave velocity parallel to the symmetry axis and ρ is the bulk density (Yang et al., 2020). The anisotropy, here exemplarily expressed for the P-wave polar anisotropy, can be quantified with the Thomsen parameters (Thomsen, 1986). For example, ϵ can be expressed as

$$\epsilon = \frac{C_{11} - C_{33}}{2C_{33}}. \quad (13)$$

If $\epsilon \ll 1$ the material can be classified as weakly anisotropic.

2.4.2 Correlation and regression analysis

In order to quantify linear statistical relationship between two independent variables x and y , the Pearson linear product-moment correlation coefficient (R) can be used. R is expressed as

$$R = \frac{\sum_{k=1}^n (x_k - \bar{x})(y_k - \bar{y})}{\left(\sum_{k=1}^n x_k^2 - n \cdot \bar{x}^2\right) \left(\sum_{k=1}^n y_k^2 - n \cdot \bar{y}^2\right)}, \quad (14)$$

with n representing the number of compared point pairs and \bar{x} and \bar{y} standing for the arithmetic mean of x and y .

Regression aims at finding a fitting function between samples of two or more random variables. For curvilinear regression, a function of a degree > 1 will be approximated for a discrete set of values. A second-degree polynomial function $f(x)$ for instance would be described as

$$f(x) = b_0 + b_1x + b_2x^2 \quad (15)$$

Thus, we would need to find $n + 1$ regression coefficients, where n is the degree of $f(x)$. In general, the regression model yields

$$f(x)_i = b_0 + b_1x_i + b_2x_i^2 + \dots + b_nx_i^n, \quad (16)$$

with $i = 1, 2, \dots, n$. The regression coefficients b_m are obtained through solving a system of linear equations as

$$\begin{pmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{pmatrix} = \begin{pmatrix} 1 & x_1^1 & \dots & x_1^m \\ 1 & x_2^1 & \dots & x_2^m \\ \vdots & \vdots & \dots & \vdots \\ 1 & x_n^1 & \dots & x_n^m \end{pmatrix} \begin{pmatrix} b_0 \\ b_1 \\ \vdots \\ b_m \end{pmatrix}, \quad (17)$$

where x and y are the samples. The function approximations as produced in regression analyses are commonly evaluated by the coefficient of determination (R^2), which is calculated through

$$R^2 = 1 - \frac{s_{res}}{s_{tot}} \in [0, 1], \quad (18)$$

where

$$s_{res} = \sum_{k=1}^n (y_k - f(x)_k)^2 \quad (19)$$

is the explained sum of squares and

$$s_{tot} = \sum_{k=1}^n (y_k - \bar{y})^2 \quad (20)$$

is the total sum of squares.

2.4.3 Spatial modeling and statistical analyses

The spatial dependence of the discrete values is evaluated through experimental semivariograms. The semivariograms are generated for the single rock faces, where measurements are available, and for the plug measurements. The empirical semivariogram is fitted by a variogram model, which is then used for the stochastic interpolation. Interpolation analyses are performed as IDW and SK realizations (Fig. 4) that are assessed through cross-validation. The power parameter for IDW is chosen to be three since this constant provides the lowest RMSE among the realizations. The search radii for each prediction is chosen to be 0.2 m in x and y direction and 0.15 m in z direction in OSB1_c to account for the sedimentary structures. For OSB2_c the search radii are chosen to be isotropic with a length of 0.2 m. To make the methods comparable, we select the maximum number of neighboring points to be 25 representing between 5 and 95% of the measurements.

We decided to waive sequential simulation as major amounts of the cubes' volumes are covered by rock samples. Thus, we do not expect a relevant kriging variance. With this in mind, it is assumed to capture most of the total variance by the measurements themselves. The interpolation results that provide the lowest cross-validation error are used for statistical analyses in order to derive correlations and regression functions between the scalar fields. Eventually, significant correlations are compared with the non-interpolated data sets. Both the spatial modeling and the statistical analyses are performed with the open-source software GeoReVi (Linsel, 2019). This software tool provides functionality for multidimensional subsurface characterization using the concept of knowledge discovery in databases, which is helpful when handling huge data sets as produced in this study.

3 Results

3.1 Sedimentological characteristics

The sandstones belong to a clinothem strata deposited in a fluvial-dominated lacustrine delta. More specific, the architectural element represents a distributary mouth bar, formed by rapid sandstone deposition in sheet-like bodies like exemplary described in Fongngern et al. (2018). The base of those bodies is typically erosive, which is why muddy rip-up clasts commonly occur above the base. Also, the beds, which deposited after the intraclast-rich basal beds, typically

