Abstract

In this study, we present an estimate of the gravity signal of the slabs beneath the Alpine mountain belt. Estimates of the gravity effect of the subducting slabs are often omitted or simplified in crustal scale models. The related signal is here calculated for alternative slab configurations at near surface height and on a satellite altitude of 225 km.

We apply three different modelling approaches in order to estimate the gravity signal from the subducting slab segments, by: i) Direct conversion of upper mantle seismic velocities to density distribution, which are then forward calculated to obtain the gravity signal. ii) Definition of slab geometries based on seismic crustal thickness and high-resolution upper mantle tomography for two competing slab configurations. The geometries are then forward calculated by assigning a constant density contrast and slab thickness. iii) Accounting for compositional and thermal variations with depth within the predefined slab geometry.

Forward calculations predict a positive gravity signal of up to 40 mGal for the Alpine slab configuration. Significant differences in the gravity anomaly patterns are visible for different slab geometries in the near surface gravity field. However, different contributing slab segments are not easily separated, especially at satellite altitude. Our results demonstrate that future studies addressing the lithospheric structure of the Alps should have to account for the subducting slabs in order to provide a meaningful representation of the geodynamic complex Alpine area.

Keywords:

Satellite gravity gradient, Alpine subduction, lithospheric and sub lithospheric structure, mantle composition, seismic tomography

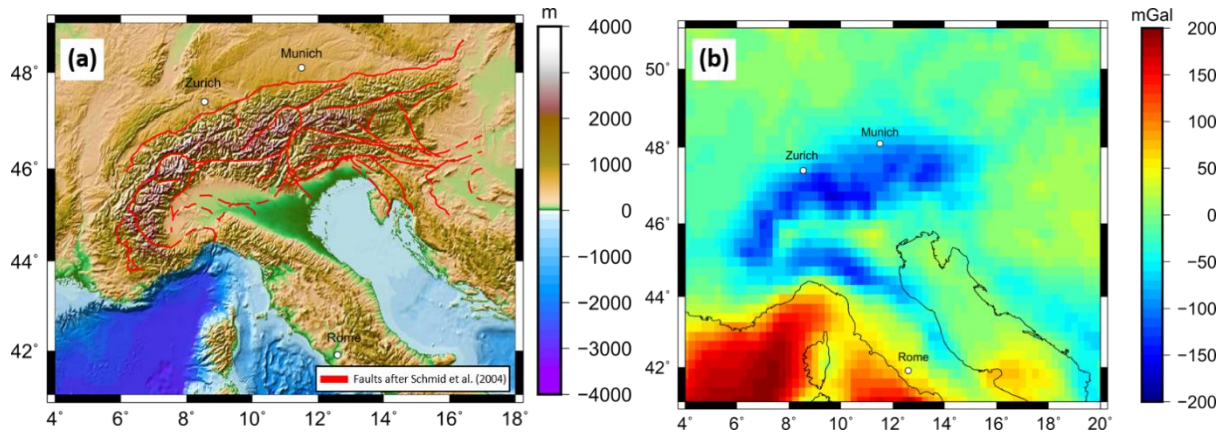

1. Introduction

Interpretation of gravity anomalies can reveal information on the architecture and tectonic setting of the lithosphere (e.g. Zeyen, & Fernàndez, 1994; McKenzie & Fairhead, 1997; Holzrichter & Ebbing, 2006; Braitenberg, 2015; Spooner et al. 2019). For subduction zones, like the Andes, several studies have shown that the gravity effect of the subducting plates is significant and has to be considered in order to study the feedback between the subducting lithosphere and the overriding plate (Götze et al. 1994; Götze & Krause 2002; Tašárová 2007; Gutknecht et al. 2014; Götze & Pail 2018; Mahatsente 2019). Subducting lithosphere has a

43 higher density than the surrounding mantle material at the same depth interval causing a
44 negative buoyancy and therefore the slab is subducted into earth's interior (e.g. Kincaid & Olson
45 1987; Ganguly et al. 2009). However, the gravitational contribution of subducting material in
46 the upper mantle to the gravity field has so far not been systematically addressed for the Alpine
47 system. In order to provide an assessment, the magnitude of the gravity signal of such sub-
48 crustal long wavelength features has to be estimated.

49 The Alpine mountain belt (Fig. 1a) is chosen for this sensitivity study because firstly a large
50 range of recent seismic topography studies imaged subducting slab segments in the Alpine
51 region (e.g. Babuska et al., 1990; Lippitsch et al., 2003; Spakman & Wortel, 2004; Mitterbauer
52 et al. 2011; Karousova et al., 2013; Zhao et al., 2016; Kästle et al., 2018; El-Sharkawy et al.,
53 2020). Those different studies suggest different configurations of slab segments (see section
54 1.1), allowing us to test how sensitive the gravity field is to varying geometries of subducting
55 slab segments. Secondly, previous Alpine models addressing the Alpine gravity field have not
56 considered any slab segments, rather they only account for the thickness of the lithosphere (e.g.
57 Ebbing et al., 2006; Spooner et al., 2019; Tadiello and Braitenberg 2020). If the contribution of
58 the slab is not considered, a significant part of the gravity field might be attributed to crustal
59 thickness variations or intra-crustal sources.

60 In addition, the Bouguer Anomaly of the Alps (Fig. 1b) shows no direct sign of subducting slabs
61 (in contrast to the Andes subduct zone) as the field is dominated by crustal thickness variations
62 (Ebbing et al., 2001, 2006) Therefore, forward modeling of the proposed slab geometries, as
63 imaged by high-resolution tomographic studies, is necessary to separate the gravity signal
64 caused by the subducting slabs from the gravity anomaly field.

 68 *ellipsoid, just above the surface of the Alps. Correction density for rock: 2670 kg/m³ and for water: 1030 kg/m³*

69 We present three different approaches to model the gravity effect of the slab segments and
 70 discuss the strengths and limitations of the applied methods. In the first approach, the alpine
 71 sup-crustal density distribution is derived by converting seismic velocities to density. This
 72 model is then forward calculated to estimate the gravity response. In the second approach, 3D
 73 slab geometries are derived by evaluating seismic crustal thickness estimations and high-
 74 resolution upper mantle tomographic models. Here, two competing slab configurations are
 75 chosen. The predefined slab geometries are then forward calculated by assigning different
 76 density contrast and slab thicknesses. The third approach uses similar predefined slab
 77 configurations as in the second approach, however, here we consider petrology, temperature,
 78 and density variation. The gravity response is calculated for all three approaches at a near
 79 surface height for the gravity disturbance and the gravity gradients at satellite altitude of 225
 80 km.

81 1.1 Alpine setting

82 The formation and present geodynamics of the Alps are linked to long lasting tectonic
 83 processes, including Adria-Europe continent-continent collision, subduction of oceanic and
 84 continental lithosphere, the formation of crustal nappes as well as extensional and
 85 compressional processes (Frisch, 1979; Stampfli & Borel, 2002; Handy, et al., 2010, 2015).
 86 The Adriatic microplate is a major driver of the present geodynamics in the Alpine region,
 87 which is trapped between the converging major plates of Europe and Africa. Adria is moving

88 counterclockwise with respect to Europe, as seen by GPS observations (e.g. Nocquet and Calais,
89 2004; Vrabec and Fodor, 2006; Serpelloni et al., 2016) and is subducted beneath the Apennines to
90 the west as well as to the east beneath the Dinarides, while colliding with Eurasia in the Alps
91 to the north (e.g. Channel & Horvath, 1976; Dewey et al., 1989; Stampfli & Borel, 2002; Handy
92 et al., 2010; Le Breton et al., 2017). Subducting slab segments have been imaged by different
93 seismological body wave travel time tomographic studies as well as surface wave tomographic
94 studies within the Alpine upper mantle (e.g. Babuska et al., 1990; Lippitsch et al., 2003;
95 Spakman & Wortel, 2004; Mitterbauer et al. 2011; Karusova et al., 2013; Zhao et al., 2016;
96 Kästle et al., 2018; El-Sharkawy et al., 2020). However, the configuration of subducting slab
97 segments remains controversial. In the Western Alps, Lippitsch et al. (2003) propose a slab
98 break-off at about 100 km depth, which is in line with the findings of Beller et al. (2018), Kästle
99 et al. (2018) and El-Sharkawy et al. (2020). In contrast, a continuous subducting slab segment
100 in the Western Alps, down to at least 250 km depth, is imaged by a number of other tomographic
101 models (e.g. Koulakov et al., 2009; Zhao et al., 2016; Hua et al., 2017; Lyu et al., 2017).

