Abstract

In this study, we present an estimate of the gravity signal of the slabs beneath the Alpine mountain belt. Estimates of the gravity effect of the subducting slabs are often omitted or simplified in crustal scale models. The related signal is here calculated for alternative slab configurations at near surface height and on a satellite altitude of 225 km.

We apply three different modelling approaches in order to estimate the gravity signal from the subducting slab segments, by: i) Direct conversion of upper mantle seismic velocities to density distribution, which are then forward calculated to obtain the gravity signal. ii) Definition of slab geometries based on seismic crustal thickness and high-resolution upper mantle tomography for two competing slab configurations. The geometries are then forward calculated by assigning a constant density contrast and slab thickness. iii) Accounting for compositional and thermal variations with depth within the predefined slab geometry.

Forward calculations predict a gravity signal of up to 40 mGal for the Alpine slab configuration. Significant differences in the gravity anomaly patterns are visible for different slab geometries in the near surface gravity field. However, different contributing slab segments are not easily separated, especially at satellite altitude. Our results demonstrate that future studies addressing the lithospheric structure of the Alps should have to account for the subducting slabs in order to provide a meaningful representation of the geodynamic complex Alpine area.

Keywords:

Satellite gravity gradient, Alpine subduction, lithospheric and sub lithospheric structure, mantle composition, seismic tomography

1. Introduction

Interpretation of gravity anomalies can reveal information on the architecture and tectonic setting of the lithosphere (e.g. Zeyen, & Fernández, 1994; McKenzie & Fairhead, 1997; Holzrichter & Ebbing, 2006; Braitenberg, 2015; Spooner et al. 2019). For subduction zones, like the Andes, several studies have shown that the gravity effect of the subducting plates is significant and has to be considered in order to study the feedback between the subducting lithosphere and the overriding plate (Götze et al. 1994; Götze & Krause 2002; Tašárová 2007 Gutknecht et al. 2014; Götze & Pail 2018; Mahatsente 2019). For lithosphere to subduct, a higher density than the surrounding mantle material at the same depth interval is required,

43 causing a negative buoyancy for the slab and therefore the slab is subducted into earth's interior
44 (e.g. Kincaid & Olson 1987; Ganguly et al. 2009). However, the gravitational contribution of
45 subducting material in the upper mantle to the gravity field has so far not been systematically
46 addressed for the Alpine system. In order to provide an assessment, the magnitude of the gravity
47 signal of such sub-crustal long wavelength features has to be estimated.

48 The Alpine mountain belt (Fig. 1a) is chosen for this sensitivity study because firstly a large
49 range of recent seismic tomography studies imaged subducting slab segments in the Alpine
50 region (e.g. Babuska et al., 1990; Lippitsch et al., 2003; Spakman & Wortel, 2004; Mitterbauer
51 et al. 2011; Karousová et al., 2013; Zhao et al., 2016; Kästle et al., 2018; El-Sharkawy et al.,
52 2020). Those different studies suggest different configurations of slab segments (see section
53 1.1), allowing us to test how sensitive the gravity field is to varying geometries of subducting
54 slab segments. Secondly, previous Alpine models addressing the Alpine gravity field have
55 considered the subcrustal mantle inhomogeneities in form of lithosphere thickness (e.g. Ebbing
56 et al., 2006; Spooner et al., 2019) or in form of mantle density variations (Tadiello and
57 Braitenberg 2021), but without identifying the isolated effect of subducting slabs segments in
58 the velocity or density variations. If the contribution of the mantle density variations is not
59 considered, a significant part of the gravity field might be attributed to crustal thickness
60 variations or intra-crustal sources.

61 In addition, the Bouguer Anomaly of the Alps (Fig. 1b) shows no direct sign of subducting slabs
62 (in contrast to the Andes subduct zone) as the field is dominated by crustal thickness variations
63 (Ebbing et al., 2001, 2006). Therefore, forward modeling of the proposed slab geometries, as
64 imaged by high-resolution tomographic studies, is necessary to separate the gravity signal
65 caused by the subducting slabs from the gravity anomaly field.

 69 *6040m above the ellipsoid, just above the surface of the Alps. Correction density for rock: 2670 kg/m³ and for water: 1030*
 70 *kg/m³*

71 We present three different approaches to model the gravity effect of the slab segments and
 72 discuss the strengths and limitations of the applied methods. In the first approach, the alpine
 73 sup-crustal density distribution is derived by converting seismic velocities to density. This
 74 model is then forward calculated to estimate the gravity response. In the second approach, 3D
 75 slab geometries are derived by evaluating seismic crustal thickness estimations and high-
 76 resolution upper mantle tomographic models. Here, two competing slab configurations are
 77 chosen. The predefined slab geometries are then forward calculated by assigning different
 78 density contrasts and slab thicknesses. The third approach uses similar predefined slab
 79 configurations as in the second approach, however, here we consider petrology, temperature,
 80 and density variation. The gravity response is calculated for all three approaches at a near
 81 surface height for the gravity disturbance and the gravity gradients at satellite altitude of 225
 82 km.

83 1.1 Alpine setting

84 The formation and present geodynamics of the Alps are linked to long lasting tectonic
 85 processes, including Adria-Europe continent-continent collision, subduction of oceanic and
 86 continental lithosphere, the formation of crustal nappes as well as extensional and
 87 compressional shortening processes (Frisch, 1979; Stampfli & Borel, 2002; Handy, et al., 2010,
 88 2015). The Adriatic microplate is a major driver of the present geodynamics in the Alpine

89 region, which is trapped between the converging major plates of Europe and Africa. Adria is
90 moving counterclockwise with respect to Europe, as seen by GPS observations (e.g. Nocquet
91 and Calais, 2004; Vrabec and Fodor, 2006; Serpelloni et al., 2016) and is subducted beneath the
92 Apennines to the west as well as to the east beneath the Dinarides, while colliding with Eurasia
93 in the Alps to the north (e.g. Channel & Horvath, 1976; Dewey et al., 1989; Stampfli & Borel,
94 2002; Handy et al., 2010; Le Breton et al., 2017). Subducting slab segments have been imaged
95 by different seismological body wave travel time tomographic studies as well as surface wave
96 tomographic studies within the Alpine upper mantle (e.g. Babuska et al., 1990; Lippitsch et al.,
97 2003; Spakman & Wortel, 2004; Mitterbauer et al. 2011; Karousová et al., 2013; Zhao et al.,
98 2016; Kästle et al., 2018; El-Sharkawy et al., 2020). However, the configuration of subducting
99 slab segments remains controversial. In the Western Alps, Lippitsch et al. (2003) propose a slab
100 break-off at about 100 km depth, which is in line with the findings of Beller et al. (2018), Kästle
101 et al. (2018) and El-Sharkawy et al. (2020). In contrast, a continuous subducting slab segment
102 in the Western Alps, down to at least 250 km depth, is imaged by a number of other tomographic
103 models (e.g. Koulakov et al., 2009; Zhao et al., 2016; Hua et al., 2017; Lyu et al., 2017).
104 A continuous subduction of Eurasia beneath the Central Alps down to at least 200 km depth is
105 imaged by different tomographic models (e.g. Lippitsch et al., 2003; Piromallo and Morelli,
106 2003; Koulakov et al., 2009; Mitterbauer et al., 2011; Hua et al., 2017; Fichtner et al., 2018; El-
107 Sharkawy et al., 2020). A potential slab gap with an approximate size of 2° is separating the
108 subducting slab segments in the Central Alps to the Eastern Alps as imaged by e.g. Lippitsch
109 et al. (2003). The slab configuration and subduction direction in the Eastern Alps remains
110 unclear. According to the classical view, Eurasia is subducting beneath Adria in a southward
111 subduction (Hawkesworth et al., 1975; Lüschen et al., 2004; 2006). This idea was challenged
112 by Lippitsch et al. (2003), Schmid et al. (2004), Kissling et al. (2006), Handy et al. (2015), and
113 Hetenyi et al. (2018). Instead, slab break-off in the eastern Alps and a northward-dipping
114 Adriatic slab in the easternmost Alps is suggested, leading to a switch of the slab polarity, as