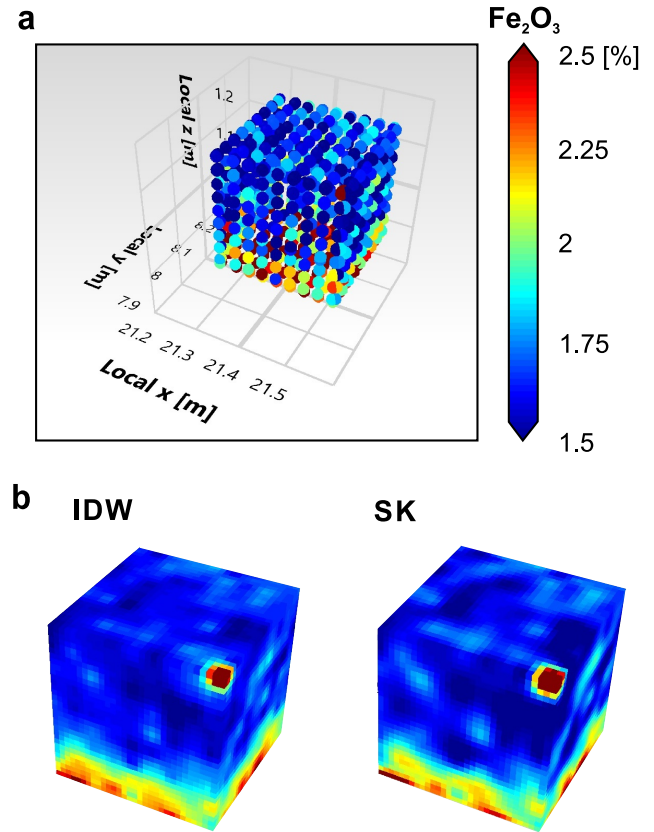

Figure 4. (a) Fe_2O_3 measurement locations on the cube faces of OSB1_c and on the rock samples extracted from the cube. The diameter of one point is 1.2 cm, which corresponds to the beam diameter of the pXRF measurement device. (b) Visual representation of the inverse distance weighting (IDW) and simple kriging (SK) realization of the 3-D scalar field of Fe_2O_3 using the discrete points displayed in (a) as known data points.

show trough or ripple-cross stratification with set heights of 5–15 cm. Vertical orientation of rip-up clasts can be observed in matrix-rich debrites or turbidites deposited under high-energy turbulent hyperpycnal to homopycnal flow conditions (Li et al., 2017). Those are unconformably overlying lacustrine, laminated mud strata from the prodelta environment. Accordingly, Bouma A-E layers (Bouma, 1962; Middleton, 1993) with a prograding trend can be identified in the outcrop. With ongoing sedimentation, the depositional energy in a Bouma sequence typically decreases, which leads to massive sandstones. OSB1_c was taken from a basal bed of the Bouma A interval, characterized by a high amount of rip-up intraclasts, normal grading and sub-horizontal pseudolayering which may occur in a Bouma A interval if the rip-up clasts experienced buoyancy during transport. OSB2_c was taken from the topmost bed, which corresponds to a Bouma E interval being characterized by a massive structure.

The average grain size in both cubes ranges from fine to very coarse sand (200–1400 μm). While the grain size dis-

tribution in OSB2_c does not show a significant variability – mainly characterized by medium to coarse sand – a normal grading is observable in OSB1_c. Here, the grain size gradually decreases from very coarse sand at the base to medium sand at the top. Likewise, sorting increases from poor to moderate. In OSB2_c the sorting is moderate throughout the entire sample volume. The components provide a low to medium sphericity while the grain shapes vary between sub-angular to sub-rounded. Locally, pelitic rip-up clasts occur with diameters of up to four centimeters. The rip-up clasts show a very low textural maturity and are oriented sub-vertically with respect to bedding.

The original rigid detrital components consist of 50–60% quartz, 20–30% strongly altered feldspar as well as 10–25% lithic fragments. Mica grains are often bent between more rigid grains. The rock matrix accounts for approximately 10–20% and is built up by detrital grains – coated by iron oxides –, ductile, autochthonous pelite grains and fine-grained quartz. According to the geochemical analyses, the rocks can be classified as lithic arenites to arkoses or wackes (Fig. 5) respectively, if the matrix content exceeds 15%, applying the classification of Herron (1988).

Thin section analysis (Fig. 6a) reveals that most of the pore space is secondary due to grain dissolution. The secondary pores are undeformed indicating that grain dissolution took place during structural inversion – probably during telogenesis according to the concept of Worden and Burley (2003). Most of the primary inter-granular volume was destroyed during mechanical compaction. ESEM analysis (Fig. 6b) confirms the presence of quartz accompanied by co-precipitated calcite, opaque phases – mainly iron oxides – and authigenic clay minerals including kaolinite and illite in the cement fraction. Thus, chemical compaction had taken place by iron oxide, quartz and clay mineral precipitation during diagenesis. Here, the earliest cement phase is represented by the opaque phases comprising a high amount of iron oxides. Following, kaolinite is formed, mainly in the secondary pore space, overgrown by illite. Often, the early cement is overgrown syntactically by quartz. The source of SiO₂ might be internal and related to feldspar dissolution.