102 A continuous subduction of Eurasia beneath the Central Alps down to at least 200 km depth is
103 imaged by different tomographic models (e.g. Lippitsch et al., 2003; Piromallo and Morello,
104 2003; Koulakov et al., 2009; Mitterbauer et al., 2011; Hua et al., 2017; Fichtner et al., 2018; El-
105 Sharkawy et al., 2020). A potential slab gap with an approximately size of 2° is separating the
106 subducting slab segments in the Central Alps to the Eastern Alps as imaged by e.g. Lippitsch
107 et al. (2003). The slab configuration and subduction direction in the Eastern Alps remains
108 unclear. According to the classical view, Eurasia is subducting beneath Adria in a southward
109 subduction (Hawkesworth et al., 1975; Lüschen et al., 2004; 2006). This idea was challenged
110 by Lippitsch et al. (2003), Schmid et al. (2004), Kissling et al. (2006), Handy et al. (2015), and
111 Hetenyi et al. (2018). Instead, slab break-off in the eastern Alps and a northward-dipping
112 Adriatic slab in the easternmost Alps is suggested, leading to a switch of the slab polarity, as
113 Adria is subducting beneath the European plate (Handy et al., 2015). The view that Adriatic and

114 not Eurasian lithosphere is subducting northwards in the Eastern Alps has been opposed by
115 Mitterbauer et al. (2011), as their model shows a northward dipping slab in the eastern most
116 Alps connected to the European plate. In an early tomographic study, Babuska et al. (1990)
117 proposed that both Eurasian and Adriatic lithosphere is subducting in the eastern Alps. In
118 subsequent studies and interpretations this model was mentioned but northward subduction of
119 Adria seems to be favoured (e.g. Karousova et al., 2013; Hetenyi et al., 2018), Recently,
120 subduction of both Eurasian and Adriatic lithosphere in the eastern Alps down to about 150 km
121 has been suggested by Kästle et al. (2020) and El-Sharkawy et al. (2020) based on surface wave
122 studies. For a more in-depth comparison and discussion of tomographic Alpine models the
123 reader is referred to e.g. Kästle et al. (2020).

124 **2. Data**

125 The Bouguer Anomaly (Fig. 1b) is based on the global model *XGM 2019* (Zingerle et al., 2019)
126 developed for spherical harmonics up to degree 719, with a resolution of ~ 25 km (half
127 wavelength). The XGM 2019 model is a global integrated gravity model, which includes
128 satellite and terrestrial measurements. The simple Bouguer Anomaly is calculated from the
129 Free-Air gravity disturbance with a correction density of 2670 kg/m^3 for topography, and a
130 correction density for water of 1030 kg/m^3 for the offshore areas. We calculated the gravity
131 contribution of the topography and bathymetry using Tesseroids and subtracting the signal
132 proportion from the Free-Air Anomaly to obtain the Bouguer Anomaly. For the topography and
133 bathymetry information, we use ETOPO1 with a 1 arc minute resolution (Amante & Eakins,
134 2009), which was regrided at a regular grid with a grid space of 25 km to match the resolution
135 of the XGM 2019 model for a maximum degree of 719. The gravity field is defined at a constant
136 station height of 6040 m above the ellipsoid, just above the surface of the Alps. The resulting
137 Bouguer Anomaly shows a gravity low in the order of -200 mGal over the high topography of
138 the Alps, indicating an isostatic compensation of the topography (e.g. Ebbing et al., 2006).

139 Additionally, we calculate the topographic correction for the gravity gradients at a station height
 140 of 225 km representing the GOCE satellite altitude. The topographic corrected gravity gradients
 141 after Bouman et al. (2016) measured by the GOCE ESA satellite mission are presented in the
 142 appendix.

143 For the definition of the slab geometry, we use crustal thickness estimates based on the receiver
 144 function study by Spada et al. (2013). The crustal thickness map was digitized and the Moho
 145 gap in the eastern Alps is filled by nearest neighbour interpolation. To avoid edge effects,
 146 surrounding areas are supplemented by the Moho depth model of the European plate by Grad
 147 et al. (2009), both data sets were merged using a cosine taper with a taper width of 2° using
 148 equation (1). The overlapping areas at the grid edges are distance weighted to obtain a smooth
 149 transition.

$$150 \quad G_{new} = T(x, y) \cdot G_1(x, y) + (1 - T(x, y))G_2 \cdot (x, y) \quad (1)$$

$$152 \quad \text{with: } T(x, y) = \cos \frac{D \cdot \pi}{2 \cdot L}$$

151 *with: G = Grids, T = taper, D = dx, L = Tapper length*

153 The merged Moho depth map is sampled at a regular grid with a cell size of 0.25° (Fig. 2) to be
 154 consisted with resolution of the topographic and gravity models.

155
 156 *Figure 2 a) digitized crustal thickness after Spada et al. (2013) with a 0.25° grid spacing, b) crustal depth estimation after*
 157 *Grad et al. (2009) with a 0.25° grid spacing c) Merged crustal thickness map from Spada et al. (2016) and Grad et al. (2009)*
 158 *with a grid resolution of 0.25° using a cosine taper with a 2° width.*

159 For the upper mantle seismic velocity, the 3-D shear wave velocity model (MeRE2020) by El-
 160 Sharkawy (2020) is used (Fig. 3). The model covers the upper mantle across the Alpine-
 161 Mediterranean area down to a depth of 300 km and absolute shear-wave velocities are given.

162 In this study, relative shear-wave velocities in the depth range from 70 to 200 km are calculated
163 with respect to a 1-D average shear wave velocity model, the background model is described
164 in El-Sharkawy (2020). The upper limit of 70 km is introduced because i) we focus on the
165 contribution of the slab segments removing therefore crustal information from the model ii) the
166 tomography model MeRE2020 is not sensitive to shallow structures, as a result the slabs are
167 not well recovered in depths shallower than 70 km iii) we want to ensure a uniform upper
168 boundary. The lower boundary of 200 km is chosen based on clear images of the Alpine Slab
169 segments to at least 200 km depth (with exception of the Western Alpine slab), as discussed in
170 section 1, and the assumptions that depth larger than 200 km will have a negligible effect on
171 the regional gravity field considered here.

172 The ambient noise tomography by Kästle et al. (2018) is used to define the geometry of the
173 Western Alpine slab segment, hence we follow the idea of a slab-breakoff in the Western Alps
174 at 100 km depth (Kästle et al., 2020) as suggested also by Lippitsch et al. (2003) and Beller et
175 al. (2018). For the eastern Alps, we consider two alternative models. For the first hypothesis,
176 the P-wave tomography by Lippitsch et al. (2003) is used, to define the Eastern Alpine slab
177 segment. The second hypothesis is based on Kästle et al. (2020) and El-Sharkawy et al. (2020).
178 It assumes southward subduction of a short Eurasian Slab as well as northward subduction of a
179 short Adriatic Slab in the eastern Alps. The slab configurations which are incorporated in the
180 Alpine density models are discussed in greater detail in section 4.1.

181 **3 Conversion of seismic velocities into density distribution**

182 Seismic velocity variations are dependent on temperature and pressure. Densities in the
183 subsurface are also temperature and pressure dependent. A conversion factor (ζ) can describe
184 the linear relation between seismic velocities variations and densities variation (e.g. Tiberi et al.
185 2001; Webb 2009). We convert seismic shear wave velocities from the tomographic model
186 MeRE2020 by El-Sharawy et al. (2020) in the depth range from 70 to 200 km, as discussed in

187 section 2, to obtain a density distribution of the upper mantle in the Alpine region based on a
188 conversion factor (ζ). The relationship between seismic velocities and densities is described in
189 equation (2), this assumption is a strong simplification of reality, but gives a first order
190 estimation of the expected relative density structure beneath the Alps.

