17 **Abstract**

18

19 The small island of Groix in southern Brittany, France, is well known for its excellent
20 outcrops of Variscan blueschists, eclogites and garnetiferous micaschists that define a Late-
21 Devonian suture between Gondwana and Armorica. The kinematics of polyphase deformation
22 in these rocks is reconstructed based on 3D microstructural analysis of inclusion trails in
23 garnet- and pseudomorphed lawsonite porphyroblasts using multiple, differently oriented thin
24 sections of single samples and X-ray tomography. Three sets of inclusion trails striking NE-
25 SW, NNW-SSE and WNW-ESE are interpreted to witness a succession of different crustal
26 shortening directions orthogonal to these trends. The curvature sense of sigmoidal- and spiral-
27 shaped inclusion trails of the youngest set is shown to be consistent with southward thrusting
28 or northward subduction of Gondwana under Armorica, provided that these microstructures
29 developed by overgrowth of actively forming crenulations instead of the previously envisaged
30 'snowball' mechanism. The latter predicts an opposite thrusting direction which is at odds with
31 the regional tectono-metamorphic zonation in the Ibero-Armorican Arc. Strongly non-

32 cylindrical folds locally found on Ile de Groix are reinterpreted as fold-interference structures
33 instead of having formed by progressive shearing. Six additional samples of lower-grade
34 footwall units of the Groix ophiolite were also studied. The oldest inclusion trails in these
35 rocks have similar trends as the youngest one in Ile de Groix. Our new inclusion-trail data for
36 southern Brittany bear a strong resemblance with those documented previously in the north-
37 western Iberian Massif and suggest about 20° clockwise rotation of Iberia during the early
38 Cretaceous opening of the Gulf of Biscay.

39

40 Key words: porphyroblast inclusion trails, FIA, Variscan subduction, Ibero-Armorican arc, Ile
41 de Groix.

42

43 **1. Introduction**

44

45 Kinematic reconstructions in polydeformed metamorphic regions are traditionally
46 based on a combination of geological mapping, study of structural relationships in outcrop,
47 orientation measurements, and study of thin sections usually cut parallel to the stretching
48 lineation to determine a shear sense. Not rarely does this approach produce paradoxical data
49 that insufficiently constrain different possible tectonic models as is certainly the case of Ile de
50 Groix as we will see. However, following a major conceptual shift concerning the formation
51 mechanism and tectonic significance of porphyroblast inclusion trails (Bell et al., 1985, 1986;
52 Bell & Johnson, 1989), 3D microstructural data for such microstructures has been shown to
53 allow detailed reconstruction of deformation histories whose complexity was previously not
54 recognized. Aerden (2004) pioneered this approach in Variscan NW Iberia in a research
55 project led by José Ramón Martínez Catalán. He distinguished 4 inclusion-trail sets with
56 specific, regionally consistent trends and relative timing. An E-W trend of the earliest formed
57 set was interpreted to record N-S directed compression and subduction with unknown polarity.
58 Subduction would have been followed by several changes in the direction of crustal
59 shortening responsible for the 3 younger sets of inclusion trails. The youngest two sets with
60 NE-SW and WNW-ESE trends were correlated with regional-scale fold-interference patterns
61 developed throughout the Iberian Massif and this, in turn, was key to rediscovering a partially
62 blind arc in central Iberia later endorsed by Martínez Catalán et al. (2012).

63

64 Here, we report a similar study of inclusion trails in the Armorican Massif focusing on
65 high-pressure metabasites of Ile de Groix, but also including data from lower-grade rocks
66 located in their footwall. The island of Groix (ca. 15 km²) is a national reserve with excellent

66 coastal outcrops of Variscan blueschists, eclogites and interlayered garnetiferous micaschists
67 that are generally accepted to represent the remains of a narrow ocean that, in the late Silurian
68 and lower Devonian separated Gondwana in the south from the Armorica microplate to the
69 north. In NW-Iberia, a similar ophiolitic unit is since long recognized and correlated with the
70 one exposed on Groix island (Arenas et al., 1995; Diaz-García et al., 1999; Ballèvre et al.,
71 2009, 2015). Closure of this ocean involved subduction of the margin of Gondwana causing
72 high-pressure metamorphism dated 370-360Ma on Ile de Groix (Bosse et al., 2005). However,
73 the polarity and kinematics of ophiolite emplacement have remained poorly constrained by
74 (micro)structural data. Indeed, not much has changed since Quinquis et al. (1978) wrote: *"the*
75 *bulk sense of shear on Groix has not yet been determined unequivocally, but may perhaps be*
76 *deduced from systematic analyses of fold asymmetry and of microstructures in and around*
77 *syntectonic garnets. The significance of glaucophane orientation in the basic rocks of Groix*
78 *also needs to be studied: the orientation is extremely variable and may not be simply related*
79 *to a shear direction."* Exactly along these lines of suggested further research, we performed a
80 detailed microstructural analysis of 10 garnetiferous blueschist samples of Ile de Groix, 4
81 samples of albite-porphyroblast bearing greenschists (Pouldu schists) cropping out along the
82 coast of the mainland, and 2 kyanite-staurolite schists collected inland from the North-
83 Armorican Zone (Fig. 1). It will be shown that behind the simple appearance of the regional
84 stretching lineation pattern on Ile de Groix, a complex tectonic evolution is hidden recorded
85 by inclusion trails in garnets and pseudomorphed lawsonite crystals. Our microstructural data
86 resolve conflicting kinematic interpretations of previous workers regarding and proposes a
87 new polyphase model for sheath folds locally found on the island.