3.2 Exploratory data analysis

In order to provide full comparability, the following section will provide an overview over the measurements derived from the rock cylinder analyses. For each property, 79 rock samples from OSB1_c and 29 from OSB2_c were investigated. An overview over the properties' ranges is provided in the Box-Whisker charts displayed in Figure 7.

The local variability of OSB1_c is significantly higher than that of OSB2_c. Intrinsic permeability of OSB1_c provides a coefficient of variation of 0.3 and a Dykstra-Parson coefficient of 0.4 while measurements from OSB2_c show values of 0.2 for the coefficient of variation and 0.18 for the Dykstra-Parson coefficient respectively. According to the

classification provided by Corbett and Jensen (1992), the intrinsic permeability of both rock cubes can be classified as being very homogeneous. Also, the intrinsic permeability does not show a significant anisotropy.

The range of values in OSB1_c for each property is greater than the range of those in OSB2_c. OSB1_c provides lower values in P- and S-wave velocity, thermal conductivity and mass fraction of Fe₂O₃ compared to OSB2_c. Intrinsic permeability and porosity in turn are greater. The mass fraction of silicon oxide and thermal diffusivity provide similar statistical parameters in both cubes, however, the ranges are marginally larger in OSB1_c. The measurements of the elastic rock properties revealed a weak anisotropy of the P-wave attenuation especially in rock cube OSB2_c. The Thomsen parameter ϵ is 0.047 for OSB1_c and 0.096 for OSB2_c. It should be noted that OSB1_c provides visible bedding structures in contrast to OSB2_c, hence, the observed degree of anisotropy is not connectable to the bedding features in this case.

Statistically significant linear correlations (Fig. 8), in the sense of passing a two-tailed significance test at the 0.05 level, were found between porosity and permeability, permeability and Fe₂O₃, v_p and v_s , v_p and SiO₂, v_p and Al₂O₃, v_p and K₂O, Fe₂O₃ and SiO₂ as well as K₂O and Al₂O₃. The strongest positive linear correlation can be observed between v_p and v_s ($R = 0.88$), K₂O and Al₂O₃ ($R = 0.70$) and porosity and permeability ($R = 0.31$). The strongest negative correlation can be observed between permeability and Fe₂O₃ ($R = -0.56$). Properties not being mentioned do not provide significant statistical correlations to others.

3.3 Sub-meter scale spatial correlation

The spatial dependence of the discrete measurements is estimated using experimental semivariograms. Therefore, the geochemical representatives SiO₂ (Fig. 9a) and Fe₂O₃ (Fig. 9b) that were measured on each of the rock faces of OSB1_c are therefore exemplary analyzed. The experimental semivariograms greatly vary from face to face in OSB1_c. The nugget effect for each experimental variogram is very low. The range of each semivariogram varies between 0.05 and 0.3 m. In the experimental semivariograms of SiO₂, two types of patterns can be identified. The faces XY Base, XZ Back and YZ Front all show ranges of approximately 0.08 m and a sill between 8 and 10%² until the semivariance exponentially increases when exceeding a lag distance of 0.2 m. The semivariance on the other faces runs similarly with ranges of 0.2 m and a sill of 4.7%². The semivariogram for Fe₂O₃ shows some similarities. Here, the faces XY Base, YZ Front and XZ Front show very low ranges between 0.05 and 0.15 m and sill between 0.1 and 0.15%² again with an exponential increase when exceeding a lag distance of 0.2 to 0.25 m. In contrast, the semivariance of YZ Back has the highest sill with 0.21%² and a range of 0.15 m, however, semivariance drops after exceeding a lag distance of 0.2 m. XZ

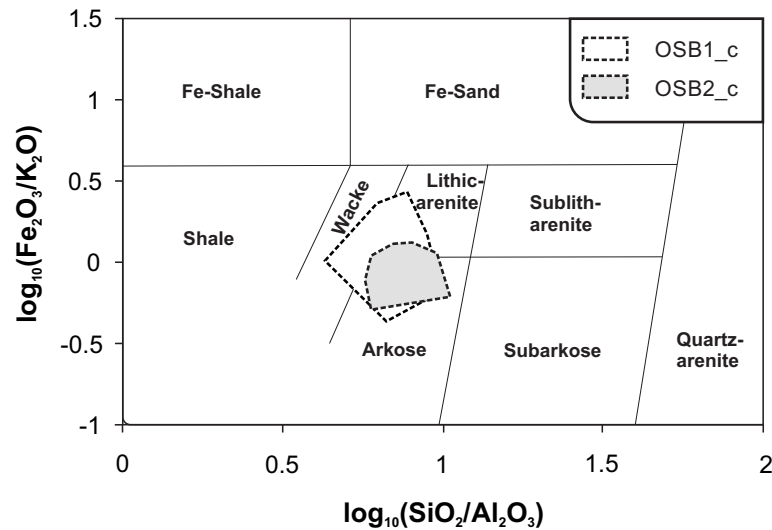

Figure 5. Petrographic classification after Herron (1988) based on the ratio of SiO_2 and Al_2O_3 and Fe_2O_3 and K_2O . The polygons show the convex hull for the measurements derived from the cubes' faces.