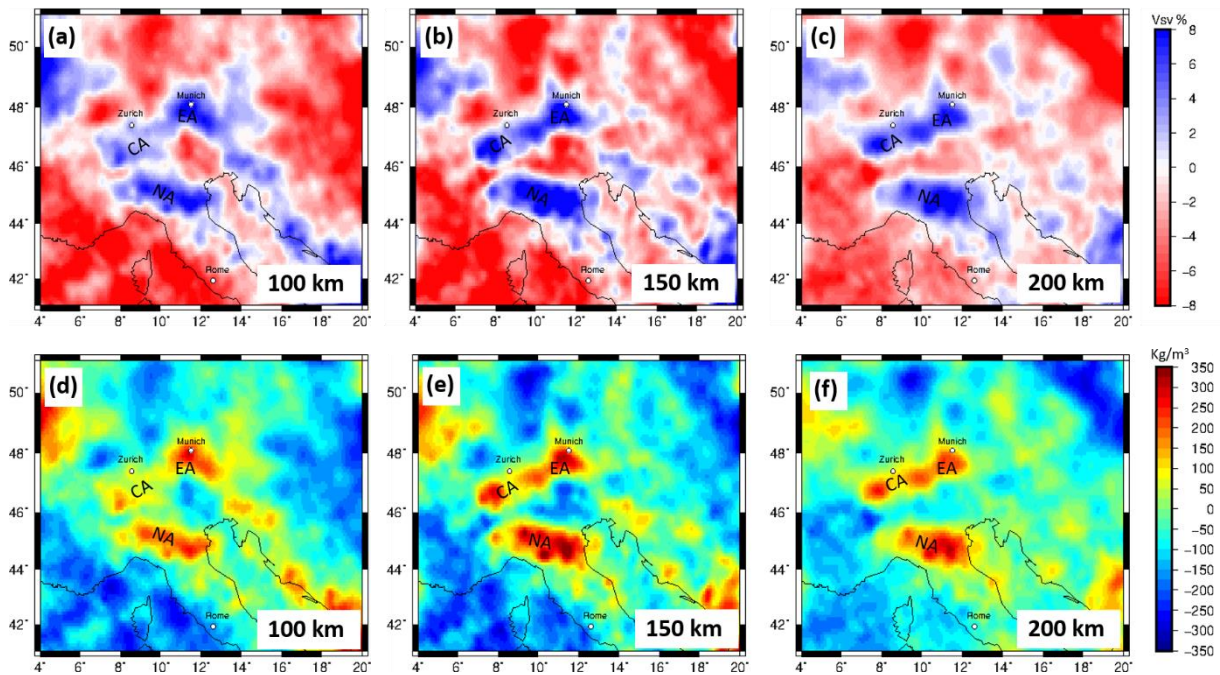

$$191 \quad \rho_{rel} = [(Vsv_{abs} + \Delta\%) - Vsv_{abs}] \cdot \zeta \quad (2)$$

192 *with: Vsv_{abs} = absolute velocities from MeRE2020;*

193 *$\Delta\%$ = percentage divagation from the MeRE2020 background model;*

194 *ζ = conversion factor*

195 The result is strongly dependent on the chosen conversion factor. A range for conversion
196 factors has been proposed in the literature for different rock types ranging from 0.1 to 0.45 (e.g.
197 Isaac et al., 1989; Isaak, 1992; Karato, 1993; Kogan and McNutt, 1993; Vacher et al., 1998).
198 The relative shear-wave velocity distribution in a 3D domain from the tomography model
199 MeRE2020 from El-Sharkawy (2020) is converted using a constant conversion factor (ζ) of 0.3.
200 The converted relative density distribution varies between -240 and 350 kg/m³. High
201 correlations between the structural pattern in the converted density distribution and the relative
202 seismic velocities are observed (Fig. 3), the similarity in the structure pattern is expected due
203 to the linear relationship we introduced here. The converted 3D relative density distribution
204 reflects the variation of seismic velocities in the Alpine lithosphere and therefore includes the
205 heterogeneities of the subduction slab segments, as seen by the tomographic models (Fig 3).
206 The relative density model is transferred into tesseroids with a horizontal expansion of 0.2° and
207 a vertical expansion of 3 km. The Tesseroid model is forward calculated in order to estimate the
208 gravity response of the converted density distribution of the Alpine lithosphere in the depth
209 interval of 70 km to 200 km.

211

212 *Figure 3 (a)-(c) Depth slices of relative surface wave velocities (V_{sv}) from MeRE2020 (El-Sharkawy et al., 2020). (d)-(f)*
 213 *converted relative density distribution in different depths based on a conversion factor (ζ) of 0.3. CA = Central Alpine Slab;*
 214 *EA = Eastern Alpine Slab; NA = Northern Apennine Slab*

215 3.1 Results

216 In the forward calculated gravity field, a gravity high with a magnitude of ~ 40 mGal is observed
 217 over the Alps (Fig. 4). That might be interpreted as relating to the proposed slab segments in
 218 the Northern Apennine and Alpine area. However, the gravity field (and gradients, see appendix)
 219 is dominated by anomalies outside the Alpine realm (Fig. 4), for instance in the Ligurian Sea
 220 and the Dinaride-Hellenide Orogen. Therefore, in the next step, we try to concentrate on the
 221 seismic anomalies in the Alpine realm that can be related to the slab segments.

222

223 *Figure 4 Forward calculated gravity signal from relative density distribution converted from relative seismic velocities using*
 224 *a conversion factor of 0.3 at a station height of 6040m.*

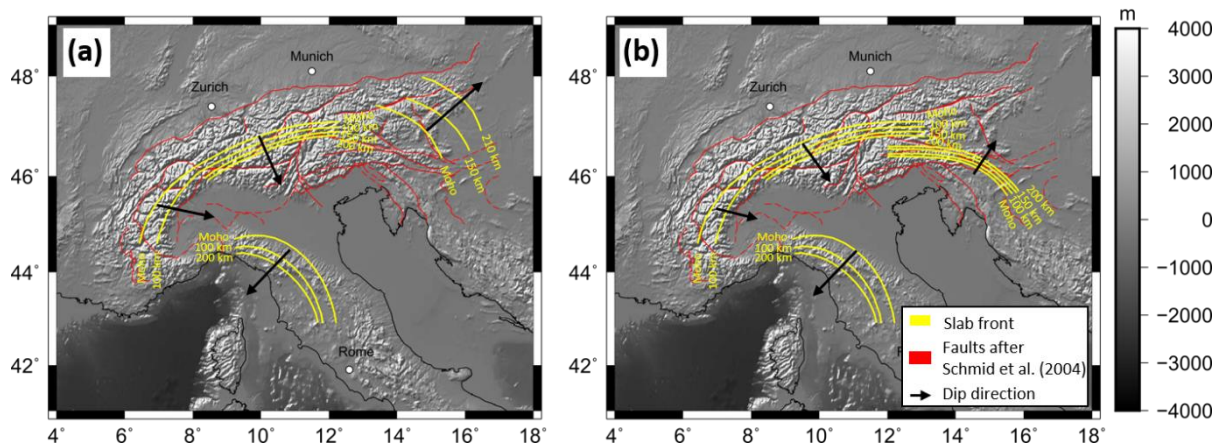

225 **4 Slab models**

226 To estimate the gravity contribution of independent slab segments we introduce different
 227 models for the subducting lithosphere. First, we use a set of models with simple constant density
 228 distribution in the slab, where the parameters, namely the density contrast and thickness of the
 229 slab segment is varied (approach 2). Secondly, we create a set of slab models accounting for
 230 compositional and thermal variations with depth (approach 3). Those models are created with
 231 the software package LitMod 3D (Fullea et al., 2009) and will be referred as LitMod models in
 232 the following. For all non-LitMod models, the gravity and gravity gradients are calculated using
 233 tesseroids, which are spherical prisms (Uieda et al., 2016).

234 **4.1 Slab modelling with constant density contrast and slab thickness**

235 We define two alternative slab configurations based on crustal thickness model by Spada et al.
 236 (2013) and several different tomographic studies, see detailed description of the slab
 237 configurations below. At different depths, isolines are picked in the crustal depth map and
 238 tomographic images, defining the upper boundary of subducting slab segments. The isoline of
 239 the crust mantle boundary (Moho interface) is used as an onset of the slab to the crust and
 240 defines the upper boundary of the subduction slab segment. At upper mantle depth, increased
 241 seismic velocity anomalies in tomographic models beneath the Alps are interpreted as contrast

242 between colder and therefore denser subducting material to the surrounding mantle material. At
 243 100, 150, and 200 km depth, the upper boundary of the slab segment is defined at the 0%
 244 contour line of the relative seismic velocity, marking the transition from rocks with low velocity
 245 to high velocity rocks. The isolines at the Moho interface, 100 km, 150 km and 200 km depth
 246 are displayed upon the Alpine topography (Fig. 5 a-b) Vertical interpolation between the upper
 247 boundary isolines at different depths (Moho depth, 100, 150 and 200 km) define a continuous
 248 surface of the upper slab boundary. The lower boundary of the slabs and therefore the thickness
 249 of the slab segment is not picked based on seismic data but assumed to have constant
 250 thicknesses for simplifications. The thickness is varied for different models from 60 to 100 km
 251 depth.