115 Adria is subducting beneath the European plate (Handy et al., 2015). The view that Adriatic and
116 not Eurasian lithosphere is subducting northwards in the Eastern Alps has been opposed by
117 Mitterbauer et al. (2011), as their model shows a northward dipping slab in the eastern most
118 Alps connected to the European plate. In an early tomographic study, Babuska et al. (1990)
119 proposed that both Eurasian and Adriatic lithosphere is subducting in the eastern Alps. In
120 subsequent studies and interpretations this model was mentioned but northward subduction of
121 Adria seems to be favoured (e.g. Karousová et al., 2013; Hetenyi et al., 2018). Recently,
122 subduction of both Eurasian and Adriatic lithosphere in the eastern Alps down to about 150 km
123 has been suggested by Kästle et al. (2020) and El-Sharkawy et al. (2020) based on surface wave
124 studies. For a more in-depth comparison and discussion of tomographic Alpine models the
125 reader is referred to e.g. Kästle et al. (2020).

126 **2. Data**

127 The Bouguer Anomaly (Fig. 1b) is based on the global model *XGM 2019* (Zingerle et al., 2020)
128 developed for spherical harmonics up to degree 719, with a resolution of ~ 25 km (half
129 wavelength). The *XGM 2019* model is a global integrated gravity model, which includes
130 satellite and terrestrial measurements. The Bouguer Anomaly is calculated from the Free-Air
131 gravity disturbance with a correction density of 2670 kg/m^3 for topography, and a correction
132 density for water of 1030 kg/m^3 for the offshore areas using Tesseroids (Uieda et al., 2016). For
133 the tesseroids, we use the topography and bathymetry from ETOPO (Amante & Eakins, 2009),
134 which was regridded at a regular grid with a grid space of 25 km to match the resolution of the
135 *XGM 2019* model for a maximum degree of 719. The gravity field is defined at a constant
136 station height of 6040 m above the ellipsoid, just above the surface of the Alps. The resulting
137 Bouguer Anomaly shows a gravity low in the order of -200 mGal over the high topography of
138 the Alps, indicating an isostatic crustal thickening in response to topography (e.g. Ebbing et al.,
139 2006). Additionally, we calculate the mass correction for the gravity gradients at a station height

140 of 225 km representing the GOCE satellite altitude. The topographic corrected gravity gradients
 141 after Bouman et al. (2016) measured by the GOCE ESA satellite mission are presented in the
 142 appendix.

143 For the definition of the slab geometry, we use crustal thickness estimates based on the receiver
 144 function study by Spada et al. (2013). The crustal thickness map was digitized and the Moho
 145 gap in the eastern Alps is filled by nearest neighbour interpolation. To avoid edge effects,
 146 surrounding areas are supplemented by the Moho depth model of the European plate by Grad
 147 et al. (2009), both data sets were merged using a cosine taper with a taper width of 2° using
 148 equation (1). The overlapping areas at the grid edges are distance weighted to obtain a smooth
 149 transition.

$$150 \quad G_{new} = T(x, y) \cdot G_1(x, y) + (1 - T(x, y))G_2 \cdot (x, y) \quad (1)$$

$$152 \quad \text{with: } T(x, y) = \cos \frac{D \cdot \pi}{2 \cdot L}$$

151 *with: G = Grids, T = taper, D = dx, L = Tapper length*

153 The merged Moho depth map is sampled at a regular grid with a cell size of 0.25° (Fig. 2) to be
 154 consisted with resolution of the topographic and gravity models.

156 *Figure 2 a) digitized Moho depth after Spada et al. (2013) with a 0.25 ° grid spacing, b) Moho depth estimation after Grad et*
 157 *al. (2009) with a 0.25 ° grid spacing c) Merged Moho depth map from Spada et al. (2016) and Grad et al. (2009) with a grid*
 158 *resolution of 0.25 ° using a cosine taper with a 2° width.*

159 For the upper mantle seismic velocity, the 3-D shear wave velocity model (MeRE2020) by El-
 160 Sharkawy et al., (2020) is used (Fig. 3). The model covers the upper mantle across the Alpine-
 161 Mediterranean area down to a depth of 300 km and absolute shear-wave velocities are given.

162 In this study, relative shear-wave velocities in the depth range from 70 to 200 km are calculated
163 with respect to a 1-D average shear wave velocity model, the background model is described in
164 El-Sharkawy et al., (2020). The upper limit of 70 km is introduced because i) we focus on the
165 contribution of the slab segments removing therefore crustal information from the model ii) the
166 tomography model MeRE2020 is not sensitive to shallow structures, as a result the slabs are
167 not well recovered in depths shallower than 70 km iii) we want to ensure a uniform upper
168 boundary. The lower boundary of 200 km is chosen based on clear images of the Alpine Slab
169 segments to at least 200 km depth (with exception of the Western Alpine slab), as discussed in
170 section 1, and the assumptions that depth larger than 200 km will have a negligible effect on
171 the regional gravity field considered here.

172 The ambient noise tomography by Kästle et al. (2018) is used to define the geometry of the
173 Western Alpine slab segment, hence we follow the idea of a slab-breakoff in the Western Alps
174 at 100 km depth (Kästle et al., 2020) as suggested also by Lippitsch et al. (2003) and Beller et
175 al. (2018). For the eastern Alps, we consider two alternative models. For the first hypothesis,
176 the P-wave tomography by Lippitsch et al. (2003) is used, to define the Eastern Alpine slab
177 segment. The second hypothesis is based on Kästle et al. (2020) and El-Sharkawy et al. (2020).
178 It assumes southward subduction of a short Eurasian Slab as well as northward subduction of a
179 short Adriatic Slab in the eastern Alps. The slab configurations which are incorporated in the
180 Alpine density models are discussed in greater detail in section 4.1.

181 **3 Conversion of seismic velocities into density distribution**

182 Seismic velocity variations are dependent on temperature and pressure. Densities in the
183 subsurface are also temperature and pressure dependent. A conversion factor (ζ) can describe
184 the linear relation between seismic velocities variations and densities variation (e.g. Tiberi et al.
185 2001; Webb 2009). We convert seismic shear wave velocities from the tomographic model
186 MeRE2020 by El-Sharawy et al. (2020) in the depth range from 70 to 200 km, as discussed in

187 section 2, to obtain a density distribution of the upper mantle in the Alpine region based on a
 188 conversion factor (ζ). The relationship between seismic velocities and densities is described in
 189 equation (2), this assumption is a strong simplification of reality, but gives a first order
 190 estimation of the expected relative density structure beneath the Alps.

$$191 \quad \rho_{rel} = [Vsv_{abs}(1 + \Delta\%) - Vsv_{abs}] \cdot \zeta = Vsv_{abs} \cdot \Delta\% \cdot \zeta \quad (2)$$

192 *with: Vsv_{abs} = absolute velocities from MeRE2020;*

193 *$\Delta\%$ = percentage deviation from the MeRE2020 background model;*

194 *ζ = conversion factor*

195 The result is strongly dependent on the chosen conversion factor. A range for conversion
 196 factors has been proposed in the literature for different rock types ranging from 0.1 to 0.45 (e.g.
 197 Isaac et al., 1989; Isaak, 1992; Karato, 1993; Kogan and McNutt, 1993; Vacher et al., 1998).
 198 The relative shear-wave velocity distribution in a 3D domain from the tomography model
 199 MeRE2020 from El-Sharkawy et al., (2020) is converted using a constant conversion factor (ζ)
 200 of 0.3. The converted relative density distribution varies between -240 and 350 kg/m³. High
 201 correlations between the structural pattern in the converted density distribution and the relative
 202 seismic velocities are observed (Fig. 3), the similarity in the structure pattern is expected due
 203 to the linear relationship we introduced here. The converted 3D relative density distribution
 204 reflects the variation of seismic velocities in the Alpine lithosphere and therefore includes the
 205 heterogeneities of the subduction slab segments, as seen by the tomographic models (Fig 3).
 206 The relative density model is transferred into tesseroids with a horizontal expansion of 0.2° and
 207 a vertical expansion of 3 km. The Tesseroid model is forward calculated in order to estimate the
 208 gravity response of the converted density distribution of the Alpine lithosphere in the depth
 209 interval of 70 km to 200 km. No horizontal extensions of the mantle model are introduced
 210 because relative densities are used and therefore edge effects are not expected to be significant
 211 and would only affect the outer most degrees of the model. The slab segments are located central
 212 in the model far away from possible artifact due border effects.