88

89 **2. Geological setting and previous work**

90

91 The Variscan (or Hercynian) orogeny took place in the Devonian and Carboniferous
92 as a consequence of Gondwana-Laurussia convergence with 2 microcontinents in between
93 these 2 giants known as Armorica and Avalonia. The resulting closure of oceanic domains
94 created multiple ophiolitic sutures whose precise location, timing and correlation continues to
95 be a major research topic (e.g. Azor et al., 2008; Faure, 2008; Ballèvre et al., 2009; Arenas et
96 al., 2016). The high-pressure rocks of Ile de Groix are part of a partially submerged ophiolitic
97 klippen belonging to a thrust nappe that separates Armorican crustal units in the hangingwall
98 outcropping to the North- and Central Armorican Domains, from North-Gondwana derived
99 crustal units below the suture outcropping in the South Armorican Domain and NW Iberia

100 (Fig. 1). Because of this regional-scale zonation, a north-dipping subduction zone associated
101 with south verging thrusts has been considered the most likely geodynamic scenario (Matte,
102 2001; Faure et al., 2008; Ballèvre et al., 2009; Ballèvre 2015). However, structural data have
103 not allowed to independently confirm this model and in fact have yielded conflicting results.

104 Lagarde (1980) concluded NW directed thrusting from shear criteria in the
105 Champtoceaux Complex (Fig. 1), implying south-east subduction. A similar kinematic was
106 deduced on Ile de Groix by Quinquis (1980), Quinquis & Choukroune (1981) and Cannat
107 (1985) from rotated snowball garnets and quartz c-axes fabrics. Recognizing the conflict with
108 respect to northward subduction, these authors proposed that this shear sense corresponds to
109 backthrusting and obduction of ophiolites in opposite direction as subduction.

110 However, Quinquis (1980) noticed that shear bands (C and C' planes) on Ile de Groix
111 indicate opposite shear senses, which was later interpreted by Shelley and Bossière (1999) in
112 terms of bulk vertical shortening and crustal thinning. These authors emphasized that shear
113 bands showing opposite displacements cannot be linked to different metamorphic conditions
114 and probably formed as conjugate sets. They also found equal amounts of oppositely shear
115 senses indicated by quartz fabrics which they measured in 57 oriented samples. Philippon et
116 al. (2009) argued on the contrary that opposite shear-band sets did form consecutively under
117 different metamorphic conditions. A first set would have developed during prograde
118 metamorphism with top-to-the SW (N140) shearing, and the second during quasi-opposite
119 top-to-the-north (N350) shearing and retrogression. However, they failed to address a top-to-
120 the-north shear sense during prograde metamorphism deduced from rotated garnets by
121 Quinquis & Choukroune (1981).

122

123 3. Microstructural methods

124

125 A total of 132 oriented thin sections were studied of 33 samples: 20 from Ile de Groix,
126 9 from the Pouldu schists and equivalent rocks cropping out in the Baye d'Audièrne, and 4
127 from the Central Armorican Zone (Fig. 1). Initially, a horizontal thin section was cut of each
128 sample to assess the interest of the rock for further study and to measure the strike of
129 inclusion trails. The latter only proved possible in about half of the samples as the other half
130 contained garnets that were too altered or contained poorly developed or absent inclusion
131 trails. Strike measurements for inclusion trails are plotted in moving-average rose diagrams
132 made with the Excel Workbook MARD (Munro & Blenkinsop, 2012).

133 Seven Ile de Groix samples containing the most promising inclusion trails were further
134 studied in 6 vertical thin sections striking N0, N30, N60, N90, N120 and N150. Such radial
135 thin-section sets allow determination of the average trend of inclusion-trail curvature axes
136 (Hayward, 1990) known as 'FIA' in the more recent literature ('Foliation Intersection- or
137 Inflexion-Axes'; Bell et al., 1992; Bell et al., 1995; Stallard et al., 2003; Kim & Sanislav,
138 2017). Application of this technique has in numerous mountain belts revealed regionally
139 consistent orientations of FIA (Kim and Sanislav, 2017 and references cited therein) thought
140 to record crustal shortening directions orthogonal to FIA trends and changes therein where
141 multiple sets of FIA can be distinguished.

142 Four of our Ile-de-Groix samples (G3, G11, G12 and G14) were studied in even
143 greater detail using X-ray computed tomography allowing study of virtual sections of any
144 orientation and location in a scanned volume, as well as quantitative analysis of mineral-grain
145 shapes.

146

147 **4. Strike and pitch measurements of inclusion-trails**

148

149 The samples studied in detail from Ile de Groix come from 3 areas in the north (G18-
150 20), east (G3, G7) and south-east (G11-15) of the island (Fig. 2a). The matrices of these rocks
151 contain a mineral/stretching lineation that exhibits significant variation but overall trends N-S
152 in the south-east of the island changing gradually towards NW-SE towards the north and west.
153 Bosse et al. (2002) inferred a thrust contact separating garnetiferous eclogites, blueschists and
154 micaschists exposed in the eastern half of the island from underlying lower-grade (albite-
155 epidote facies) rocks outcropping in the western half (Triboulet, 1974; Schulz, 2001).

156 Since stretching lineations on Groix are associated with a foliation that generally dips
157 gently or subhorizontal, shearing-induced rotation of porphyroblasts can be expected to have
158 resulted in inclusion trails that broadly strike orthogonal to the lineation (Fig. 3a). Our
159 measurements, however, show exactly the opposite, a NNE-SSW strike maximum of
160 inclusion trails subparallel to the stretching lineation. This is only a first indication that the
161 classic interpretation of internal foliations based on Zwart (1960), Spry (1963) or Roosenfeld
162 (1970) may be incorrect and that the alternative model proposed by Bell (1985) and Bell et al.
163 (1986) has to be considered. The latter claims that sigmoidal and spiral-shaped inclusion trails
164 form by punctuated overgrowth of one or multiple crenulation cleavages by porphyroblasts
165 that rotate little or not during deformation due to the micro-partitioning of deformation
166 between cleavage planes and microlithons (Fig. 3b). FIAs represent 'fossil' crenulation axes in

167 this model and this explains why FIA are commonly parallel to crenulation- and fold-axes in
168 the matrix (Aerden, 1995, 2004, 1998, Sayab, 2005, Aerden et al., 2013; Bell & Sanislav,
169 2011).