252
 253 *Figure 5 Defined isolines based on crustal thickness estimations and seismological tomography models for the upper slab*
 254 *boundary for (a) Configuration 1 and (b) Configuration 2. Black arrows indicate the subduction direction. In red the fault*
 255 *configuration after Schmid et al. (2004).*

256 3.1.1 Alternative slab configurations

257 We define two different slab configurations. Configuration 1 (Fig. 5a) features a northeast
 258 subducting slab segment in the Eastern Alps based on Lippitsch et al. (2003). A Central Alpine
 259 slab segment is defined based on Lippitsch et al. (2003) and MeRE2020 (El-Sharkawy et al.,
 260 2020) subducting in south-southeast direction. The Eastern and Central Alpine slab segments
 261 are separated by a slab gap and show perpendicular subduction directions. The east-southeast-
 262 ward subducted slab segment in the Western Alps is defined using the tomographic model of
 263 Kästle et al. (2018), supporting the idea of slab break-off at about 100 km depth. Only attached

264 slab segments are considered, ignoring potential mantle upwelling in the break off zone and
265 neglecting the potentially remaining detached slab segment in larger depths. In addition, a
266 southwest-subducting slab segment beneath the northern Apennines is considered down to
267 about 200 km depth, as imaged by MeRE2020 (El-Sharkawy et al., 2020) because of its
268 proximity to the western Alps.

269 Configuration 2 (Fig. 5b) considers a slab configuration mainly based on the interpretation of
270 the MeRE2020 model (Fig. 3) by El-Sharkawy et al. (2020). In the Eastern Alps, both a short
271 southward subducting Eurasian slab segment as well as a short northward subducting Adriatic
272 slab are assumed. The Central and Western Alpine slab segments as well as the slab beneath the
273 northern Apennines are identical to Configuration 1.

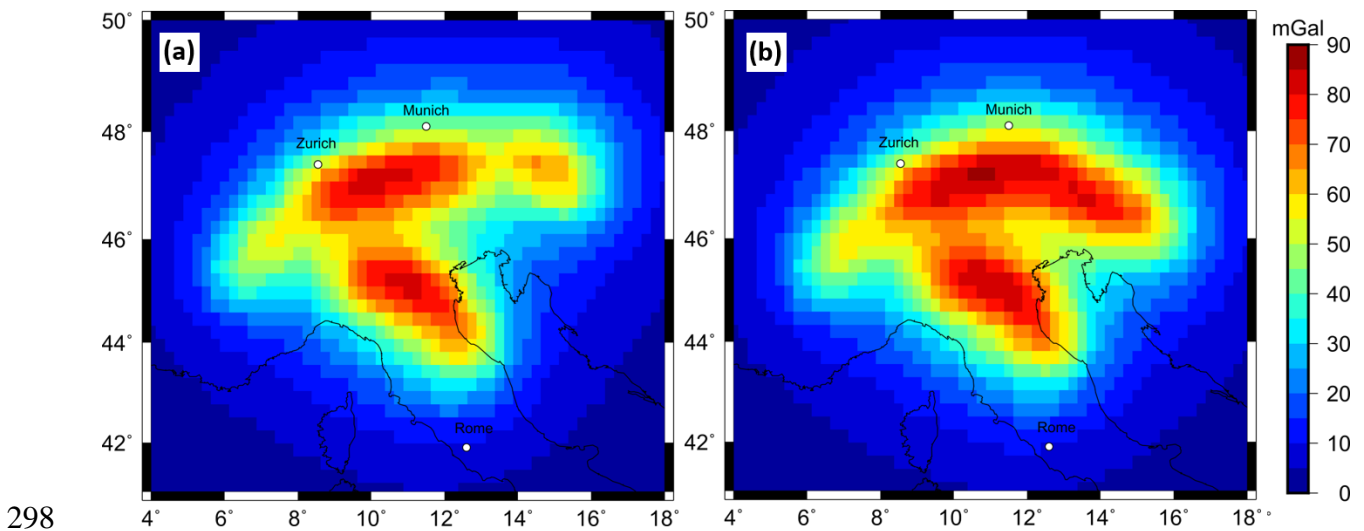

274 4.1.2 Forward calculation

275 To estimate the gravity effect of the slab configurations, the geometries are discretized into
276 tesseroids with a 0.2° extension in the horizontal domain and a vertical size of 20 km. The
277 tesseroids range from 40 km to 200 km depth. First, a constant density contrast is assigned to
278 the entire slab. We test density contrasts from 20 kg/m^3 to 80 kg/m^3 . The thickness of the Alpine
279 slab is not well constrained. We test for three slab volumes by assigning three slab thicknesses,
280 60 km, 80 km and 100 km based on studies on other subducting slab segments (e.g. Wang et
281 al., 2020). Due to the curved geometries of the proposed slab segments rectangular tesseroids
282 with a horizontal expansion of 0.2° will either over- or under-estimate the volume of a
283 subducting slab at the edges of the slab. The percentage volume share of each tesseroid to the
284 slab geometry is calculated. The assigned density contrast of the tesseroids which does not lay
285 fully within the slab geometry is decreased according to the percentage volume within the slab
286 geometry. Therefore, the density distribution correlates to the hypothetical slab positions and
287 volumes in the Alpine subsurface without increasing the discretisation resolution of the
288 tesseroid model beyond the uncertainty of gravity measurements and seismic tomographies.

289 The offset between the 40 km upper tesseroïd boundary to the slab onset at the crust in 44 km
290 depth is corrected using the same process.

291 4.1.3 Results

292 Forward calculated slab models for predefined slab geometries of Configuration 1 and 2 with a
293 constant density contrast of 60 kg/m^3 and a constant thickness of 80 km result in a sharp gravity
294 signal ranging from 70 mGal to 100 mGal (Fig. 6). Both models generate gravity signals in the
295 order of magnitude of 70 mGal in the Central Alpine region as well as in the Apennine. The
296 gravity signal in the Eastern Alps differ for the two hypotheses (Fig. 6 a, b). The Western Alpine
297 slab segment shows the weakest signal in both models.

299 *Figure 6 Forward calculated gravity disturbance signal at a station height of 6040 m for predefined sub-crustal slab geometries*
300 *with a content density contrast of 60 kg/m^3 and a constant thickness of 80 km. (a) predefined slab configuration 1 (b) predefined*
301 *slab configuration 2..*

302 The gravity signal ranges from 30 to 110 mGal depending on the assigned density contrast and
303 thickness for both slab geometry models (Fig. 7). The highest magnitude of forward calculated
304 gravity signal is in the order of 110 mGal and is observed for a slab model with a density
305 contrast of 80 kg/m^3 and a constant slab thickness of 100 km, while the lowest signal is
306 produced by a combination of 20 kg/m^3 density contrast and a slab thickness of 60 km. Similar
307 gravity response is produced by different combinations of density contrast and volume. The
308 signal pattern is influenced by the predefined slab geometry, while the magnitude of the gravity
309 signal is depending on the density contrast and thickness (Fig. 7).

310

311 *Figure 7 Forward calculated gravity disturbance signal for 12 different combination of density contrast and slab thickness for*
 312 *sub-crustal slab configuration 1 at a station height of 6040 m.*

313 Forward calculated gravity gradients at satellite height show the same dependency of signal
 314 strength (see Appendix).

315 **4.2 Geophysical and petrological modelling with LitMod**

316 For modelling the Alpine slab segments taking temperature and pressure variations as well as
 317 composition of the lithosphere and sub lithosphere into account, the geophysical and
 318 petrological modelling software LitMod 3D is utilized (Fullea et al.,2009). LitMod 3-D is a
 319 finite difference code, which allows the modelling of lithospheric and sub lithospheric

320 structures down to 400 km depth by solving the heat transfer, thermodynamical, rheological,
321 geopotential, and isostasy equations (Afonso et al., 2008; Fullea et al., 2010).

322 A LitMod model consists of a set of crustal, lithospheric- and sub lithospheric layers
323 characterized by their petrophysical and thermal properties, which are used as input data (Fullea
324 et al., 2010). LitMod provides as an output i.e. the density -, temperature-, pressure- distribution
325 as well as the forward calculated gravity disturbance and gravity gradients (Fullea et al. 2009).