Back provides the highest degree of similarity with a range of 0.3 m and a sill of $0.09\%^2$ using a spherical approximation. Both geochemical properties show a zonal anisotropy where the sill shows different magnitudes along different directions (Wackernagel, 2003; Allard et al., 2016).

3.4 Spatial pattern analysis

The spatial distributions of the rock properties are interpolated with Shepard's inverse distance weighting (IDW) and simple kriging (SK). Both realizations of a single scalar field provide comparable patterns, which is due to the high sampling density. The interpolation errors are also located in similar ranges, however, IDW seems to be more sensitive to outliers resulting in much higher interpolation errors with regard to properties like P-wave velocity or mass fraction of SiO_2 (Table 1). IDW tends to underestimate the maximum and minimum values in the scalar fields. Thus, petrophysical and geochemical contrasts are more distinctly reproduced in the stochastic approach. Also, the IDW realization shows the bull's eye effect, which is a typical artifact of IDW interpolations (Shepard, 1968). Accordingly, the simple kriging realizations are used for further analyses.

The rock properties exhibit a multitude of spatial patterns. Here, discrete, layered and homogeneous patterns, both connected and disconnected to primary sedimentary structures, could be observed in the interpolations.

3.4.1 Patterns connected to sedimentary structures

A bedding-connected pattern is exhibited in the intrinsic permeability and Fe_2O_3 interpolation results of OSB1_c. The mass fraction of Fe_2O_3 varies between 1.25 and 5% in OSB1_c. In the histogram displayed in Figure 11 outliers

Table 1. RMSE and MAE for the interpolation results of IDW and SK for OSB1_c. k = permeability; Φ = effective porosity; λ = thermal conductivity; α = thermal diffusivity; v_p = P-wave velocity.

	RMSE IDW	RMSE SK	MAE IDW	MAE SK
k	.19	.17	.15	.14
Φ	.54	.59	.4	.42
λ	.23	.22	.18	.16
α	.14	.17	.1	.1
v_p	64.19	60.95	52.21	44.74
SiO_2	4.07	3.25	3.05	2.09
Al_2O_3	.8	.83	.66	.66
K_2O	.25	.26	.19	.2
Fe_2O_3	.93	.32	.86	.21

were removed according to Tukey's outlier detection method (Tukey, 1977). The local histogram of OSB1_c's intrinsic permeability shows a bimodal distribution ranging from 0.7 to 3.9 mD. The application of Tukey's method revealed no statistical outliers in this scalar field.

The bedding structures in OSB1_c are well reflected by the spatial pattern of the interpolated intrinsic permeability gradually increasing from low values between 0.7 and 2 mD in the lower beds to higher values between 2 and 4 mD in the upper beds (Fig. 10).

The spatial distribution of the mass fraction of Fe_2O_3 in OSB1_c provides a reciprocal trend compared to the permeability. Here, the lowermost bed shows a significantly higher content compared to the upper beds. Both scalar fields show zonal anisotropy. The Fe_2O_3 content is an indicator for the detrital matrix, pseudomatrix and cement content that in turn would explain the reciprocal relationship with the permeability measurements. In siliciclastic systems, iron can be con-

Figure 6. (a) Representative thin section taken from rock cube OSB2_c. The sandstone consists mainly of quartz (Qtz), altered feldspars with residual mineral aggregations (sericite, Ser), altered biotite (Bt) and ductile grains (DG). Feldspar dissolution lead to a high grade of secondary porosity (Molenaar et al., 2015) while the vast majority of the inter-granular pore space is filled with primary and pseudomatrix (PM), which is rich in iron oxides. (b) Environmental scanning electron microscope (ESEM) image of the authigenic clay minerals (mainly kaolinite (Kln) and illite (Illt)) built in the pore space. Mineral abbreviations were taken from Whitney (2010).

tained in clay minerals (up to 30wt% (Brigatti et al., 2006)), mafic components or in iron-rich oxides, hydroxides or carbonates. Local excesses in the Fe_2O_3 content exist in the spatial distribution. Those can be explained by clay-rich intraclasts observed on the rock faces. When comparing the pattern to Figure 2 at both XZ-oriented cube faces, rip-up clasts can be observed where high Fe_2O_3 mass fractions occur. Those areas provide the maximum values of the Fe_2O_3 distribution.