214

215 *Figure 3 (a)-(c) Depth slices of relative surface wave velocities (V_{sv}) from MeRE2020 (El-Sharkawy et al., 2020). (d)-(f)*
 216 *converted relative density distribution in different depths based on a conversion factor (ζ) of 0.3. CA = Central Alpine Slab;*
 217 *EA = Eastern Alpine Slab; NA = Northern Apennine Slab*

218 3.1 Results

219 In the forward calculated gravity field, a gravity high with a magnitude of ~ 40 mGal is observed
 220 over the Alps (Fig. 4). That might be interpreted as relating to the proposed slab segments in
 221 the Northern Apennine and Alpine area. However, the gravity field (and gradients, see appendix)
 222 is dominated by anomalies outside the Alpine realm (Fig. 4), for instance in the Ligurian Sea
 223 and the Dinaride-Hellenide Orogen. Therefore, in the next step, we try to concentrate on the
 224 seismic anomalies in the Alpine realm that can be related to the slab segments.

225

226 *Figure 4 Forward calculated gravity signal from relative density distribution converted from relative seismic velocities using*
 227 *a conversion factor of 0.3 at a station height of 6040m.*

228 **4 Slab models**

229 To estimate the gravity contribution of independent slab segments we introduce different
 230 models for the subducting lithosphere. First, we use a set of models with simple constant density
 231 distribution in the slab, where the parameters, namely the density contrast and thickness of the
 232 slab segment is varied (approach 2). Secondly, we create a set of slab models accounting for
 233 compositional and thermal variations with depth (approach 3). Those models of approach 3 are
 234 created with the software package LitMod 3D (Fullea et al., 2009) and here the slabs are strictly
 235 vertical due to software limitations. Slab models created within LitMod will be referred as
 236 LitMod models in the following. For all non-LitMod models, the gravity and gravity gradients
 237 are calculated using tesseroids, which are spherical prisms (Uieda et al., 2016).

238 **4.1 Slab modelling with constant density contrast and slab thickness**

239 We define two alternative slab configurations based on crustal thickness model by Spada et al.
 240 (2013) and several different tomographic studies, see detailed description of the slab
 241 configurations below. At different depths, isolines are picked in the Moho depth map and
 242 tomographic images, defining the upper boundary of subducting slab segments. The isoline of
 243 the crust mantle boundary (Moho interface) is used as an onset of the slab to the crust and
 244 defines the upper boundary of the subduction slab segment. At upper mantle depth, increased

245 seismic velocity anomalies in tomographic models beneath the Alps are interpreted as contrast
 246 between colder and therefore denser subducting material to the surrounding mantle material. At
 247 100, 150, and 200 km depth, the upper boundary of the slab segment is defined at the 0%
 248 contour line of the relative seismic velocity, marking the transition from rocks with low velocity
 249 to high velocity rocks. The isolines at the Moho interface, 100 km, 150 km and 200 km depth
 250 are displayed upon the Alpine topography (Fig. 5 a-b) Vertical interpolation between the upper
 251 boundary isolines at different depths (Moho depth, 100, 150 and 200 km) define a continuous
 252 surface of the upper slab boundary. The lower boundary of the slabs and therefore the thickness
 253 of the slab segment is not picked based on seismic data but assumed to have constant
 254 thicknesses for simplifications. The thickness is varied for different models from 60 to 100 km
 255 depth.

257 *Figure 5 Defined isolines based on crustal thickness estimations and seismological tomography models for the upper slab*
 258 *boundary for (a) Configuration 1 and (b) Configuration 2. Black arrows indicate the subduction direction. In red the fault*
 259 *configuration after Schmid et al. (2004).*

260 3.1.1 Alternative slab configurations

261 We define two different slab configurations. Configuration 1 (Fig. 5a) features a northeast
 262 subducting slab segment in the Eastern Alps based on Lippitsch et al. (2003). A Central Alpine
 263 slab segment is defined based on Lippitsch et al. (2003) and MeRE2020 (El-Sharkawy et al.,
 264 2020) subducting in south-southeast direction. The Eastern and Central Alpine slab segments
 265 are separated by a slab gap and show perpendicular subduction directions. The east-southeast-
 266 ward subducted slab segment in the Western Alps is defined using the tomographic model of

267 Kästle et al. (2018), supporting the idea of slab break-off at about 100 km depth. Only attached
268 slab segments are considered, ignoring potential mantle upwelling in the break off zone and
269 neglecting the potentially remaining detached slab segment in larger depths. In addition, a
270 southwest-subducting slab segment beneath the northern Apennines is considered down to
271 about 200 km depth, as imaged by MeRE2020 (El-Sharkawy et al., 2020) because of its
272 proximity to the western Alps.

273 Configuration 2 (Fig. 5b) considers a slab configuration mainly based on the interpretation of
274 the MeRE2020 model (Fig. 3) by El-Sharkawy et al. (2020). In the Eastern Alps, both a short
275 southward subducting Eurasian slab segment as well as a short northward subducting Adriatic
276 slab are assumed. The Central and Western Alpine slab segments as well as the slab beneath the
277 northern Apennines are identical to Configuration 1.

278 4.1.2 Forward calculation

279 To estimate the gravity effect of the slab configurations, the geometries are discretized into
280 tesseroids with a 0.2° extension in the horizontal domain and a vertical size of 20 km. The
281 tesseroids range from 40 km to 200 km depth. First, a constant density contrast is assigned to
282 the entire slab. We test density contrasts from 20 kg/m^3 to 80 kg/m^3 . The thickness of the Alpine
283 slab is not well constrained. We test for three slab volumes by assigning three slab thicknesses,
284 60 km, 80 km and 100 km based on studies on other subducting slab segments (e.g. Wang et
285 al., 2020). Due to the curved geometries of the proposed slab segments rectangular tesseroids
286 with a horizontal expansion of 0.2° will either over- or under-estimate the volume of a
287 subducting slab at the edges of the slab. The percentage volume share of each tesseroid to the
288 slab geometry is calculated. The assigned density contrast of the tesseroids which does not lay
289 fully within the slab geometry is decreased according to the percentage volume within the slab
290 geometry. Therefore, the density distribution correlates to the hypothetical slab positions and
291 volumes in the Alpine subsurface without increasing the discretisation resolution of the
292 tesseroid model beyond the uncertainty of gravity measurements and seismic tomographies.

293 The offset between the 40 km upper tesseroïd boundary to the slab onset at the crust in 44 km
294 depth is corrected using the same process.