326 The assigned composition for the different layers is calculated using a LitMod subroutine which
327 utilizes the *Perple_X* algorithm of Connolly (2009). *Perple_X* calculates in the LitMod
328 implementation the specific bulk rock properties based on the six main lithospheric oxides
329 (SiO_2 , Al_2O_3 , FeO , CaO , Na_2O) by minimizing Gibbs free energy equation. The Alpine
330 lithosphere and sub lithosphere as well as the proposed slab segments are modelled using
331 standard global lithospheric and sub lithospheric compositions to test the influence of
332 compositional variations within the slab segments on the gravitational signal. Here, we use the
333 so-called Tecton and Proterozoic type-composition (Table 1). Those compositions were chosen
334 for a model with a homogeneous crust, lithosphere and sub-lithosphere, where the density
335 changes as a function of temperature and pressure based on the assigned compositions. The
336 different slab composition is introduced to test whether a compositional contrast, in addition to
337 the expected thermal difference, results in a significant density contrast between the slab and
338 the surrounding material.

339 *Table 1: Mineralogical composition for the lithospheric and sub lithospheric structure.*

Major Oxide Compositions	Aver. Tecton Gnt. SCLM ^a	Aver. Tecton Gnt. Peridotite ^a	Average Proterozoic Massif	PUM ^b	DMM ^c
SiO_2	44.5	45	45.2	45	44.7
Al_2O_3	3.5	3.9	2	4.5	3.98
FeO	8	8.1	7.9	8.1	8.1
MgO	39.8	38.7	41.6	37.8	37.8

CaO	3.1	3.2	1.9	3.6	3.17
Na ₂ O	0.26	0.24	0.13	0.36	0.13

340 ^a Classifications according to Griffin et al. (1999b), ^b McDonough & Sun (1995), ^c Workman & Hart (2005) DMM = Depleted
341 mid-oceanic ridge basalt mantle, PUM = primitive upper mantle.

342 First, we create a reference model (M_0) without a slab segment. This model contains topography
343 from the ETOPO1 dataset (Amante and Eakins, 2009), the Moho depth from Spada et al. (2013)
344 and Grad et al. (2009). The lithosphere asthenosphere boundary (LAB) is a required interface
345 for the LitMod 3D to divide the model between the lithosphere and sub lithosphere and to assign
346 compositions. We introduce a fixed technical LAB at a depth of 100 km throughout the model
347 despite of the presence of slabs as the LAB is defined as the 1300°C isotherm. This set-up avoids
348 that the isotherm follows the geometrical shape of the slab, which would lead to a location in
349 unrealistic large depths (>200 km). In addition, we neglect the topography of the LAB for
350 several reasons: i) the information of the lithospheric thickness in the Alpine forelands is spare
351 and under ongoing discussions, ii) the fixed depth value is based on thermal isostasy LAB
352 estimations from Artemieva et al. (2019), which shows a LAB depth in the range of 80 to 120
353 km depth in the Alpine forelands. This technical LAB is used to parameterize the model and is
354 not meant to represent the topography of the LAB.

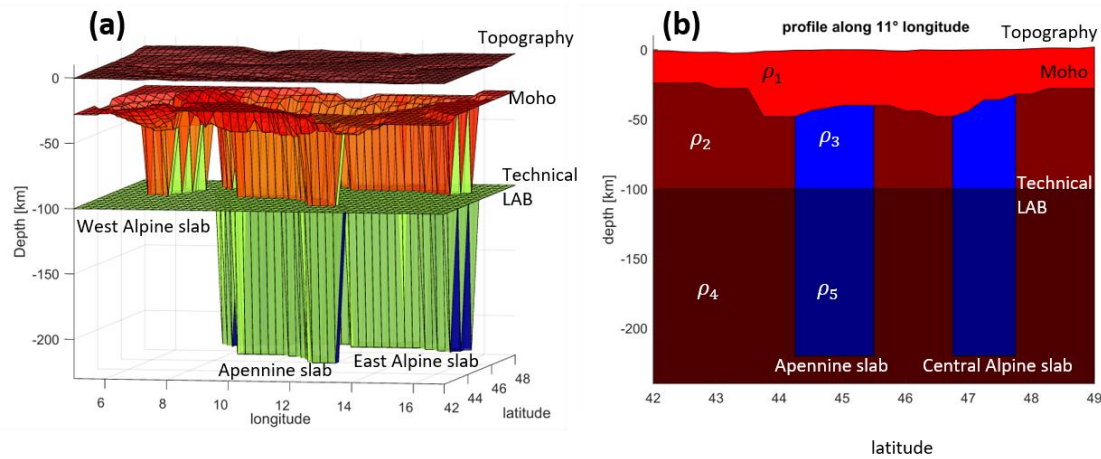

355 Slab segments are introduced stepwise for the lithosphere and sub lithosphere domains into the
356 model as well as thermal anomalies for the slab segment beneath the technical LAB, which
357 describes the 1300°C isotherm (Table 2). Calculating the difference to the reference model (M_0)
358 allows to estimate the effect a slab segments has on the density, temperature distribution of the
359 Alpine subsurface and therefore on the Alpine gravity field based on slab position, slab
360 geometry and composition.

361 *Table 2: Different LitMod models and there incorporated lithospheric and sub lithospheric structures and compositions.*

Models	Slab geometries	Slab composition (mantle)	Mantle composition	Slab composition (sub lithosphere)	Sub lithosphere composition	Thermal anomaly within sub lithospheric slab

M₈	Configuration 2	Average Proterozoic Massif	aver. Tecton Gnt.	-	PUM	-

362 A positive density contrast between subducting material and the surrounding mantle material
363 results in a negative buoyancy force. A density contrast is introduced into the LitMod model by
364 a difference in composition between the subducting denser slab and the surrounding mantle
365 (Fig. 9). Here, we use Tecton like compositions for the lithosphere and the subducting slab
366 segments since the Alpine slab segments result from continent-continent collision (Tables 1 and
367 2). A later model features a Proterozoic slab composition (M₈). Depleted mid-oceanic ridge
368 basalt mantle (DMM) and primitive upper mantle (PUM) are used for the sub lithospheric
369 domain. Additional to the density contrast within the sub lithosphere, a temperature anomaly of
370 – 100 K is introduced for the sub lithospheric part. Later models include a variation of
371 temperature anomalies (M₅, M₆, M₇). Note those compositions are used as a first order test and
372 serve as a starting point for synthetic slab models to illustrate the compositional and thermal
373 effect on the gravity signal by influencing the density distribution. They do not necessary
374 represent the compositional mantle environment in the Alpine region.

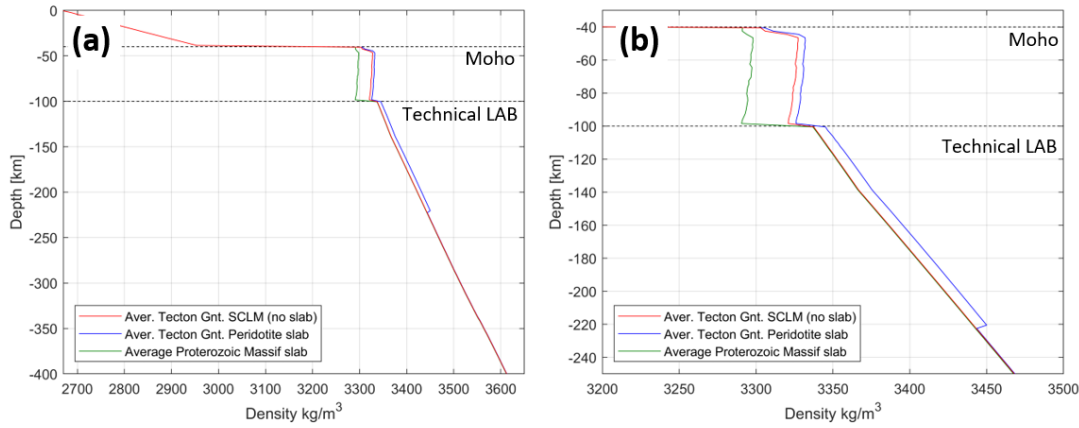

375

380 4.2.1 Results

381 The gravity signal of the predefined slab segments is forward calculated as well as the
 382 background model without incorporation of slab segments. The residual between both forward
 383 calculations gives the gravitational contribution of the slab segments, while other gravitational
 384 effects, like the topography or crustal thickness variation are not considered.