3.4.2 Patterns decoupled from sedimentary structures

Other scalar fields are decoupled from depositional bounding surfaces. For instance, the geochemical mass fractions of K_2O (Fig. 12) and Al_2O_3 (Fig. 13) provide a significant positive correlation unconnected to visible structural boundaries. Typically, those geochemical properties are indicative for the presence of orthoclase feldspar (KAlSi_3O_8) and/or illite ($\text{KAl}_3\text{Si}_3\text{O}_{10}(\text{OH})_2$) in siliciclastic environments. The mass ratio of both components is roughly 1:3 to 1:4, which

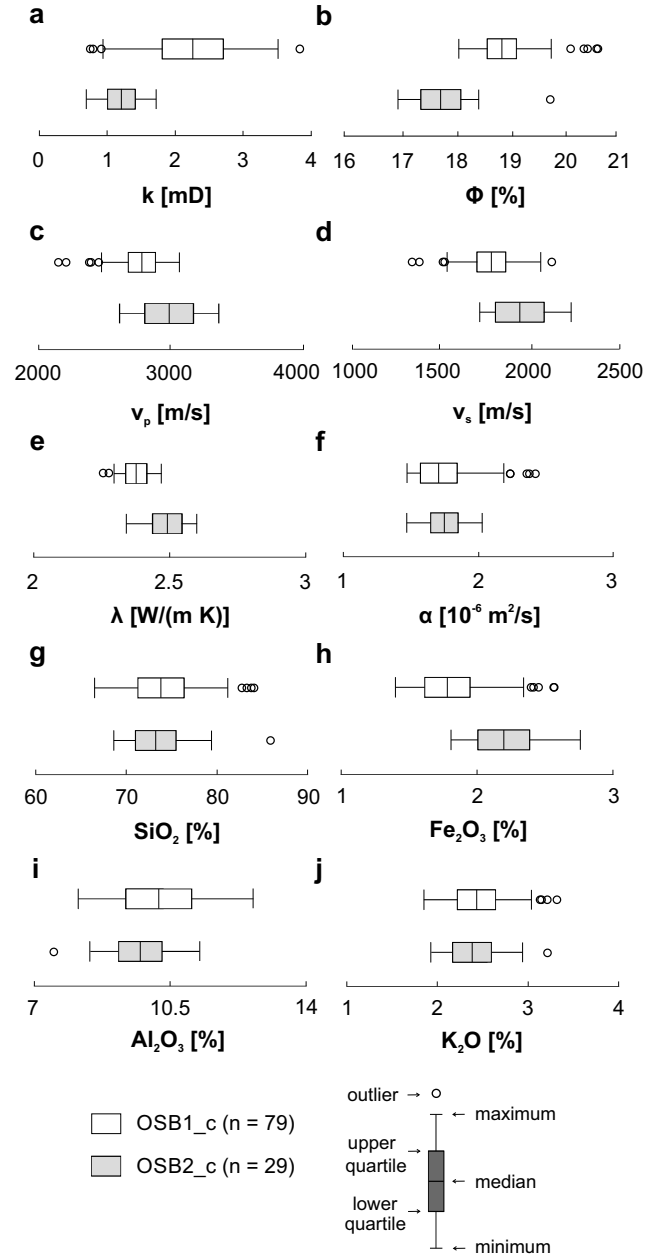

Figure 7. Box-Whisker charts showing the empirical distribution of the rock properties measured on the rock cylinders taken from the rock cubes. Outliers were detected according to Tukey's method (Tukey, 1977) where a value is tested to be in the 1.5-times inner-quartile-range of the arithmetic mean. (a) Intrinsic permeability k (b) Effective porosity ϕ (c) P-wave velocity v_p (d) S-wave velocity v_s (e) Thermal conductivity λ (f) Thermal diffusivity α and the mass fraction of (g) Silicon oxide SiO_2 (h) Iron oxide Fe_2O_3 (i) Aluminum oxide Al_2O_3 and (j) Potassium oxide K_2O .

is in accordance to the illite fraction that was observed in thin section and ESEM analyses. Only minor amounts of orthoclase feldspar could be found in the thin sections. Thus,

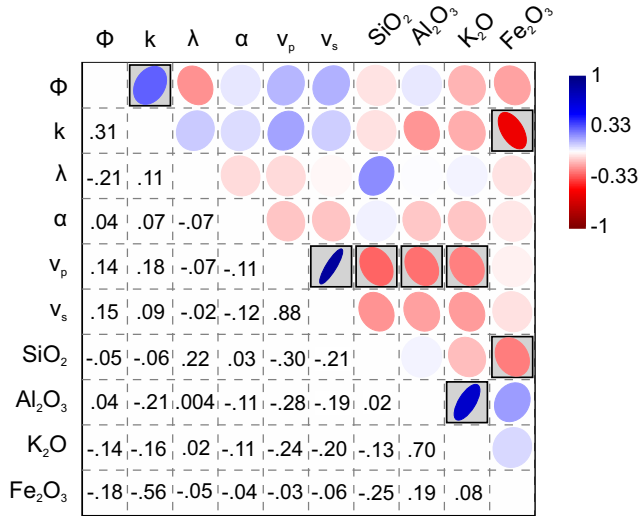

Figure 8. Matrix visualization of the Pearson correlation coefficient derived from the plug measurements. Statistically significant correlations with a P-value ≤ 0.05 are highlighted by gray boxes. The diameter of the ellipses' conjugate axes is dependent on the correlation coefficient. The smaller the length of the axis, the stronger is the correlation. The matrix is diagonal meaning that the Pearson correlation coefficient as numerical expression is located at the diagonal position relative to each ellipsis. Φ = effective porosity; k = permeability; λ = thermal conductivity; α = thermal diffusivity; v_p = P-wave velocity; v_s = S-wave velocity.

we assume that the correlation of K_2O and Al_2O_3 can be traced back to the illite phases.