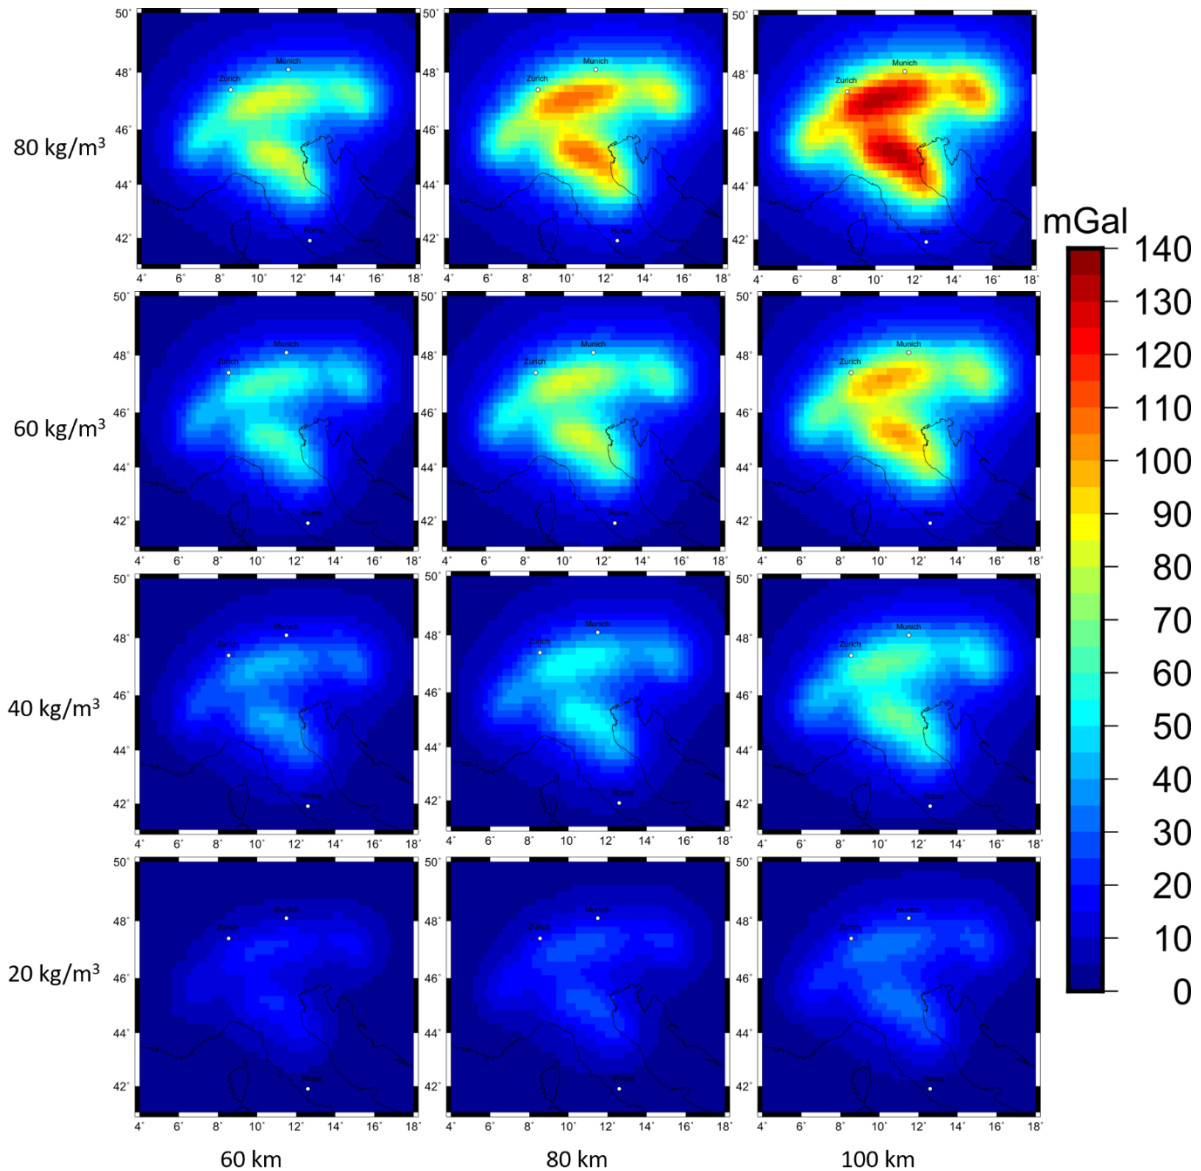

295 4.1.3 Results

296 Forward calculated slab models for predefined slab geometries of Configuration 1 and 2 with a
297 constant density contrast of 60 kg/m^3 and a constant thickness of 80 km result in a sharp gravity
298 signal ranging from 70 mGal to 100 mGal (Fig. 6). Both models generate gravity signals in the
299 order of magnitude of 70 mGal in the Central Alpine region as well as in the Apennine. The
300 gravity signal in the Eastern Alps differ for the two hypotheses (Fig. 6 a, b). The Western Alpine
301 slab segment shows the weakest signal in both models.

303 *Figure 6 Forward calculated gravity disturbance signal at a station height of 6040 m for predefined sub-crustal slab geometries*
304 *with a content density contrast of 60 kg/m^3 and a constant thickness of 80 km. (a) predefined slab configuration 1 (b) predefined*
305 *slab configuration 2.*

306 The gravity signal ranges from 30 to 110 mGal depending on the assigned density contrast and
307 thickness for both slab geometry models (Fig. 7). The highest magnitude of forward calculated
308 gravity signal is in the order of 110 mGal and is observed for a slab model with a density
309 contrast of 80 kg/m^3 and a constant slab thickness of 100 km, while the lowest signal is
310 produced by a combination of 20 kg/m^3 density contrast and a slab thickness of 60 km. Similar
311 gravity response is produced by different combinations of density contrast and volume. The
312 signal pattern is influenced by the predefined slab geometry, while the magnitude of the gravity
313 signal is depending on the density contrast and thickness (Fig. 7).

314

315 *Figure 7 Forward calculated gravity disturbance signal for 12 different combination of density contrast and slab thickness for*
 316 *sub-crustal slab configuration 1 at a station height of 6040 m.*

317 Forward calculated gravity gradients at satellite height show the same dependency of signal
 318 strength (see Appendix). The forward calculated gravity field of approach 2 differs significantly
 319 from the forward calculated gravity field of the complete mantle density inhomogeneity of
 320 approach 1 (Fig. 4), which only reaches a positive mantle effect of maximum 50 mGal.

321 **4.2 Geophysical and petrological modelling with LitMod**

322 For modelling the Alpine slab segments taking temperature and pressure variations as well as
 323 composition of the lithosphere and sub lithosphere into account, the geophysical and
 324 petrological modelling software LitMod 3D is utilized (Fullea et al.,2009). LitMod 3-D is a

325 finite difference code, which allows the modelling of lithospheric and sub lithospheric
 326 structures down to 400 km depth by solving the heat transfer, thermodynamical, rheological,
 327 geopotential, and isostasy equations (Afonso et al., 2008; Fullea et al., 2010).

328 A LitMod model consists of a set of crustal, lithospheric- and sub lithospheric layers
 329 characterized by their petrophysical and thermal properties, which are used as input data (Fullea
 330 et al., 2010). LitMod provides as an output i.e. the density -, temperature-, pressure- distribution
 331 as well as the forward calculated gravity disturbance and gravity gradients (Fullea et al. 2009).
 332 The assigned composition for the different layers is calculated using a LitMod subroutine which
 333 utilizes the Perple_X algorithm of Connolly (2009). Perple_X calculates in the LitMod
 334 implementation the specific bulk rock properties based on the six main lithospheric oxides
 335 (SiO₂, Al₂O₃, FeO, CaO, Na₂O) by minimizing Gibbs free energy equation. The Alpine
 336 lithosphere and sub lithosphere as well as the proposed slab segments are modelled using
 337 standard global lithospheric and sub lithospheric compositions to test the influence of
 338 compositional variations within the slab segments on the gravitational signal. Here, we use the
 339 so-called Tecton and Proterozoic type-composition (Table 1). Those compositions were chosen
 340 for a model with a homogeneous crust, lithosphere and sub-lithosphere, where the density
 341 changes as a function of temperature and pressure based on the assigned compositions. The
 342 different slab composition is introduced to test whether a compositional contrast, in addition to
 343 the expected thermal difference, results in a significant density contrast between the slab and
 344 the surrounding material.