170 Further evidence supporting a 'non-rotational' origin of sigmoidal and spiral-shaped in
171 Ile de Groix is provided by garnets in samples G7, G11 and G14. These exhibit the same
172 characteristic truncation surfaces that Bell & Johnson (1989) drew attention to. They showed
173 that these truncations in spiral garnets from different orogens systematically align along
174 vertical and horizontal axes, something that has been amply confirmed by later research (e.g.
175 Bell et al., 1992; Hayward, 1992; Aerden, 1994, 1998, 2004; Mares, 1998; Bell & Sapkota,
176 2012; Sayab, 2005; Shah et al., 2009; Aerden and Ruiz Fuentes, 2020). Oriented line
177 drawings of spiral garnets in G7, G14 and G11 also show orthogonal preferred orientations of
178 their truncations (Fig. 4) in agreement with their origin by stepwise overgrowth of successive
179 subvertical and subhorizontal crenulation cleavages.

180

181 **5. Curvature sense of inclusion trails**

182

183 The above mentioned rotational and non-rotational models deduce an opposite shear
184 sense from a given inclusion trail curvature sense. Quinquis & Choukroune (1981) reported
185 that out of a total of 29 thin sections they studied cut parallel to the stretching lineation, 26
186 contained sigmoidal or spiral-shaped inclusion trails indicating top-to-the north shearing. As
187 they assumed the traditional 'rotational' model, it follows that their inclusion trails
188 predominantly curve anticlockwise when viewed in westward direction. In effect, we found
189 the same predominance in our samples after counting the number of clockwise vs.
190 anticlockwise trails in all vertical thin sections striking N-0, N30, N120 and N150. That is all
191 thin sections making a small angles with the regional stretching lineation. This resulted in 99
192 anticlockwise and 27 clockwise inclusion trails (viewing westward), a ratio of about 4:1.

193 According to the 'non-rotational' model, the observed asymmetry, in principle, implies
194 crustal shortening with a component of north-side-up shearing on vertical foliations
195 alternating with gravitational collapse with a component of top-to-the south shearing on
196 horizontal foliations (Bell & Johnson, 1989, their Figs. 16 and 17). Note that this is consistent
197 with the northward subduction interpreted by most authors from the regional
198 tectonometamorphic zonation in the Ibero-Armorican Arc. Quinquis & Choukroune (1981),
199 however, deduced an opposite thrusting direction from the same inclusion trails and attempted

200 to reconcile this with a northward subduction by invoking backthrusting and ophiolite
201 obduction, for which there is little independent evidence.

202 Strain shadows around porphyroblasts composed of quartz, feldspar and chlorite do
203 not show consistent asymmetries. In fact, they are commonly rather symmetrical or showing
204 opposite asymmetries even on both sides of the same porphyroblast. Where a clear
205 asymmetry is observed it is consistent with the shear sense indicated by inclusion trail
206 curvature according to the non-rotational model only (Figs. 5a, b).

207 So, we could have finished our paper here with the conclusion that no reconciliation is
208 needed, if not a more detailed 3D study of porphyroblasts had revealed a far more complex
209 tectonic history including different tectonic transport directions associated with multiple
210 inclusion-trail sets and FIA.

211

212 **6. Average FIAs**

213

214 Hayward (1990) devised a method for constraining the average trend of porphyroblast
215 FIAs in a sample using a radial set of vertical thin sections in which the asymmetry (i.e.
216 curvature sense) of inclusion trails is recorded. Where the asymmetry flips between two thin
217 sections, the FIA passes between them. We successfully applied the method in 5 Ile de Groix
218 samples, whose average FIAs are shown in Fig. 2b. FIAs are constrained to within 30° trend
219 ranges but 10° for samples G7 from which 2 extra thin sections were cut. Additionally, the
220 plunge direction was determined from the asymmetry of inclusion trails in horizontal thin
221 sections.

222 In the next section it will be shown that average FIAs can be matched to specific
223 orientation maxima seen in the rose diagrams for inclusion trails strikes (Fig. 2b), although
224 not necessarily the strongest maximum. In sample G12 a correlation is not possible, though,
225 due to large variation of individual FIAs about a mean vector whose trend does not match the
226 strikes of associated inclusion-trails.

227 No results average FIAs could be determined in samples G18 and G20 as no clear
228 asymmetry switch was observed between the different thin sections. In fact, most thin
229 sections contain inclusion trails showing opposite curvature senses, probably reflecting the
230 presence of more than just one FIA sets in these samples with different orientations. G3, G13
231 and G15 contained mostly straight inclusion trails and insufficient numbers of
232 asymmetrically curved ones to apply the technique.

233

234 **7. X-ray tomography**

235

236 *7.1. Sample G11*

237

238 G11 is a blueschist from 'Amer' in the SE of the island (Fig. 2a). It contains garnet
239 porphyroblasts as well as rectangular pseudomorphs composed of a mixture of white mica,
240 chlorite, albite and epidote after lawsonite probably (Cogné et al., 1966; Felix & Fransolet,
241 1972; Ballèvre et al., 2003). Lawsonite relics have never been found, though, and some
242 authors have argued that the replaced mineral was plagioclase (Shelley & Bossière, 1999).
243 Lawsonite, as a high-pressure mineral, should have grown partially synchronous with garnet
244 on a prograde path, whereas plagioclase is more likely to have formed during retrogression.
245 G11 therefore provides us with an opportunity to investigate the relative timing of garnet and
246 hence the origin of pseudomorphs from a microstructural perspective.

247 Inclusion trails in garnet vary from simple to sigmoidal to spiral-shaped but do not
248 curve more than about 90° from the center to the rim (Figs. 5a, b, c, g and 6). We used the *Fiji*
249 image-analysis software (Schindelin et al., 2012) to measure the spatial orientation of
250 relatively straight inclusion-trails or inclusion-trail segments visible in our tomographic scans
251 (Tiff image stacks). This was done by fitting the strike and pitch angles of these elements,
252 measured on 3 mutually orthogonal (virtual) sections, to great circles. The curvature axes of
253 inclusion-trails or 'FIA' were measured using the radial slicing technique detailed in Aerden &
254 Ruiz-Fuentes (2020) which is completely analogous to the thin-section based technique of
255 Hayward (1990) and Bell et al. (1995).