Higher fractions of Al_2O_3 are supposedly due to higher kaolinite ($Al_2Si_2O_5(OH)_4$) fractions in the clay mineral assemblages. The patterns are diffuse showing autocorrelated areas of slightly enriched and depleted mass fractions. Enriched areas seem to be connected, building network-like patterns, while depleted areas are more isolated.

4 Discussion

The overall aim of this study was to quantify the three-dimensional inter-dependencies of thermophysical, hydraulic, elastic and geochemical scalar fields in sandstone media at the lithofacies scale and to identify the controlling factors for the property distributions. With a high-resolution study at the lithofacies scale, statistical and spatial inter-relationships between characteristic physicochemical fields could be discovered and traced back to depositional and diagenetical processes.

4.1 Petrophysical and geochemical characteristics

Recent multi-scale modeling approaches without the usage of local constraints show that the prediction of permeability and porosity in siliciclastic systems is still challenging (Nor-

dahl et al., 2014). Geological sampling almost never includes the entire domain that is investigated. With sampling densities of 25.4% and 18.2%, we reached a very high degree of coverage. Studies such as Hurst and Rosvoll (1991) showed that a very high sampling density is necessary to cover the entire variance of permeability at the lithofacies scale. The interpolations performed in this study reproduce the global histogram properly and also outliers are accounted for. This, in fact, implies that the sampling density was selected adequately in order to capture the total variability present in the physical and geochemical scalar fields. This condition is typically only fulfilled in sequential simulations (Robertson et al., 2006) rather than in conventional interpolations.

Although statistically significant correlations may imply a natural relationship between physicochemical properties, this relationship could also be based on random processes requiring causality to be verified. Weak correlations were found between the effective porosity and the intrinsic permeability, which are positively correlated usually (Pape et al., 1999). This relationship can be traced back to the Kozeny–Carman equation that connects the permeability with the effective pore throat radius r_{eff}^2 and a formation factor F like

$$k = r_{eff}^2 / (8 \cdot F). \quad (21)$$

The formation factor is defined as the ratio of tortuosity and porosity showing that porosity and permeability provide a positive formal relationship empirically. A high amount of secondary pores, produced by feldspar dissolution, did not significantly contribute to the permeability in the investigated sandstones since those pores are often hydraulically isolated. Consequently, secondary porosity did not necessarily lead to increasing radii of the effective pore throats rather than increasing tortuosity. Also, recrystallized quartz cement – blocking a large amount of the pore throats – must be taken into account. Both effects, in turn, resulted in a degraded permeability. Additionally to the geometrical aspects previously mentioned, the alteration products in form of clay minerals occupy the pore space, which lead to larger adhesive effects that hinder the ability to transport fluids as well. This observation is in good agreement with observations made by Molenaar et al. (2015) in Rotliegend rocks from the Donnersberg Formation. In addition, these observations are well reflected by the very low values of the intrinsic permeability in both rock cubes. Another reason for the very low intrinsic permeability is the high amount of primary clay and the low maturity of deltaic sheet-like distributary mouth bar deposits (Tye and Hickey, 2001).

The linear correlation analysis revealed a significant negative relationship between hydraulic and geochemical properties that fits to a polynomial regression (Fig. 14). It should be considered that the geochemical measurements cover a very different measurement area – represented by a spot of 1.2 cm diameter and around 0.5 cm penetration depth compared to the hydraulic measurements performed on an entire rock