345 *Table 1: Mineralogical composition for the lithospheric and sub lithospheric structure.*

Major Oxide Compositions	Aver. Tecton Gnt. SCLM ^a	Aver. Tecton Gnt. Peridotite ^a	Average Proterozoic Massif	PUM ^b	DMM ^c
SiO ₂	44.5	45	45.2	45	44.7
Al ₂ O ₃	3.5	3.9	2	4.5	3.98
FeO	8	8.1	7.9	8.1	8.1

MgO	39.8	38.7	41.6	37.8	37.8
CaO	3.1	3.2	1.9	3.6	3.17
Na ₂ O	0.26	0.24	0.13	0.36	0.13

346 ^a Classifications according to Griffin et al. (1999b), ^b McDonough & Sun (1995), ^c Workman & Hart (2005) DMM = Depleted
347 mid-oceanic ridge basalt mantle, PUM = primitive upper mantle.

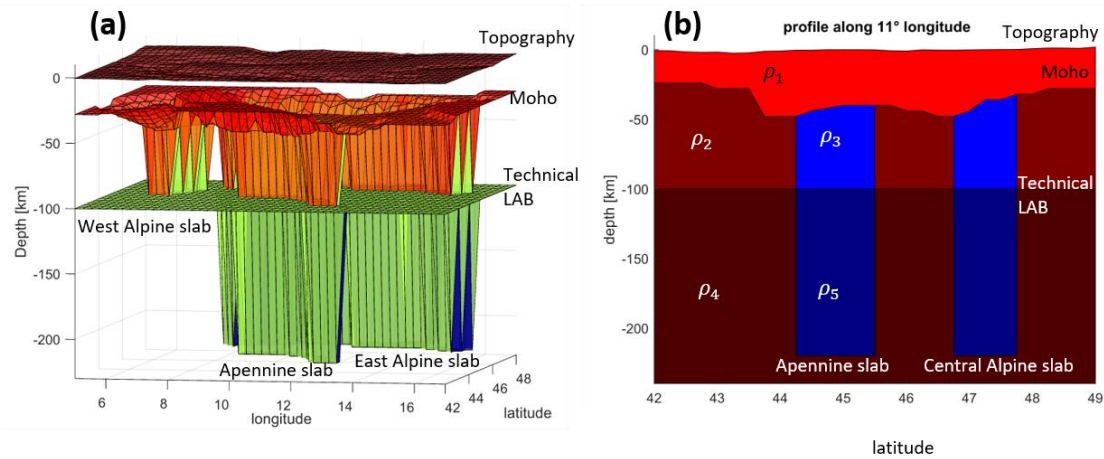

348 First, we create a reference model (M_0) without a slab segment. This model contains topography
349 from the ETOPO1 dataset (Amante and Eakins, 2009), the Moho depth from Spada et al. (2013)
350 and Grad et al. (2009). The lithosphere asthenosphere boundary (LAB) is a required interface
351 for the LitMod 3D to divide the model between the lithosphere and sub lithosphere and to assign
352 compositions. We introduce a fixed technical LAB at a depth of 100 km throughout the model
353 despite of the presence of slabs as the LAB is defined as the 1300°C isotherm. This set-up avoids
354 that the isotherm follows the geometrical shape of the slab, which would lead to a location in
355 unrealistic large depths (>200 km). In addition, we neglect the topography of the LAB for
356 several reasons: i) the information of the lithospheric thickness in the Alpine forelands is spare
357 and under ongoing discussions, ii) the fixed depth value is based on thermal isostasy LAB
358 estimations from Artemieva et al. (2019), which shows a LAB depth in the range of 80 to 120
359 km depth in the Alpine forelands. This technical LAB is used to parameterize the model and is
360 not meant to represent the topography of the LAB. The modelled slab segments are extending
361 vertically downwards.

362 Slab segments are introduced stepwise for the lithosphere and sub lithosphere domains into the
363 model as well as thermal anomalies for the slab segment beneath the technical LAB, which
364 describes the 1300°C isotherm (Table 2). Calculating the difference to the reference model (M_0)
365 allows to estimate the effect a slab segments has on the density, temperature distribution of the
366 Alpine subsurface and therefore on the Alpine gravity field based on slab position, slab
367 geometry and composition.

368 *Table 2: Different LitMod models and there incorporated lithospheric and sub lithospheric structures and compositions.*

Models	Slab geometries	Slab composition (mantle)	Mantle composition	Slab composition (sub lithosphere)	Sub lithosphere composition	Thermal anomaly within sub lithospheric slab

M₈	Configuration 2	Average Proterozoic Massif	aver. Tecton Gnt.	-	PUM	-

369 A positive density contrast between subducting material and the surrounding mantle material
370 results in a negative buoyancy force. A density contrast is introduced into the LitMod model by
371 a difference in composition between the subducting denser slab and the surrounding mantle
372 (Fig. 9). Here, we use Tecton like compositions for the lithosphere and the subducting slab
373 segments since the Alpine slab segments result from continent-continent collision (Tables 1 and
374 2). A later model features a Proterozoic slab composition (M₈). Depleted mid-oceanic ridge
375 basalt mantle (DMM) and primitive upper mantle (PUM) are used for the sub lithospheric
376 domain. Additional to the density contrast within the sub lithosphere, a temperature anomaly of
377 – 100 K is introduced for the sub lithospheric part. Later models include a variation of
378 temperature anomalies (M₅, M₆, M₇). Note those compositions are used as a first order test and
379 serve as a starting point for synthetic slab models to illustrate the compositional and thermal
380 effect on the gravity signal by influencing the density distribution. They do not necessary
381 represent the compositional mantle environment in the Alpine region.

382

 386 *petrophysical and thermal property variations for each layer.*

387 4.2.1 Results

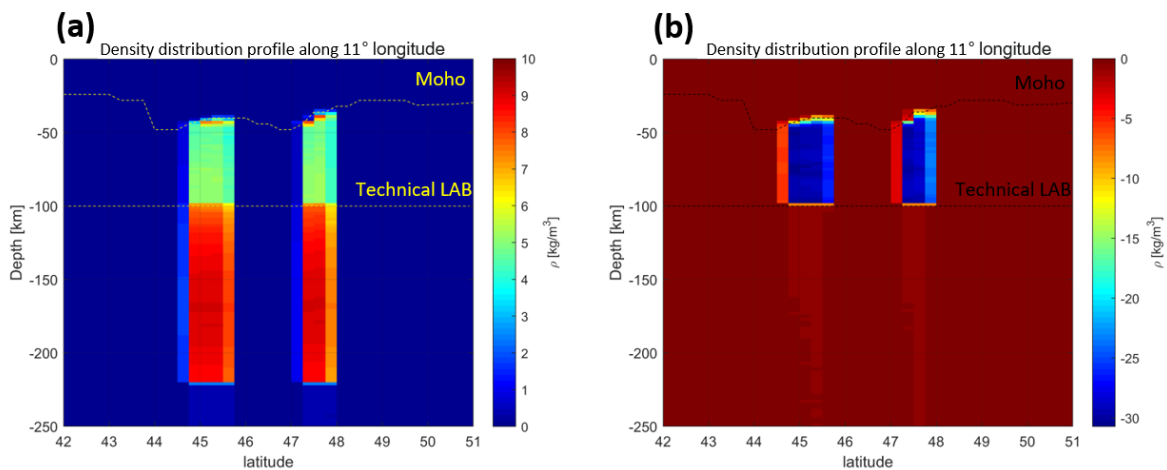

388 The gravity signal of the predefined slab segments is forward calculated as well as the
 389 background model without incorporation of slab segments. The residual between both forward
 390 calculations gives the gravitational contribution of the slab segments, while other gravitational
 391 effects, like the topography or crustal thickness variation and mantle variations outside the slab
 392 are not considered.