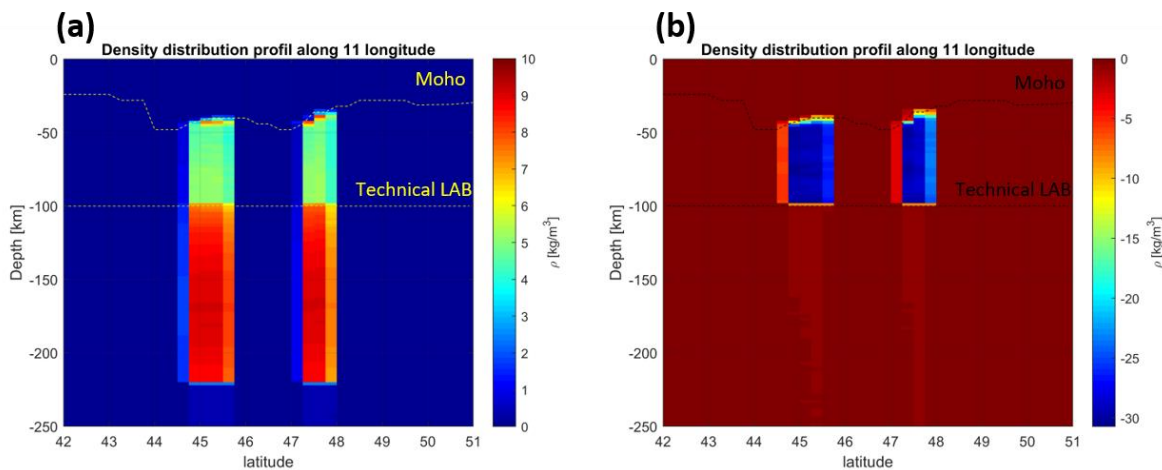

385 A slab segment with an average Tecton Gnt. composition (M_1, M_2) results in a slightly denser
 386 material compared to the surrounding mantle (M_0), while a slab segment with a Proterozoic
 387 composition (M_8) shows a less dense lithospheric structure compared to the reference model
 388 (M_0), this composition results in less dense slab segment, which would not be subducted due to
 389 the positive buoyancy (Fig. 10). However, we aim to illustrate the effect composition has on
 390 the density distribution within the slab and to the surround mantle and show the importance of
 391 correct compositional information, therefore we focus on the difference in density contrast
 392 between slab and surrounding mantle and neglecting the sign of the density contrast.

393

394 *Figure 9 (a) density profile at 11° longitude and 45° latitude for the full vertical model space of 400 km depth. Density profiles*
 395 *for 3 different models (M_0 , M_1 , M_9) with different compositional properties are shown. (b) Zoomed in profile at the depth range*
 396 *of present slab segments.*

397 The difference in density distribution (density contrast) within the slab segments with a Tecton
 398 composition (M_1 , M_3) to the reference model (M_0) is in the order of 5 kg/m^3 for the lithosphere
 399 and in the order of 10 kg/m^3 for the sub lithospheric domain (Fig. 10a). The density variations
 400 within the lithospheric and sub lithospheric slab domain are less than 1 kg/m^3 resulting from
 401 both depth dependent variations in pressure and temperature. Between lithosphere and sub
 402 lithosphere, a rapid increase in density contrast is observed (Fig. 10a). The density contrast of
 403 a lithospheric Proterozoic slab composition (M_9) to the reference model (M_0) is in the order of
 404 -30 kg/m^3 (Fig. 10b).

405

406 *Figure 10 (a) residual density contrast for lithospheric and sub lithospheric slab segments of model (M_3) with Tecton like*
 407 *composition within the lithosphere and PUM and DMM composition in the sub lithosphere with an additional thermal anomaly*
 408 *of -100° K for the sub lithospheric slab segment to the background model (M_0). (b) Residual lithospheric density contrast of a*
 409 *Proterozoic lithospheric slab segment (M_8) to a Tecton compositional surrounding mantle (M_0). Residual density contrast is*
 410 *limit to the technical LAB as the sub-lithospheric part is identical to the reference model (see also Fig. 9b)*

411 The gravity signal caused by the proposed slab segment configurations is estimated for
 412 lithosphere and sub lithosphere separately. The forward calculated gravity effect, at topographic
 413 surface level, for the slab configuration 1 for the lithospheric part is in the order of 4 mGal
 414 while the sub lithospheric gravity signal is in the range of 7 mGal (Fig. 12a, b). The combined
 415 gravity signal is in the order of 12 mGal (Fig. 12c). The gravity signal in the Eastern Alps for
 416 Configuration 2 is significant larger in the order of 17 mGal for the combined model (Fig. 12f).

417

418 *Figure 11 Residual of the forward calculated g_z gravity signal of lithospheric slabs at surface station height based on LitMod*
 419 *models with Tecton like compositions in the lithosphere and PUM and DMM compositions in the sub lithosphere (M_1 , M_2 , M_3 ,*
 420 *M_4) with an additional thermal anomaly of $-100^\circ k$ for the sub lithospheric slab segment, for predefined slab Configuration to*
 421 *the background model (M_0). (a)-(c) Configuration 1. (d)-(f) Configuration 2. Crustal and topographic contribution are nullified.*

422 The calculated gravitational effect of a slab segment with Proterozoic composition and a Tecton
 423 surrounding mantle composition is in the order of -40 mGal for the g_z component (Fig. 12 a).

424

425 *Figure 12 (a) Forward calculated gravity effect of a Proterozoic lithospheric slab segment to a Tecton compositional*
 426 *surrounding mantle for configuration 2, obtained by calculating the residual between M_8 and M_0 . (b) gravity signal produced*
 427 *by purely compositional effect in the sub lithosphere between a PUM and DMM composition, obtained by calculating the*
 428 *residual between M_5 and M_6 . (c) gravity signal produced by purely thermal anomaly of -100°K for a sub lithospheric slab*
 429 *segment, obtain by calculating the residual between M_3 and M_6 . (d) gravity signal produced by purely thermal anomaly of*
 430 *-200°K for a sub lithospheric slab segment obtained by calculating the residual between M_6 and M_7 .*

431 The gravity response to a compositional variation within the sub lithosphere between the
 432 incorporated slab segment (DMM composition) and the surrounding mantle (PUM composition)
 433 is in the order of 4 mGal (Fig. 12b). The gravity response for a pure thermal anomaly of -100
 434 K within the sub lithospheric slab segment is in the order of 16 mGal (Fig. 12c), while a pure
 435 thermal anomaly of -200 K within the sub lithospheric slab segment is in the order of 21 mGal.

436 5 Discussion

437 The imprint of the gravity response caused by the density distribution based on direct
 438 conversion of seismic velocities (approach 1) is visible, however, individual and independent
 439 slab segments cannot be identified (Fig. 4). The strength of this approach is that it is fast to

440 implement and can provide a first order characterization of the gravity signal and slab
441 geometries of subducting lithosphere. However, a clear characterization of subducting slab
442 segments is not possible. First of all, the density model depends on the resolution and
443 regularization of the seismological model, which can lead to distortions in the gravity response
444 (e.g. Root, 2020). The method is dependent on the choice of the conversion factor and might
445 overestimate the density (see the large negative anomaly in the Ligurian Sea). The conversion
446 factor is a strong simplification of nature and for such a geodynamic complex area, a constant
447 conversion factor is not adequate.

448 The forward calculated gravity field with competing predefined slab geometries (approach 2)
449 shows a clear gravity signal, where the individual slab segments are distinguishable (Fig. 6).

450 A relative gravity low related to the slab gap in the Eastern Alps is a prominent feature in the
451 gravity signal of Configuration 1 (Fig. 6a). The eastern Alpine slab segment of Configuration
452 1, due to its relatively small volume, result in a lower signal compared to the Central Alpine
453 slab segment.

454 Configuration 2 shows a larger gravity signal in the Eastern Alps up to 100 mGal (Fig. 6b)
455 compared to Configuration 1. The increase of the gravity signal is attributed to the subduction
456 of both Eurasian and Adriatic lithosphere in the Eastern Alps. The gravity signal shows a
457 continuous transition from the Central Alps to the Eastern Alps, where the contribution of the
458 destined slab segment cannot be distinguished in the resulting gravity field (Fig. 6b). In the
459 Western Alps, Configuration 1 and 2 show a lower gravity signal compared to the Central Alps.
460 This is attributed to the much shallower Western Alpine slab segment that penetrate down to
461 100 km depth.