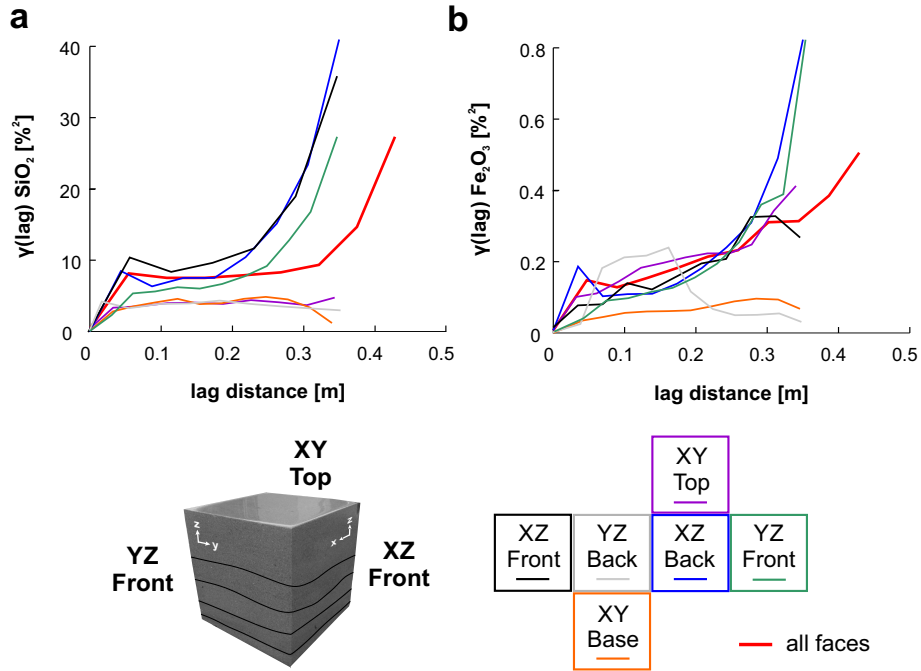

Figure 9. Empirical semivariograms of the mass fraction of SiO_2 (a) and Fe_2O_3 (b) in rock cube OSB1_c grouped by the investigated rock face.

Figure 10. Spatial distribution of the intrinsic permeability modeled with a simple kriging interpolation. The histogram shows a bimodality of the distribution split up into the basal beds and uppermost beds.

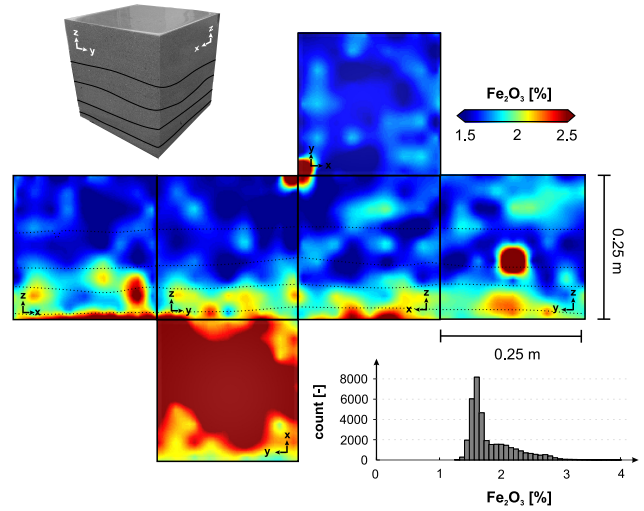

Figure 11. Spatial distribution of the mass fraction of Fe_2O_3 modeled with a simple kriging interpolation. As in the intrinsic permeability interpolation, a bimodality can be observed in the empirical histogram.

cylinder of 40 mm height and diameter. Additionally, instead of using highly-precise stationary X-ray fluorescence devices for measurements, a portable, faster device was used to efficiently derive spatial trends in the objects of investigation. This technique weakens the implications for absolute values, however, the trends observed in the measurements from the portable device are in good agreement with trends observed

by stationary devices. Also, the observed geochemical characteristics are in well accordance with geochemical properties of quartz-rich sandstone varieties that were investigated in Bhatia (1983) or Baiyegunhi et al. (2017).

Geochemical analyses, in contrast to petrographic ones, limit the interpretations of geological processes as mineral phases can only be assumed and not determined for certain.

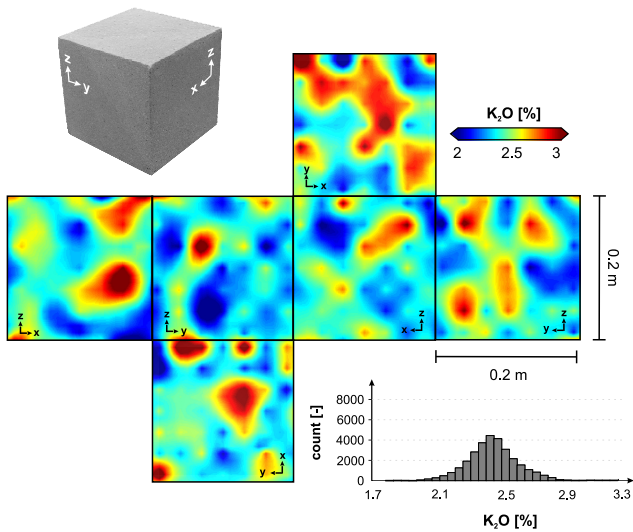

Figure 12. Spatial distribution of the mass fraction of K_2O modeled with a simple kriging interpolation. The pattern is decoupled from primary sedimentary structures and shows a network-like structure.

Figure 13. Spatial distribution of the mass fraction of Al_2O_3 modeled with a simple kriging interpolation. The pattern is decoupled from primary sedimentary structures and shows a network-like structure.