256 The X-ray scan of G11 revealed the existence of relatively large elongate crystals with
257 high X-ray attenuation (higher than garnet) and hence density, which in section were
258 identified as an Fe-rich opaques, partially or completely replaced by brown-reddish goethite
259 (Fig. 5d, h). Some of these opaques attain porphyroblast sizes and contain scarce inclusion
260 trails. Reflected-light imaging showed that the opaque phase is a mixture of ilmenite and
261 magnetite, the latter possibly replacing the former. The shape orientation of these crystals was
262 characterized by automatic calculation of best-fit ellipsoids using Fiji's *BoneJ* plugin (Doube
263 et al., 2010). Ellipsoid long-axes (X) strongly align with the macroscopic
264 mineral/stretching/intersection lineation, whereas the XY planes lie in the plane of the matrix
265 foliation.

266 Garnets with sigmoidal- or spiral-shaped inclusion trails in sample G11 were
267 measured both in the center and in the rims where they become strongly deflected or

268 truncated by younger inclusion trails. The porphyroblast-rim measurements tightly define a
269 steeply SW dipping plane, whereas porphyroblast-core foliations vary significantly from
270 steeply NW dipping to shallowly W-dipping. Intersection lines of core and rim planes
271 measured in the same porphyroblast agree well with the FIAs measured independent by
272 virtual radial-slicing. FIAs dip moderately west in the sample, and confirmed the average FIA
273 trend already deduced from the radial thin sections (Fig. 2b). The orientations measured for
274 simple (straight) inclusion trails coincide with the ones measured in the cores and rims of
275 sigmoidal and spiral-shaped trails, suggesting they represent both microfabrics and grew at
276 different times. Based on the above data we may confidently interpret the bimodal inclusion-
277 trail strikes in the rose diagram for G11 as reflecting the same two sets of inclusion trails with
278 an older NNW-SSW striking and a younger WNW-ESE striking set.

279 Lawsonite pseudomorphs in G11 also exhibit visible inclusion trails in the X-ray scans
280 (Fig. 5e, f, and h) although these are less finely spaced and well defined as in garnet. These
281 trails have a straight to weakly sigmoidal geometry oblique to the matrix foliation and
282 subparallel to inclusion trails in garnet-rim. This suggests lawsonite growth after garnet cores
283 but synchronous with garnet rims, consistent with previously reported large pseudomorphs
284 sometimes including garnet (e.g. Ballèvre et al., 2003). Significantly, the asymmetry or
285 curvature sense of inclusion trails in the pseudomorphs is opposite as in garnets when viewed
286 in a N-S vertical sections. This implies a component of top-to-the-S shearing during the
287 growth of porphyroblast cores, followed by top-to-the-N shearing when the garnet rims and
288 lawsonite developed. Interestingly, Philippon et al. (2009) proposed the same shear-sense
289 reversal (top-to-N140, then top-to-N350) from different sets of shear bands in the area of
290 Amer, but note that their interpretation is only compatible with the observed inclusion-trail
291 curvature senses if one accepts a 'non-rotational' origin.

292

293 7.2. Sample G12

294

295 G12 is a similar blueschist as G11 from the same outcrop but no lawsonite
296 pseudomorphs were found in it. The tomographic data for this sample reveals an early NNW-
297 SSE striking foliation preserved in porphyroblast cores and as simple inclusion trails,
298 overprinted by a steeply S-dipping foliation preserved in garnet rims. The garnet-rim foliation
299 is in turn deflected or truncated by a subhorizontal crenulation cleavage that causes
300 transposition in the matrix and constitutes the composite 'main foliation'. The same opaque
301 minerals as described in G11 are also present with the difference that now also occur as large

302 inclusions within garnets, often occupying a central position suggesting that the garnets
303 nucleated on those grains. Opaques in the matrix are strongly elongated NW-SE subparallel to
304 the strike of inclusion trails in the garnets.

305 The above data allow confident correlation of the different peaks in the strike rose
306 diagrams for G11 and G12 in Fig. 2b. These peaks correspond to (1) an early NE-SW striking
307 foliation preserved in the cores of spiral-shaped inclusion trails, (2) a younger NNW-SSE
308 striking foliation included in the cores of sigmoidal inclusion trails with variable dip angles,
309 and (3) a still younger ESE-WNW foliation preserved in garnet rims and in lawsonite
310 pseudomorphs. Note however that the average FIA trends determined for both samples are
311 quite different falsely suggesting they record different deformation histories. This difference
312 results from the variable dip angles of inclusion trails sharing the same strike and relatively
313 steep plunges of FIAs.

314

315 7.3. Sample G14

316

317 G14 is another blueschist sample from Amer that contains numerous relatively small
318 (1-2 mm) garnets with straight, sigmoidal or spiral-shaped inclusion-trails. The spiral patterns
319 exhibit significantly greater curvature (up to 180°; Fig. 4b) as in G11 and G12. Unfortunately,
320 only a few garnets had visible inclusion trails in the tomographic scan because of their very
321 fine grain size and profuse fracturing of garnets. A few inclusion-trail planes could be
322 measured plus 5 FIAs that plunge steeply in different directions (Fig. 7a).

323 The same elongate opaque crystals as found in G3, G11 and G12 are also present
324 aligned with the macroscopic stretching/mineral lineation. Their XY planes (normal to Z)
325 have variable dips but consistent N to NE strike parallel to that of most inclusion-trails (Fig.
326 2b). An interesting fold structures outlined by an epidote-rich layer was found whose axial
327 trace also trends NE-SW suggesting a genetic link with the inclusion trails further supported
328 by the available 3D data (Fig. 7a). E-W sections through the fold (Fig. 7c) show its refolding
329 with subhorizontal axial suggesting subvertical shortening and probably related to the
330 horizontal crenulation cleavage in G7 (Fig. 4a). In plan view the fold is transected by N-S
331 striking cleavage zones also outlined by irregularly folded quartz lenses (Fig. 7d).