462 The gravity signal is influenced by both the assigned density contrast and thickness of the slab.
463 A trade of between both parameters is clearly observable as the same gravity response of the
464 slab configuration can be achieved with different values of density contrast and slab thickness.

465 Therefore, making it impossible to derive slab properties in form of density contrast and slab
466 thickness from the gravity field (Fig. 7).

467 The calculated densities in LitMod 3-D models (approach 3) are estimated taking temperature
468 and pressure variations into account based on an assigned composition. The composition has a
469 strong influence on the resulting density contrast. In the case that the compositional contrast
470 between slab segment and surrounding mantle is small, the density contrast is consequently
471 small as well (Fig. 9 and 10a). With increasing compositional differences, the density contrast
472 increases as well. A strong density contrast within the slab segment is recognizable between
473 lithospheric and sub lithospheric domain (Fig. 10a and b), while the variations between the slab
474 and surrounding mantle remain small.

475 The gravity signal shows in the Eastern Alps significant larger signal from the lithosphere and
476 sub lithosphere domain for Configuration 2 (Fig. 11d, e, and f) compared to Configuration 1
477 (Fig. 11a- c). The different slab segments are distinguishable with the exception of the two slab
478 segments in the Eastern Alps in Configuration 2 (Fig. 11). The contribution from the
479 lithospheric domain to the gravity signal is smaller than from the sub lithospheric domain (Fig.
480 11b, and e). However, the slab gap and the eastern slab segment feature can be recognized in
481 the lithospheric part in Configuration 1 but not in the gravity signal of the full model.

482 The Proterozoic slab segment has a larger gravity response compared to the Tecton-like
483 composition. This gravitational signal is negative due to the less dense Proterozoic composition
484 in comparison to the reference model (M_0) (Fig. 12a).

485 Sub lithospheric composition has only a small influence on the gravity field, in the order of 4
486 mGal (Fig. 12b). However, a thermal anomaly within the sub lithospheric slab in the order of -
487 100K result in a gravitational response of 16 mGal (Fig. 12c) and for a -200 K anomaly in the
488 order of 21 mGal (Fig. 12d). Both the composition and the thermal variation influence the
489 density and consequently the gravity response. However, the thermal component is a much
490 larger contributor.

491 For the three approaches (section 3, 4.1 and 4.2) a measurable gravity effect of the subducting
492 slab segments is observable. The independent slab segments are distinguishable to a certain
493 degree with the exception of the bivergent slab configuration in the Eastern Alps (Fig. 6, and
494 11) and the model containing converted density from seismic velocities (Fig 4) , while the slab
495 configurations cannot be separated at satellite altitude (Appendix). Forward calculated gravity
496 anomalies from converted density distribution suggest a gravitational signal of the slab
497 segments in the order of 40 mGal which corresponds to a density contrast of 20 to 40 kg/m³ in
498 the models with predefined slab geometry. The models with a Tecton like composition suggest
499 a gravity effect of the slab segments in the order of only 16 mGal, corresponding to a density
500 contrast of 20 kg/m³ in the simple model. Increasing the compositional difference with a Tecton
501 composition suggests a gravity signal in order of 30 mGal and is in line with the converted
502 density model.

503 All three methods show a positive gravity signal contribution, which can be related to sub-
504 crustal density variations for approach 1 and to predefined sub-crustal slab segments for
505 approach 2 & 3, up to 40 mGal to the Alpine gravity field. That is significant in comparison to
506 the observed Bouguer Anomaly with a minimum of ~-200 mGal. If this contribution is not
507 considered, a significant part of the gravity signal is attributed to crustal thickness or intra-
508 crustal sources. Due to the long-wavelength appearance of the gravity effect, that might not be
509 relevant for small-scale or local studies, the effect is only seen as a shift. For gravity models of
510 larger areas (e.g. Eastern Alps) or even the entire regions that should not be neglected. For one,
511 estimates of crustal thickness or the mass distribution are significantly biased, and placing the
512 Alps in the geodynamic context of the surrounding requires a careful and complete
513 consideration of all sources in order to provide realistic density distribution required for
514 geodynamic models (e.g. Reuber et al., 2019).

515 **6 Conclusions**

516 We have addressed the potential gravity effect of proposed slab segments in the Alpine region
517 using three different modelling approaches.

518 • Converted density from seismic tomography: In the resulting gravity signal the imprint
519 of slab segments is visible, however, distinguishing between the different and
520 independent slab segments is not possible.

521 • Models with predefined slab segments are dependent on the assigned density contrast
522 and volume as well as on the predefined positions of the slab segments. The gravity
523 signal caused by the slab segments are sharp and can be separated for the different slab
524 segments for the gravity field at the surface. Significant gravity contributions from slab
525 segments below 200 – 250 km to the Alpine gravity are unlikely.

526 • Combined petrophysical-geophysical modelling results in the most complex models.
527 The calculated density variation within the slab is rather small compared to the density
528 contrast between lithosphere and sub lithosphere. The density distribution within the
529 slabs, and consequently the gravity field, is highly influenced by the slab composition
530 and thermal structure.

531 Sub-crustal density variation (approach 1) and predefined slab segments (approach 2 & 3)
532 suggest a positive sub-crustal gravity contribution of up to 40 mGal. Even though this might be
533 considered as an end of the envelope calculations, this value is significant, even compared to
534 the observed Bouger anomaly low of -200 mGal along the Alps. Previous studies compensated
535 this effect by lithosphere thickness and/or intra-crustal sources, future studies should
536 incorporate subducting slab structures in order to provide a meaningful representation of the
537 geodynamic complex Alpine area. Precise estimations of the slab density structure require a
538 correct crustal density and crustal thickness model. With the integration of further observables,
539 it might be possible to judge on the correct slab configuration beneath the Alps. Furthermore,
540 future studies based on the AlpArray Network will be of high interest in better defining slab
541 geometries as well as their properties.

542 **Competing interests**

543 The authors declare that they have no conflict of interest.

544 **Author contributions**

545 ML carried out the gravity modelling, visualized and interpreted the results and prepared the
546 first manuscript draft. JE supervised the gravity modelling and interpretation, designed the
547 original research project, acquisition of the financial support for the project leading to this
548 publication and writing (reviewing and editing). TM defined the slab configurations based on
549 tectonic and seismological knowledge and writing (reviewing and editing). AE created and
550 provided the surface wave tomography model MeRE2020 and writing (reviewing and editing).

551 **Acknowledgment**

552 The authors thank the reviewers, Carla Braitenberg and an anonymous referee for their valuable
553 suggestions, which helped to improve the manuscript significantly.

554 This study is part of the projects "Integrierte 3D Modellierung des Schwere- und
555 Temperaturfelds zum Verständnis von Rheologie und Deformation der Alpen und ihrer
556 Vorlandbecken - INTEGRATE" and "Surface Wavefield Tomography of the Alpine Region to
557 Constrain Slab Geometries, Lithospheric Deformation and Asthenospheric Flow in the Alpine
558 Region" funded by German Research Foundation (DFG) in the SPP Mountain Building
559 Processes in 4D.

824 **Appendix A Gravity Gradients at satellite height**

825 For all Alpine density models presented above (section 3, 4.1 and 4.2) we have also calculated
826 gravity gradients at a station height of 225 km. This station height corresponds to the second
827 mission phase of GOCE (Gravity field and steady-state ocean circulation explorer) carried out
828 by ESA (European Space Agency).

829 We anticipated that gravity gradients measured by the GOCE satellite mission are sensitive to
830 the slab segments in the Alpine region. Our result show, that the long wavelength signal of the
831 different present slab segments contributes to a large-scale gravity response where the different
832 contributor cannot be separated. Therefore, we conclude that against our anticipation gravity
833 gradients at satellite height are in fact not sensitive to the Alpine slab configuration. We show
834 here, the gravity gradients (mainly the g_{zz} component) for completeness.

835 Measured gravity gradients from the GOCE mission (Bouman et al., 2016), which were
836 corrected for topography and bathymetry ranges from 2.5 to -2.5 E at satellite altitude of 225
837 km height (Fig. 13). A negative gravity anomaly of -2.5 E in the g_{zz} component is observed
838 equivalent to the vertical g_z component (Fig. 13). However, no clear sign for subducting
839 lithosphere can be observed in any component of the gravity gradient tensor.