A high mass fraction of Fe_2O_3 may imply that the rock is rich in iron-bearing minerals like clay minerals, hematite, magnetite, goethite, lepidocrite or ferrihydrite (Costabel et al., 2018), however, a precise classification of the mineral phase is not possible. Iron oxides are more common in secondary precipitates that usually form during eo- and mesodiagenesis (Pettijohn et al., 1987). The degrading impact of iron-oxide-rich coatings on permeability and porosity in unconsolidated sand and gravel has been shown in studies like Costabel et al. (2018). The amount of detrital iron-rich phases like hematite

present in the rock matrix is typically less (Walker et al., 1981; Turner et al., 1995; Ixer et al., 1979) compared to the secondary amount. In our case, however, thin section and ESEM analyses revealed that a high degree of inter-granular matrix is still preserved, especially at the base of OSB2_c where high amounts of mud and mud intraclasts are incorporated from basal erosion. The small grain size of the matrix offers a great surface area for iron-oxide-rich precipitates, which might have further enforced degradation of porosity and permeability. Primary matrix typically plugs the pore throats of porous, matrix-rich media. This reduces the ability to conduct fluids compared to matrix-free ones. However, due to progressive compaction we cannot quantify for certain how large the amount of the primary matrix is compared to the pseudomatrix produced by plastic compaction of ductile, clay-rich grains and by feldspar dissolution.

A significant correlation between K_2O and Al_2O_3 could be detected. The spatial distribution resembles a network-like structure that might be either a product of diffusive mass transport during meso- or telodiagenesis or might reflect the distribution of feldspar grains and its residues in the sandstone. During feldspar alteration, SiO_2 gets dissolved and K remains in the alteration products, which could be an implication for the meso-scale network-like structure, in which pore fluids could have had migrated. This relationship is underlined by a negative, yet non-significant correlation of K_2O with SiO_2 .

5 Conclusions

Significant, non-intuitive relationships between the physical and geochemical scalar fields at the lithofacies scale have been revealed with a deductive approach of spatial field modeling and statistical data analysis. All in all, the following conclusions can be drawn from this study:

1. As specific properties such as the mass fraction of Fe_2O_3 preserve sedimentological textures well in their spatial distribution, other properties seem to be completely decoupled from depositional bounding surfaces. These scalar fields probably reflect processes that might have had taken place during diagenetical overprint of the rocks as a result of burial and exhumation. These processes produce diffuse patterns, like discussed with regard to the correlation of K_2O and Al_2O_3 .
2. This study demonstrates that the observation of bedding structures does not necessarily indicate a stronger polar anisotropy compared to macroscopically unstructured lithologies. Here, the microscopic characteristics like the amount of secondary porosity might play a more important role in the attenuation of physical waves than the bounding surfaces.
3. It could be shown that hydraulic properties are dependent on the inter-granular matrix and cement amount,

Figure 14. Regression analysis of the relationship between intrinsic permeability and mass fraction of Fe_2O_3 in the interpolated scalar fields of the rock cube OSB2_c. R_p^2 is the coefficient of determination for the plug measurements and R_i^2 is the coefficient of determination for the interpolated values.

which are in turn controlled by depositional processes and eogenetical precipitates. Those findings are not new (see Wilson and Pittman (1977) or Nordahl et al. (2014)), however, have not been evaluated in lithofacies-scale 3-D environments yet. We assume that primary matrix and ductile grain content has the most detrimental effect on rock permeability. Ductile grains were mechanically deformed during compaction leading to plugged pore throats. Feldspar dissolution has a highly productive effect on porosity but not on permeability.

4. We demonstrate that the strength of statistical correlation can be preserved in spatial interpolations as long as the sampling density is sufficient. If the sampling density is too low, a statistical correlation might be feigned inadvertently.
5. As shown in this study, the local geological variability should not be underestimated as an uncertainty factor in spatial predictions and up-scaling procedures. In fact, the local geological variability of physicochemical properties might nearly cover the variability being present in an entire formation. Therefore, a high-resolution analysis of physicochemical rock properties can assist in assessing the uncertainty of field-scale property models, which is induced by the local geological variability at the lithofacies scale.

Code and data availability. GeoReVi is an open-source software for Windows systems available under <https://github.com/ApirsAL/GeoReVi>. The executables are available in the repository under

<https://github.com/ApirsAL/GeoReVi/blob/master/binaries/>. The measurements are available under <https://www.doi.org/10.6084/m9.figshare.11791407.v2>

Sample availability. The investigated rock samples are available at the Institute of Applied Geosciences Darmstadt and can be requested under linsel@geo.tu-darmstadt.de. Also, the samples are registered in the System for Earth Sample Registration (SESAR, www.geosamples.org).

Author contributions. AL conceptualized and prepared the manuscript. AL and SW conducted the laboratory and field measurements. JH contributed to the conceptualization of the study. MH was the overall supervisor of the study.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. The authors are grateful for the permission to work in the sandstone quarry of the company Konrad Müller GmbH in Obersulzbach, Germany. Also, we would like to thank Reimund Rosmann and the IWAR (Technische Universität Darmstadt, Germany) for the preparation of the rock cubes. We are extremely thankful to Mattia Pizzati and Giacomo Medici for their time and effort in putting together constructive reviews. AL has received financial support by a PhD scholarship from the Friedrich-Ebert-Stiftung, which is gratefully acknowledged.