332

333 7.4. Sample G3

334

335 G3 was collected close to Fort Nosterven on the east coast of the island, about 1 km south of
336 Plage du Trech. Garnets in this glaucophane-epidote schist have well developed straight and
337 sigmoidal inclusion trails whose strikes were measured in thin section. Unfortunately, the
338 trails were poorly visible in the tomographic scan. The few that could be measured dip steeply
339 NW, similar as the inclusion trails in garnet cores of samples G11 (Fig. 8a; compare with Fig.
340 6). A correlation is also likely with the average FIA determined in sample G7 (collected a bit
341 further north at Plage du Trech) and gently SSW plunging fold axes measured there by
342 Audren (1974, unpublished data; Fig. 8b). One individual garnet FIA defined by sigmoidal
343 inclusion trails could be constrained by virtual radial slicing. Inclusion-trails in the rim of this
344 porphyroblast are approximately subvertical with N120 strike and hence can be correlated
345 with inclusion trails in the garnet rims in G11 and G12.

346

347 **8. Interpreted deformation history**

348

349 The above microstructural data lead us to interpret a succession of 3 shortening
350 directions that produced 3 sets of steeply dipping inclusion trails associated with different
351 strike maxima. The preservation of their original orientations was possible due to non-
352 rotational behavior of porphyroblasts. These foliations could may have alternated with
353 subhorizontal ones related to intermitted gravitational collapse stages, but the predominantly
354 moderate to steep plunges of FIAs in the samples studied with X-ray tomography suggests
355 these events were in any case weak. Otherwise, predominantly subhorizontal FIA plunges
356 would be expected (cf. Bell et al., 2005; Aerden & Ruiz-Fuentes, 2020). The latest
357 subhorizontal cleavage however developed penetratively and caused extensive transposition
358 earlier steep fabrics and related upright folds. The growth of garnet rims and lawsonite
359 porphyroblasts was probably triggered by incipient development stages of this foliation (cf.
360 Bell & Hayward, 1991*) but would have ceased soon afterwards as the rocks were exhumed.

361 The earliest formed steep foliation with NE-SW strike preserved in G3, G11 and G14
362 corresponds to orthogonal SE-NW crustal shortening. This early foliation was reoriented and
363 modified in the matrix during the development of a younger N-S to NNE-SSW striking
364 foliation. Its intersection with the pre-existing NE-SW foliation explains the steeply dipping
365 FIA measured in G14. This event corresponded to ENE-WSW directed compression. A third
366 steeply foliation dipping steeply south with E-W to WNW-strike is preserved in garnet rims
367 and as simple inclusion trails in G11 and G12, as well as in lawsonite pseudomorphs of G11.
368 It was created during N-E to NNE-SSW compression close to peak-metamorphic conditions

369 as this is when lawsonite is likely to have formed (Ballèvre et al., 2003). The presence of this
370 foliation also in G3 and G14 is reflected in minor N100-N280 peaks in their strike rose
371 diagrams (Fig. 2b) and confirmed by the 3D data (Figs. 7a and 8a).

372 In view of the above interpreted polyphase evolution, we must now reconsider the
373 significance of predominantly anticlockwise curving inclusion trails in sections striking close
374 to the regional lineation being viewed towards the west. We were not able to determine the
375 ratio's of clockwise vs. anticlockwise ratio's associated with each of the 3 internal foliation
376 sets that have been distinguished. However, it is likely that the curvature sense of inclusion
377 trails in thin sections striking N330, N0, N30 and N60 is mainly determined by the oldest
378 (NE-striking) and youngest (E-W striking) internal sets as these that intersect those thin
379 section planes at a high angle. In contrast, the intermediate NNW-SSE striking inclusion trail
380 set should produce opposite curvature senses in the same thin sections and this might be the
381 reason why about 25% of all garnet porphyroblasts we counted curve in opposite direction as
382 the other 75%.

383 In summary, the oldest NE-SW striking inclusion trails may be linked to NW directed
384 subduction and SE directed thrusting. The polarity of the intermediate NNW-SSE striking
385 internal foliation remains undetermined. The dominant asymmetry of the youngest WNW-
386 ESE striking trails included in garnet rims of G11 and G12 and in lawsonite are consistent
387 with N-directed subduction.

388 The reversed curvature sense of inclusion-trails in the pseudomorphs of sample G11
389 indicates a change to top-to-the-N shearing on the penetrative subhorizontal crenulation
390 cleavage, which caused refolding and transposition all previous fabrics and structures. Shelley
391 and Bossière (2005) related this deformation to wholesale crustal thinning and exhumation.
392 However, considering that HP metamorphism of Ile de Groix rocks is Late-Devonian (360-
393 370Ma; Bosse et al., 2005) and that the Variscan orogeny continued until at least 300Ma, we
394 vertical shortening can also be considered in the context of a gravitationally spreading thrust
395 wedge with plate convergence and subduction continued below the wedge (cf. Bell &
396 Johnson, 1992 - their Figs 16 and 17).

397

398 **9. Correlation of microstructural- and field data**

399

400 In this section we review field data from previous workers and assess their relationship
401 with the new microstructural data. Cogné et al (1966) made numerous structural observations
402 and measurements all along the coast of the island and concluded 2 principle deformation

403 phases, apart from a third post-metamorphic phase that created E-W trending chevron-type
404 folds. Their first deformation was responsible for tight to isoclinal folds with strongly sheared
405 limbs associated with a stretching/mineral lineation. The average trend of these 'fundamental
406 folds' as they called them is N165 in the south east of the island, N-S in the east and changes
407 to NW-SE in the north-west. The second deformation phase caused refolding of the
408 'fundamental' folds associated with a steeply SW dipping crenulation cleavage trending N130-
409 140. Significantly, Cogné et al. (1966) noticed that mineral lineations defined by glaucophane
410 exhibit highly variable relationships with respect to fold axes, commonly being parallel to
411 them, but locally oblique and clearly predating the folding, or still elsewhere associated with
412 the younger refolding event. In this last case, 2 sets of glaucophane lineations were locally
413 observed oblique to each other (see their Fig. 12, p 70).