393 A slab segment with an average Tecton Gnt. composition (M_1 , M_2) results in a slightly denser
 394 material compared to the surrounding mantle (M_0), while a slab segment with a Proterozoic
 395 composition (M_8) shows a less dense lithospheric structure compared to the reference model
 396 (M_0), this composition results in less dense slab segment, which would not be subducted due to
 397 the positive buoyancy (Fig. 10). However, we aim to illustrate the effect composition has on
 398 the density distribution within the slab and to the surrounding mantle and show the importance
 399 of correct compositional information, therefore we focus on the difference in density contrast
 400 between slab and surrounding mantle and neglecting the sign of the density contrast.

401
 402 *Figure 9 (a) density profile at 11° longitude and 45° latitude for the full vertical model space of 400 km depth. Density profiles*
 403 *for 3 different models (M_0 , M_1 , M_9) with different compositional properties are shown. (b) Zoomed in profile at the depth range*
 404 *of present slab segments.*

405 The difference in density distribution (density contrast) within the slab segments with a Tecton
 406 composition (M_1 , M_3) to the reference model (M_0) is in the order of 5 kg/m^3 for the lithosphere
 407 and in the order of 10 kg/m^3 for the sub lithospheric domain (Fig. 10a). The density variations
 408 within the lithospheric and sub lithospheric slab domain are less than 1 kg/m^3 resulting from
 409 both depth dependent variations in pressure and temperature. Between lithosphere and sub
 410 lithosphere, a rapid increase in density contrast is observed (Fig. 10a). The density contrast of
 411 a lithospheric Proterozoic slab composition (M_9) to the reference model (M_0) is in the order of
 412 -30 kg/m^3 (Fig. 10b).

413
 414 *Figure 10 (a) residual density contrast for lithospheric and sub lithospheric slab segments of model (M_3) with Tecton like*
 415 *composition within the lithosphere and PUM and DMM composition in the sub lithosphere with an additional thermal anomaly*
 416 *of -100° k for the sub lithospheric slab segment to the background model (M_0). (b) Residual lithospheric density contrast of a*
 417 *Proterozoic lithospheric slab segment (M_8) to a Tecton compositional surrounding mantle (M_0). Residual density contrast is*
 418 *limited to the technical LAB as the sub-lithospheric part is identical to the reference model (see also Fig. 9b)*

419 The gravity signal caused by the proposed slab segment configurations is estimated for
 420 lithosphere and sub lithosphere separately. The forward calculated gravity effect, at topographic
 421 surface level, for the slab configuration 1 for the lithospheric part is in the order of 4 mGal
 422 while the sub lithospheric gravity signal is in the range of 7 mGal (Fig. 12a, b). The combined
 423 gravity signal is in the order of 12 mGal (Fig. 12c). The gravity signal in the Eastern Alps for
 424 Configuration 2 is significantly larger in the order of 17 mGal for the combined model (Fig.
 425 12f).

426
 427 *Figure 11 Residual of the forward calculated g_z gravity signal of lithospheric slabs at surface station height based on LitMod*
 428 *models with Tecton like compositions in the lithosphere and PUM and DMM compositions in the sub lithosphere (M_1 , M_2 , M_3 ,*
 429 *M_4) with an additional thermal anomaly of -100° k for the sub lithospheric slab segment, for predefined slab Configuration to*
 430 *the background model (M_0). (a)-(c) Configuration 1. (d)-(f) Configuration 2. Crustal and topographic contribution are nullified.*

431 The calculated gravitational effect of a slab segment with Proterozoic composition and a Tecton
 432 surrounding mantle composition is in the order of -40 mGal for the g_z component (Fig. 12 a).

433

434 *Figure 12 (a) Forward calculated gravity effect of a Proterozoic lithospheric slab segment to a Tecton compositional*
 435 *surrounding mantle for configuration 2, obtained by calculating the residual between M_8 and M_0 . (b) gravity signal produced*
 436 *by purely compositional effect in the sub lithosphere between a PUM and DMM composition, obtained by calculating the*
 437 *residual between M_5 and M_6 . (c) gravity signal produced by purely thermal anomaly of -100°K for a sub lithospheric slab*
 438 *segment, obtain by calculating the residual between M_3 and M_6 . (d) gravity signal produced by purely thermal anomaly of*
 439 *-200°K for a sub lithospheric slab segment obtained by calculating the residual between M_6 and M_7 .*

440 The gravity response to a compositional variation within the sub lithosphere between the
 441 incorporated slab segment (DMM composition) and the surrounding mantle (PUM composition)
 442 is in the order of 4 mGal (Fig. 12b). The gravity response for a pure thermal anomaly of -100
 443 K within the sub lithospheric slab segment is in the order of 16 mGal (Fig. 12c), while a pure
 444 thermal anomaly of -200 K within the sub lithospheric slab segment is in the order of 21 mGal.

445 5 Discussion

446 The imprint of the gravity response caused by the density distribution based on direct
 447 conversion of seismic velocities (approach 1) is visible, however, individual and independent
 448 slab segments cannot be identified (Fig. 4). The strength of this approach is that it is fast to

449 implement and can provide a first order characterization of the gravity signal and slab
450 geometries of subducting lithosphere. However, a clear characterization of subducting slab
451 segments is not possible. First of all, the density model depends on the resolution and
452 regularization of the seismological model, which can lead to distortions in the gravity response
453 (e.g. Root, 2020). The method is dependent on the choice of the conversion factor and might
454 overestimate the density (see the large negative anomaly in the Ligurian Sea). The conversion
455 factor is a strong simplification of nature and for such a geodynamic complex area, a constant
456 conversion factor is not adequate.

457 The forward calculated gravity field with competing predefined slab geometries (approach 2)
458 shows a clear gravity signal, where the individual slab segments are distinguishable (Fig. 6).

459 A relative gravity low related to the slab gap in the Eastern Alps is a prominent feature in the
460 gravity signal of Configuration 1 (Fig. 6a). The eastern Alpine slab segment of Configuration
461 1, due to its relatively small volume, result in a lower signal compared to the Central Alpine
462 slab segment.

463 Configuration 2 shows a larger gravity signal in the Eastern Alps up to 100 mGal (Fig. 6b)
464 compared to Configuration 1. The increase of the gravity signal is attributed to the subduction
465 of both Eurasian and Adriatic lithosphere in the Eastern Alps. The gravity signal shows a
466 continuous transition from the Central Alps to the Eastern Alps, where the contribution of the
467 destined slab segment cannot be distinguished in the resulting gravity field (Fig. 6b). In the
468 Western Alps, Configuration 1 and 2 show a lower gravity signal compared to the Central Alps.
469 This is attributed to the much shallower Western Alpine slab segment that penetrate down to
470 100 km depth.

471 The gravity signal is influenced by both the assigned density contrast and thickness of the slab.
472 A trade of between both parameters is clearly observable as the same gravity response of the
473 slab configuration can be achieved with different values of density contrast and slab thickness.

474 Therefore, making it impossible to derive slab properties in form of density contrast and slab
475 thickness from the gravity field (Fig. 7).

476 The calculated densities in LitMod 3-D models (approach 3) are estimated taking temperature
477 and pressure variations into account based on an assigned composition. The composition has a
478 strong influence on the resulting density contrast. In the case that the compositional contrast
479 between slab segment and surrounding mantle is small, the density contrast is consequently
480 small as well (Fig. 9 and 10a). With increasing compositional differences, the density contrast
481 increases as well. A strong density contrast within the slab segment is recognizable between
482 lithospheric and sub lithospheric domain (Fig. 10a and b), while the variations between the slab
483 and surrounding mantle remain small.