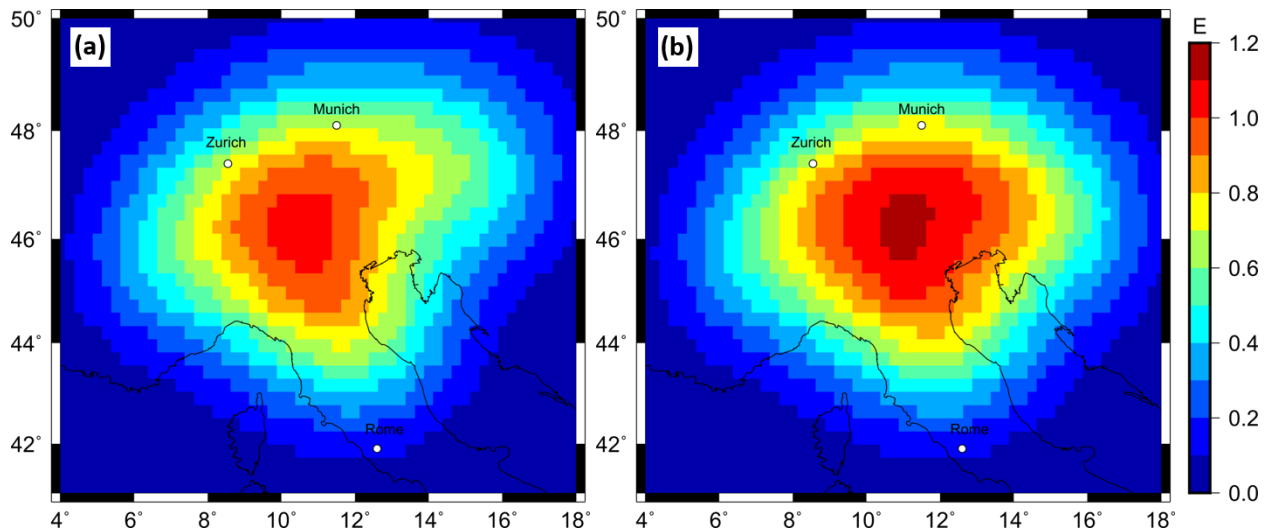

840
841 *Figure 13 GOCE gradients at 225 km height after Bouman et al. (2016) corrected for topography and bathymetry with a 5°*
842 *extension to remove far field effects. The gravity gradients are presented in a North-East-Up coordinate system.*

843 The forward calculated gzz component at 225 km station height from a density model (section
844 3) with converted densities ranges from -3.5 E to 0.7 E (Fig. 14). A positive gravity signal of
845 about 0.5 E in the Apennine and Alpine region is observed which could be linked to subducting
846 slab segments. However, it is impossible to separate specific slab segments.

847
848 *Figure 14 Forward calculated gzz gravity signal from relative density distribution converted from relative seismic velocities*
849 *using a conversion factor of 0.3 for the at 225 km station height.*

850 Forward calculated tesseroid models (section 4.1) for slab configuration 1 and 2 with a constant
 851 density contrast of 60 kg/m^3 and a constant thickness of 80 km result in a less sharp gravity
 852 signal for the gzz component at a station height of 225 km (Fig. 15) compared to the gz
 853 component at station height of 6040 m (Fig. 6). The gravity signal for the gzz component is in
 854 the range of 0.8 E to 1 E. At satellite altitude the gravity signal is observed as a large area with
 855 a positive gravity effect for Configuration 1 and 2. The contribution of the different slab
 856 segments to this positive gravity effect is not distinguishable. The only recognizable difference
 857 is the size of this positive gravity signal. Configuration 1 shows a smaller anomaly, due to a
 858 lower volume of subducting material in the Eastern Alps.

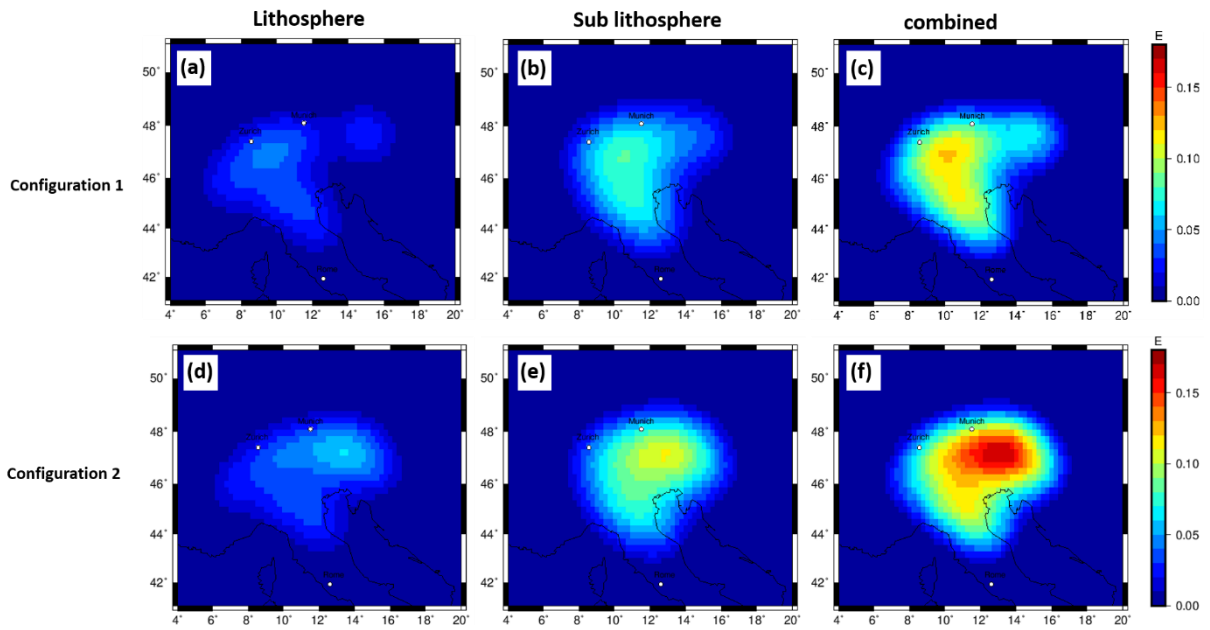

859
 860 *Figure 15 Forward calculated gzz gravity signal at a station height of 225 km from predefined sub-crustal slab geometries with*
 861 *a content density contrast of 60 kg/m^3 and a constant thickness of 80 km. (a) slab configuration of hypothesis 1 (b) slab*
 862 *configuration of hypothesis 2.*

863 In Addition, the signal strength for the forward calculated gzz component show the same
 864 dependency of signal strength to the density contrast and slab thickness (Fig. 16) as the gz
 865 component (Fig. 7). The signal strength of the gzz component ranges for the 12 different
 866 combinations from 0.3 E to 2 E (Fig. 16). The gravity signal cannot be separated and affiliated
 867 to a certain slab segment. The gzz gradient signal shows a large blurry gravity high over the
 868 Alps, which thins out to the edges.

869
 870 *Figure 16 Forward calculated gzz gravity signal for 12 different combination of density contrast and slab thickness at a station*
 871 *height of 225 km for sub-crustal slab configuration 1.*

872 The gravity effect for the LitMod models (section 4.2) with the slab Configuration 1 shows in
 873 the lithosphere domain a signal strength of about 0.05 E, while the sub lithospheric gravity
 874 signal is in the range of 0.1 E for the gzz component at satellite altitude of 225 km height. The
 875 combined gravity signal is in the order of 0.14 E (Fig. 17). A Proterozoic slab produces a larger
 876 amplitude in signal strength, however the different slab segments can again not be separated
 877 (Fig. 18).

878
879
880
881
882

Figure 17 forward calculated gzz gravity signal at satellite altitude of 225 km based on LitMod models with tecton like compositions in the lithosphere and PUM and DMM compositions in the sub lithosphere (M_1, M_2, M_3, M_4) with an additional thermal anomaly of -100°K for the sub-lithospheric slab segment, for predefined slab Configuration to the background model M_0 . (a)-(c) for Configuration 1. (d)-(f) for Configuration 2. Topographic and crustal effects are nullified.

883
884
885

Figure 18 Forward calculated gravity effect for the gzz component at satellite height of a Proterozoic lithospheric slab segment to a Tecton compositional surrounding mantle for Configuration 2 obtained by calculating the residual between M_8 and M_0 .