414 Boudier and Nicolas (1976) distinguished 4 deformation phases (D1-D4), the youngest
415 of which corresponds to the chevron-type structures of Cogné et al. (1966). D1 refers to the
416 mineral-lineation (L_1) which they interpreted to have been reoriented by N165 trending folds
417 (D2 and D3). At an outcrop studied in particular detail at Vallon du Lavoir (Fig. 2a), a N120
418 orientation maximum of L_1 was found (Fig. 9b) and interpreted as the original trend. This
419 opposes Cogné et al.'s (1966) interpretation of early N165 trending folds overprinted by
420 younger N130 ones, which is in better agreement with our microstructural data. An
421 unpublished sketch and corresponding orientation measurements by Claude Audren (1974;
422 redrafted in Fig. 9a), held at the 'Maison de la Reserve Naturelle Le Bail' on Ile de Groix,
423 further supports Cogné et al.'s (1966) and our interpretation by depicting refolding of a N165
424 lineation around a N120 trending fold axes.

425 Quinquis & Choukroune (1980) endorsed a late origin of the N120 trending folds
426 described by Cogné et al. (1966) but considered them post-metamorphic structures. In their
427 view, the N120 maximum defined by glaucophane at Vallon du Lavoir is only coincidental
428 and without regional tectonic significance. They predicted that on a regional scale the
429 lineation varies symmetrically between N120 and N200 due to sheath folding driven by top-
430 to-N340 progressive shearing. However, their interpretation was based principally on
431 analogue modeling of sheath folds (Cobbold & Quinquis, 1980) rather than on new structural
432 or microstructural data.

433 The above contradictory interpretations of the original orientation of L_1 and its timing
434 relative to folding are not surprising in view of the polyphase character of ' L_1 ' associated with
435 different foliations shown herein and recognized earlier by Cogné et al. (1966). Significantly,
436 the bimodal trends of L_1 seen in the field data Boudier & Nicolas (1976) collected across the

437 island (Fig. 9c, 10a) reflect the orientations of the 3 sets of inclusion trails distinguished in
438 this paper.

439

440 **10. Pouldu schists, Tréogat Formation and Central Armorican Domain samples**

441

442 The 'Pouldu schists' are greenschists of volcano-sedimentary origin (Triboulet, 1992)
443 locally hosting abundant plagioclase porphyroblasts. Inclusion trails in these crystals were
444 measured in 3 oriented samples (PO2, PO3, PO5) plus a fourth sample (AU-1) collected from
445 a similar greenschist unit known as the Tréogat Formation (Luck et al., 2002) cropping out in
446 the Baye d'Audièrne. Inclusion trails in these samples broadly strike E-W and are tentatively
447 correlated with the also E-W to WNW-ESE striking youngest internal foliation found in
448 garnets and lawsonite of Ile de Groix. Three of these samples contain a N060 striking
449 crenulation cleavage in the matrix, which is included in the rims of some porphyroblasts.

450 (NOTE TO EDITOR AND REVIEWERS: we have not received on time 4 N-S striking
451 vertical thin sections of these samples, in which we plan to determine the curvature sense of
452 inclusion trails. We hope to incorporate that extra data in a later version of this manuscript).

453 Two staurolite-kyanite schists from the Central Armorican Domain, located about 5km
454 NNE of Quimper, were also studied. The age of metamorphism in these 2 samples is roughly
455 constrained by granite ages to the period of 350-320Ma (Schulz et al., 1998), and hence post-
456 dates the high-pressure metamorphism (360-370Ma) of Ile de Groix. Inclusion trails in these
457 samples trend N060 and my correlate with the N060 crenulation cleavage observed in the
458 matrix of our greenschist samples.

459

460 **11. Discussion**

461

462 *11.1. Comparison with inclusion-trails in NW-Iberia*

463

464 Figure 10 compares our new inclusion-trail data from Brittany are compared with that
465 of Aerden (2004) for the Basal Unit of the allochthonous complexes of NW-Iberia. This unit
466 comprises orthogneises and high-pressure micaschists retrogressed in greenschist facies
467 representing the subducted margin of Gondwana (Arenas et al, 1995; Martínez-Catalán, 1996)
468 with a similar structural position as the Pouldu Schists, below an ophiolitic unit. Three sets of
469 inclusion trails striking E-W, NE-SW and NNW-SSE were distinguished in this unit
470 preserved in plagioclase and garnet porphyroblasts. The oldest of these with E-W trend were

471 related to the high-pressure event dated 370-360Ma (Van Calsteren et al., 1979; Santos
472 Zalduegui, et al. 1995; Abati et al., 2010; Li & Massonne, 2017), and hence synchronous with
473 the metamorphism of Ile de Groix (Bosse et al., 2005). The 2 younger internal foliations sets
474 formed at lower pressures and their age was only loosely constrained to pre-320 Ma.

475 To account for the Cretaceous anticlockwise rotation of Iberia during formation of the
476 Gulf of Biscay, the current northern margin Iberian is placed back against the conjugate
477 margin of south Brittany in Fig. 10 implying 20° clockwise back-rotation of Iberia. Although
478 this reconstruction produces a good match of inclusion-trail strikes in both massifs (Fig. 10b),
479 it poses question around the relative timing evidence of Aerden (2004). He interpreted that the
480 (presently) NNW-SSE striking inclusion trails in the Basal Unit (colored blue in Fig. 9)
481 postdate E-W striking ones (yellow), opposite to what has been concluded herein. As he
482 based this on only a sample with bimodal strikes of inclusion trails (sample 1. - Fig. 9a) we
483 believe there is scope for re-assessing the relative timing of Aerden (2004) using X-ray
484 tomography.