484 The gravity signal shows in the Eastern Alps significant larger signal from the lithosphere and
485 sub lithosphere domain for Configuration 2 (Fig. 11d, e, and f) compared to Configuration 1
486 (Fig. 11a- c). The different slab segments are distinguishable with the exception of the two slab
487 segments in the Eastern Alps in Configuration 2 (Fig. 11). The contribution from the
488 lithospheric domain to the gravity signal is smaller than from the sub lithospheric domain (Fig.
489 11b, and e). However, the slab gap and the eastern slab segment feature can be recognized in
490 the lithospheric part in Configuration 1 but not in the gravity signal of the full model.

491 The Proterozoic slab segment has a larger gravity response compared to the Tecton-like
492 composition. This gravitational signal is negative due to the less dense Proterozoic composition
493 in comparison to the reference model (M_0) (Fig. 12a).

494 Sub lithospheric composition has only a small influence on the gravity field, in the order of 4
495 mGal (Fig. 12b). However, a thermal anomaly within the sub lithospheric slab in the order of -
496 100K result in a gravitational response of 16 mGal (Fig. 12c) and for a -200 K anomaly in the
497 order of 21 mGal (Fig. 12d). Both the composition and the thermal variation influence the
498 density and consequently the gravity response. However, the thermal component is a much
499 larger contributor.

500 For the three approaches (section 3, 4.1 and 4.2) a measurable gravity effect of the subducting
501 slab segments is observable. The independent slab segments are distinguishable to a certain
502 degree with the exception of the bivergent slab configuration in the Eastern Alps (Fig. 6, and
503 11) and the model containing converted density from seismic velocities (Fig 4), while the slab
504 configurations cannot be separated at satellite altitude (Appendix). Forward calculated gravity
505 anomalies from converted density distribution suggest a gravitational signal of the slab
506 segments in the order of 40 mGal which corresponds to a density contrast of 20 to 40 kg/m³ in
507 the models with predefined slab geometry. The models with a Tecton like composition suggest
508 a gravity effect of the slab segments in the order of only 16 mGal, corresponding to a density
509 contrast of 20 kg/m³ in the simple model. Increasing the compositional difference with a Tecton
510 composition suggests a gravity signal in order of 30 mGal and is in line with the converted
511 density model.

512 All three methods show a positive gravity signal contribution, which can be related to sub-
513 crustal density variations for approach 1 and to predefined sub-crustal slab segments for
514 approach 2 & 3, up to 40 mGal to the Alpine gravity field. That is significant in comparison to
515 the observed Bouguer Anomaly with a minimum of ~-200 mGal. If this contribution is not
516 considered, a significant part of the gravity signal is attributed to crustal thickness or intra-
517 crustal sources. Due to the long-wavelength appearance of the gravity effect, that might not be
518 relevant for small-scale or local studies, the effect is only seen as a shift. For gravity models of
519 larger areas (e.g. Eastern Alps) or even the entire regions that should not be neglected. For one,
520 estimates of crustal thickness or the mass distribution are significantly biased, and placing the
521 Alps in the geodynamic context of the surrounding requires a careful and complete
522 consideration of all sources in order to provide realistic density distribution required for
523 geodynamic models (e.g. Reuber et al., 2019).

524 **6 Conclusions**

525 We have addressed the potential gravity effect of proposed slab segments in the Alpine region
526 using three different modelling approaches.

527 • Converted density from seismic tomography: In the resulting gravity signal the imprint
528 of slab segments is visible, however, distinguishing between the different and
529 independent slab segments is not possible.

530 • Models with predefined slab segments are dependent on the assigned density contrast
531 and volume as well as on the predefined positions of the slab segments. The gravity
532 signal caused by the slab segments are sharp and can be separated for the different slab
533 segments for the gravity field at the surface. Significant gravity contributions from slab
534 segments below 200 – 250 km to the Alpine gravity are unlikely.

535 • Combined petrophysical-geophysical modelling results in the most complex models.
536 The calculated density variation within the slab is rather small compared to the density
537 contrast between lithosphere and sub lithosphere. The density distribution within the
538 slabs, and consequently the gravity field, is highly influenced by the slab composition
539 and thermal structure.

540 Sub-crustal density variation (approach 1) and predefined slab segments (approach 2 & 3)
541 suggest a positive sub-crustal gravity contribution of up to 40 mGal. Even though this might be
542 considered as a maximum gravity estimation of slabs, this value is significant, even compared
543 to the observed Bouguer Anomaly low of -200 mGal along the Alps. The interpretation of
544 density variation in the mantle in terms of subducting slab structures is a means to provide a
545 meaningful representation of the geodynamic complex Alpine area. For future studies correct
546 slab density structure are crucial to provide a representation of the Alpine geodynamic setting.
547 Precise estimations of the slab density structure require a correct crustal density and crustal
548 thickness model. With the integration of further observables, it might be possible to judge on
549 the correct slab configuration beneath the Alps. Furthermore, future studies based on the

550 AlpArray Network will be of high interest in better defining slab geometries as well as their
551 properties.

552 **Competing interests**

553 The authors declare that they have no conflict of interest.

554 **Author contributions**

555 ML carried out the gravity modelling, visualized and interpreted the results and prepared the
556 first manuscript draft. JE supervised the gravity modelling and interpretation, designed the
557 original research project, acquisition of the financial support for the project leading to this
558 publication and writing (reviewing and editing). TM defined the slab configurations based on
559 tectonic and seismological knowledge and writing (reviewing and editing). AE created and
560 provided the surface wave tomography model MeRE2020 and writing (reviewing and editing).

561 **Acknowledgment**

562 The authors thank the reviewers, Carla Braitenberg and an anonymous referee for their valuable
563 suggestions, which helped to improve the manuscript significantly.

564 This study is part of the projects "Integrierte 3D Modellierung des Schwere- und
565 Temperaturfelds zum Verständnis von Rheologie und Deformation der Alpen und ihrer
566 Vorlandbecken - INTEGRATE" and "Surface Wavefield Tomography of the Alpine Region to
567 Constrain Slab Geometries, Lithospheric Deformation and Asthenospheric Flow in the Alpine
568 Region" funded by German Research Foundation (DFG) in the SPP Mountain Building
569 Processes in 4D.

837 **Appendix A Gravity Gradients at satellite height**

838 For all Alpine density models presented above (section 3, 4.1 and 4.2) we have also calculated
839 gravity gradients at a station height of 225 km. This station height corresponds to the second
840 mission phase of GOCE (Gravity field and steady-state ocean circulation explorer) carried out
841 by ESA (European Space Agency).

842 We anticipated that gravity gradients measured by the GOCE satellite mission are sensitive to
843 the slab segments in the Alpine region. Our result show, that the long wavelength signal of the
844 different present slab segments contributes to a large-scale gravity response where the different
845 contributor cannot be separated. Therefore, we conclude that against our anticipation gravity
846 gradients at satellite height are in fact not sensitive to the Alpine slab configuration. We show
847 here, the gravity gradients (mainly the gzz component) for completeness.

848 Measured gravity gradients from the GOCE mission (Bouman et al., 2016), which were
849 corrected for topography and bathymetry ranges from 2.5 to -2.5 E at satellite altitude of 225
850 km height (Fig. 13). A negative gravity anomaly of -2.5 E in the gzz component is observed
851 equivalent to the vertical gz component (Fig. 13). However, no clear sign for subducting
852 lithosphere can be observed in any component of the gravity gradient tensor.