485 In contrast, the relative timing of NW-SE striking inclusion trails in NW Iberia
486 (marked with red lines in Fig. 9) was based on more abundant microstructural and field
487 criteria. Consequently, these microstructures cannot be correlated with much older NW-SE
488 trails in samples of Ile de Groix, but a correlation is possible with internal foliations in the 2
489 samples from the Central Armorican Domain, and the crenulation cleavages in the Pouldu
490 schists (Fig. 2c and d).

491 We checked the curvature sense of inclusion trails in Aerden's (2004) thin sections
492 associated with the W-E to NW-SE FIAs (marked yellow in Fig. 10a) this author determined
493 in 6 samples of the Basal-Unit. In samples 3-4, 10, 14 and 20, inclusion trails curve
494 anticlockwise viewing west. In samples 2 and 19 they curve clockwise. A larger number of
495 anticlockwise trails is as observed in Ile de Groix, but we realize that more samples need to be
496 studied before firm conclusions can be drawn regarding thrusting directions in NW Iberia.

497

498 *11.2. Origin of sheath folds*

499

500 Based on a study of quartz fabrics in 57 samples, Shelley and Bossière (1999)
501 concluded that many of the folds of Ile de Groix island nucleated with their axes subparallel
502 to the maximum stretching direction (X) instead of parallel to Y and subsequently rotating
503 towards X by progressive shearing (cf. Quinquis and Choukroune, 1981). Both models
504 assume a single progressive deformation with subhorizontal flow plane that ignores the

505 polyphase character of the main foliation and lineation shown herein. This complexity places
506 the significance of fold-axes parallel stretching lineations and the origin of non-cylindrical
507 folds in a quite different light. We interpret these as having formed by vertical flattening
508 superposed on folds with steeply dipping axial planes and variably plunging fold-axes (Fig.
509 10). Depending on the original geometry of precursor folds, new folds nucleated with straight
510 axes parallel to X or with strong curvature.

511

512 **12. Conclusion**

513

514 (1) The blueschist-eclogite facies rocks of Ile de Groix experienced 4 successive
515 tectonic events potentially reflected in a also complex PT path (Schulz et al., 2001).
516 Corresponding fabrics are preserved as inclusion trails that maintained their original
517 orientations due to limited or no rotation of porphyroblasts during ductile deformation.

518 (2) In specific orientations and dominant curvature sense of inclusion trails allow the
519 following reconstruction. (Stage-I) Early NW-directed subduction of Gondwana. (Stage-2) E-
520 W crustal shortening with unconstrained subduction polarity, but probably to westward given
521 the preceding subduction direction. (Stage III) Northward subduction until peak metamorphic
522 conditions were reached. (Stage IV) Exhumation associated with vertical shortening and a
523 component of top-to-the-north shearing indicated by the asymmetry of inclusion trails in
524 lawsonite pseudomorphs as well as late shear bands (Philippon et al, 2009). A subhorizontal
525 crenulation cleavage associated with this event transposes all earlier fabrics. Inclusion-trails
526 studied in 4 additional greenschist samples from the lower-grade footwall of the Groix
527 ophiolite strike E-W, parallel to the youngest set of inclusion trails in the blueschist samples
528 from the island.

529 (3) The curvature sense of sigmoidal and spiral-shaped inclusion trails indicates top-
530 to-the south thrusting which agrees with regional-geological evidence only when a 'non-
531 rotational' original of these microstructures is accepted. The traditional 'rotational'
532 interpretation implied an opposite and shear sense conflicting with the regional tectono-
533 metamorphic structure of southern Brittany.

534 (4) The strikes of 3 sets of inclusion trails documented herein can be tentatively
535 correlated with 3 similar sets reported earlier in NW-Iberia (Aerden, 2004). The coincidence
536 of microstructural directions between both regions is maximized assuming only 20° rotation
537 of Iberia during opening of the Gulf of Biscay, significantly less as ca. 35° rotation generally
538 concluded from paleomagnetic data (Gong et al., 2009).

539 (5) Fold axes parallel to stretching lineations and rare sheath folds reported on Groix
540 did not form by progressive uni-direction shearing, but by vertical shortening and horizontal
541 shearing superposed on steeply dipping pre-existing foliations and folds with variable plunges.
542

543 **Acknowledgements**

544

545 The first author wishes to thank José Ramón Martínez Catalán for his support and
546 friendship ever since he started a postdoc in Salamanca in 1996. We thank Michel Ballèvre
547 for helping us obtain permission to collect samples on Ile de Groix and for suggesting we
548 sample the Pouldu schists as well. Ile de Groix national-park guide Catherine Robert (and her
549 dog) provided Aerden with helpful information and pleasant company during field work.
550 Bernhardt Schulz is thanked for clarifying various aspects about the petrology of the studied
551 rocks. This research was partially funded by a travel grant from Junta de Andalucía to Aerden
552 in 2006. ...Reviewers, Editors.....

716

717 FIGURE CAPTION

718

719 Fig. 1. Simplified geological maps of southern Brittany and NW-Iberia showing the location
720 of ophiolite outcrops and samples studied herein and by Aerden (2004) in NW Iberia.

721

722 Fig. 2. (a) Stretching lineation pattern of Ile de Groix and sample locations. (b) Moving-
723 average rose diagrams for inclusion-trail strikes. Encircled pie-cake symbols represent
724 average FIA trends in samples determined from radial thin sections and the FIA plunge
725 direction. Also the sense of inclusion-trail curvature is indicated viewing down the FIA
726 plunge (anticlockwise in G14, G12, G11; clockwise in G19 and G7). (c) Data for samples
727 from the Pouldu schistes (PO2, 3, 5) and the Tréogat formation (AU1). Arrows represent
728 crenulation axes in the matrix. (d) Data for 2 staurolite-kyanite schists from the Central
729 Armorican Domain. The 4 inclusion-trail sets proposed in this paper are marked with magenta,
730 blue, yellow and red trend lines, from the oldest to the youngest set.

731

732 Fig. 3. (a) Rotational interpretation of sigmoidal and spiral-shaped inclusion trails from Ile de
733 Groix and the range (purple) of inclusion trail strikes predicted by this model. (b) 'Non-
734 rotational' interpretation of the same inclusion trails according to Bell et al (1986) and Bell &
735 Johnson (1989) consistent with orthogonal truncations and inclusion trails striking subparallel
736 to stretching lineations, crenulation- and fold-axes. (c) Strikes measured in all 10 samples
737 from Groix agree better with the non-rotational model.

738

739 Fig. 4. (a) Sketches of well developed 'rotational' inclusion trails in oriented vertical thin
740 sections of samples G7 and G14 showing vertical and horizontal alignment of internal
741 truncations (purple lines). (b) Rose diagram plotting the orientations of all individual dashes
742 that make up the dashed lines representing inclusion trails in the drawings measured with the
743 image/analysis program *Fiji*. The plot demonstrates bimodal orientations of the inclusion
744 trails related to the orthogonal sets of truncations.

745

746 Fig. 5. All photographs of G11. (a and b) Garnet porphyroblast (parallel and crossed polars)
747 with sigmoidal trails in a N-S striking vertical section. Barb of N-arrow points upward. Note
748 top-to-the south shear sense suggested by asymmetric strain shadows, inconsistent with
749 porphyroblast rotation. (c) Garnet with spiral-shaped truncation inclusion trails a
750 porphyroblast core and rim zone. (d) Opaque mineral with elongate shape replaced by
751 Goethite. (e and f). Lawsonite pseudomorphs (parallel and crossed polars) showing weakly
752 sigmoidal inclusion trails oblique to the matrix foliation. (g) Tomographic image of a strongly
753 curved inclusion trails garnet in G12. (h) Tomographic image of an elongate lawsonite
754 pseudomorph, garnet (Gt) and opaque large opaque crystal.

755

756 Fig. 6. Stereoplots (equal angle, lower hemisphere) of internal foliations and FIAs measured
757 in garnet and lawsonite pseudomorphs in samples G11 and G12. Also shown are 2 contoured
758 stereoplots plotting maximum and minimum elongation directions of relatively large opaques
759 present in the matrix of G11 and G12. See legend. The data can be matched to different sets
760 of inclusion trails drawn with corresponding colors in garnets and a representative lawsonite
761 pseudomorphs. The Mn concentration map is for one of the porphyroblasts with truncational
762 inclusion trails.

763

764 Fig. 7. Tomographic images and microstructural data for sample G14. (a) Stereoplot of
765 internal foliation planes, FIAs (grey boxes), long- and short axes of opaque minerals, and the
766 axial plane of cm-scale folds. (b and c) Map- and cross-section views of a fold outlined by an
767 epidote-rich layer. Its axial trace trends NNE-SSW oblique to N-S trending cross-cutting
768 cleavage zones also visible in (d). The cross-section shows refolding with subhorizontal axial
769 planes suggesting a component of vertical flattening associated with the main cleavage
770 (compare with Fig. 4a, b).

771

772 Fig. 8. (a) 3D microstructural data for sample G3. See legend for explanation. (b) Field data
773 collected by Claude Audren about 1 km north of at the location of sample G7 (Plage du
774 Trech) and the average FIA trend we determined for this sample from radial thin sections
775 (magenta pie-cake segment). The FIA trend coincides with fold axes measured in the field.
776 Note that this conflicts with models assuming sheath folding and porphyroblast rotation.
777 Stretching lineations vary greatly reflecting the polyphase origin of this fabric.

778

779 Fig. 9. (a) Structural data collected by C. Audren and a corresponding sketch of isoclinal folds
780 he drew at Vallon de Kérigant (location marked in Fig. 2a). The sketch is accurately redrafted
781 and data re-plotted in lower hemisphere, equal angle projection (Audren used upper
782 hemisphere, equal angle). Refolding of a N165 trending lineation around the nose of a N120
783 trending fold is demonstrated. (b) Lineations (L1) measured nearby (a) by Boudier & Nicolas
784 (1976) at Vallon du Lavoir showing a N120 trend maximum of L1 (yellow lines) oblique to
785 B2 fold axes in the same outcrop (blue lines). (c) Structural data from the same authors for the
786 entire island. Note the bimodal pattern of L1. Magenta, blue and yellow trend lines show how
787 this data can be correlated with the 3 sets of inclusion trails given the same colors in Figs 2, 5,
788 7 and 8.

789

790 Fig. 10. (a) Inclusion trails-strikes in the newly studied rocks and those measured by Aerden
791 (2004) in 18 samples from the Basal Unit of NW-Iberia. The microstructures are correlated as
792 4 age sets marked with magenta, blue, yellow and red trend bars (from older to younger sets).
793 Field data from Boudier and Nicolas (1976) and that of Engels (1972) and van Zuuren (1969)
794 also show a good match. (b) Rose diagrams plotting inclusion-trail directions marked blue
795 and yellow for different amounts of Iberia back-rotation. The directions line up best with 20°
796 back-rotation, which is the current angle between the North-Iberia margin and that of southern
797 Brittany.

798

799 Fig. 11. Conceptual models showing how vertical shortening and horizontal stretching can
800 produce highly variable fold geometries depending on the original orientations of folded
801 planes or pre-existing folds. Note how strongly curved fold axes can form without need of
802 extremely large shears trains. Adding a (horizontal) shearing component in the direction of X
803 and/or Y can be expected to further modify the fold-interference patterns.tt

Code/Data availability

All data are presented in the paper itself. No supplement is needed.

Author contributions

Aerden did the field work, conducted most of the research and wrote the manuscript

Sayab made and studied part of the thin sections.

Forde participated in part of the field work.

Ruiz-Fuentes studied part of the thin sections.