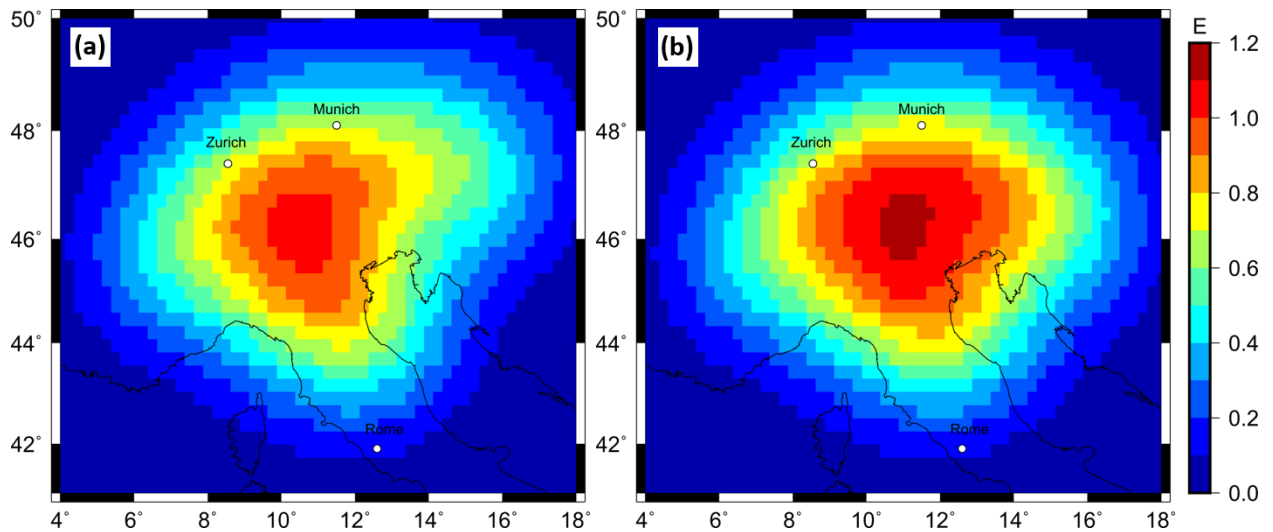

853
854 *Figure 13 GOCE gradients at 225 km height after Bouman et al. (2016) corrected for topography and bathymetry with a 5°*
855 *extension to remove far field effects. The gravity gradients are presented in a North-East-Up coordinate system.*

856 The forward calculated gzz component at 225 km station height from a density model (section
857 3) with converted densities ranges from -3.5 E to 0.7 E (Fig. 14). A positive gravity signal of
858 about 0.5 E in the Apennine and Alpine region is observed which could be linked to subducting
859 slab segments. However, it is impossible to separate specific slab segments.

860
861 *Figure 14 Forward calculated gzz gravity signal from relative density distribution converted from relative seismic velocities*
862 *using a conversion factor of 0.3 for the at 225 km station height.*

863 Forward calculated tesseroïd models (section 4.1) for slab configuration 1 and 2 with a constant
 864 density contrast of 60 kg/m^3 and a constant thickness of 80 km result in a less sharp gravity
 865 signal for the gzz component at a station height of 225 km (Fig. 15) compared to the gz
 866 component at station height of 6040 m (Fig. 6). The gravity signal for the gzz component is in
 867 the range of 0.8 E to 1 E. At satellite altitude the gravity signal is observed as a large area with
 868 a positive gravity effect for Configuration 1 and 2. The contribution of the different slab
 869 segments to this positive gravity effect is not distinguishable. The only recognizable difference
 870 is the size of this positive gravity signal. Configuration 1 shows a smaller anomaly, due to a
 871 lower volume of subducting material in the Eastern Alps.

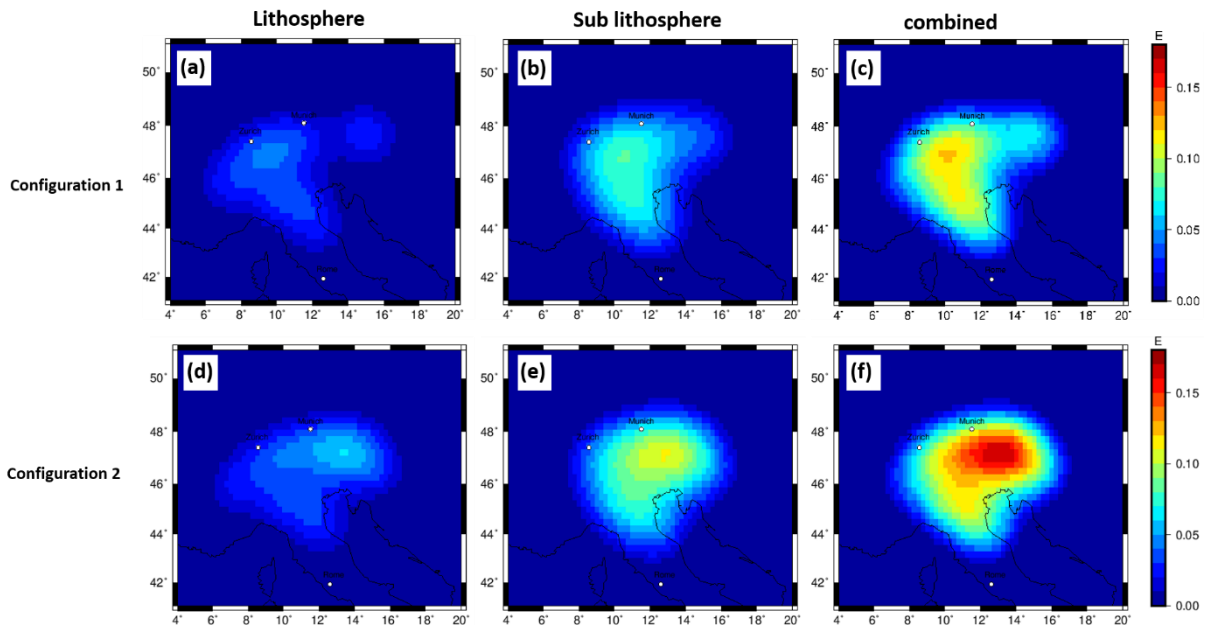

872
 873 *Figure 15 Forward calculated gzz gravity signal at a station height of 225 km from predefined sub-crustal slab geometries with*
 874 *a content density contrast of 60 kg/m^3 and a constant thickness of 80 km. (a) slab configuration of hypothesis 1 (b) slab*
 875 *configuration of hypothesis 2.*

876 In Addition, the signal strength for the forward calculated gzz component show the same
 877 dependency of signal strength to the density contrast and slab thickness (Fig. 16) as the gz
 878 component (Fig. 7). The signal strength of the gzz component ranges for the 12 different
 879 combinations from 0.3 E to 2 E (Fig. 16). The gravity signal cannot be separated and affiliated
 880 to a certain slab segment. The gzz gradient signal shows a large blurry gravity high over the
 881 Alps, which thins out to the edges.

882
883 *Figure 16 Forward calculated gzz gravity signal for 12 different combination of density contrast and slab thickness at a station*
884 *height of 225 km for sub-crustal slab configuration 1.*

885 The gravity effect for the LitMod models (section 4.2) with the slab Configuration 1 shows in
886 the lithosphere domain a signal strength of about 0.05 E, while the sub lithospheric gravity
887 signal is in the range of 0.1 E for the gzz component at satellite altitude of 225 km height. The
888 combined gravity signal is in the order of 0.14 E (Fig. 17). A Proterozoic slab produces a larger
889 amplitude in signal strength, however the different slab segments can again not be separated
890 (Fig. 18).

891
892
893
894
895

Figure 17 forward calculated gzz gravity signal at satellite altitude of 225 km based on LitMod models with tecton like compositions in the lithosphere and PUM and DMM compositions in the sub lithosphere (M_1, M_2, M_3, M_4) with an additional thermal anomaly of -100°K for the sub-lithospheric slab segment, for predefined slab Configuration to the background model M_0 . (a)-(c) for Configuration 1. (d)-(f) for Configuration 2. Topographic and crustal effects are nullified.
