7 **Abstract.** To discover or delineate mineral deposits and other geological features such as faults and lithological boundaries in
8 their host rocks, seismic methods are preferred for imaging the targets at great depth. One major goal for seismic methods is
9 to produce a reliable image of the reflectors underground given the typical discontinuous geology in crystalline environment
10 with low signal-to-noise ratio. In this study, we investigate the usefulness of reverse time migration (RTM) imaging algorithm
11 in hardrock environment by applying it to a 2D dataset, which was acquired in the Ludvika mining area of central Sweden.
12 We provide a how-to solution for applications of RTM in future and similar datasets. When using the RTM imaging technique
13 properly, it is possible to obtain high-fidelity seismic images of the subsurface. Due to good amplitude preservation in the
14 RTM image, the imaged reflectors provide indications to infer their geological origin. In order to obtain the reliable RTM
15 image, we performed a detailed data pre-processing flow to deal with random noise, near-surface effects and irregular receiver
16 and source spacing which are possible to downgrade the final image if ignored. Exemplified with the Ludvika data, the resultant
17 RTM image not only delineates the iron-oxide deposits down to 1200 m depth as shown from previous studies, but also
18 provides a better inferred ending of sheet-like mineralization. Additionally, the RTM image provides much-improved
19 reflection of the dike and crosscutting features relative to the mineralized sheets when compared to the images produced by
20 Kirchhoff migration in the previous studies. Two of the imaged crosscutting features are considered to be crucial when
21 interpreting large-scale geological structures at the site and the likely disappearance of mineralization at depth. Using a field
22 dataset acquired in hardrock environment, we demonstrate the usefulness of RTM imaging workflows for deep targeting
23 mineral deposits.

24 1 Introduction

25 Seismic methods are favourable for deep targeting in mineral exploration, because of their ability to image targets at great
26 depth (>500 m). (e.g., Malehmir et al., 2012b). Compared to other geophysical methods (e.g., gravity, magnetic and/or
27 electromagnetic), the seismic methods investigate the properties (i.e., impedance) of the subsurface in an elastic (or acoustic)-

1 wave-equation-based way during seismic data processing and imaging (Eaton et al., 2003). Generally speaking, due to the less
2 attenuation effects of the seismic waves as a function of depth compared to EM methods, they tend to hold better resolution at
3 depth than EM methods although they do have sensitivity to different properties. Seismic methods may provide an image of
4 the targets with high resolution at depth when the survey is designed to record the signal reflected from the targets directly
5 below the survey area/line. In such a seismic survey, a seismic source (e.g., a sudden impact produced by a weight drop) should
6 be employed to generate seismic wavefields with sufficient energy and frequency bandwidth (e.g., Brodic et al., 2019; Pertuz
7 et al., 2020). The adequate energy ensures the wavefields propagate down to the depth of targets and travel back to the surface.
8 A reasonable frequency bandwidth of the wavefields contributes to a suitable resolution image of the target area (ten Kroode
9 et al., 2013).

10

11 Although seismic methods have been well established and proven successful to delineate complex geological structures in
12 sedimentary basins for hydrocarbon exploration (e.g., Sheriff and Geldart, 1995), their applications to delineate deep targets
13 for mineral exploration are still relatively limited (Malehmir et al., 2012a and references therein; Buske et al., 2015; Malehmir
14 et al., 2020a and references therein). There are several reasons for this hurdle. First, exploring deep-seated deposits is
15 economically costlier compared to that at the shallow subsurface (<500 m). Second, the strong scattered waves due to abundant
16 small heterogeneities and complex structures in hardrock environment (Cheraghi et al., 2013; Bellefleur et al., 2018; Bräunig
17 et al., 2020), will contaminate the reflections from targets of mineralization and cause difficulties to image the targets.
18 However, exploration of mineral deposits (especially the deep ones) using seismic methods has become more appreciated by
19 both the industry and the academia (Malehmir et al., 2020 and references therein). Two main factors can account for this
20 success. First, seismic data acquisition and processing have become cheaper and more affordable by exploration companies.
21 Second, seismic imaging techniques have become computationally feasible and well developed to handle complex subsurface
22 structures (O'Brien, 1983; Bednar, 2005). Regardless, the potential of prestack depth imaging algorithms (e.g., Kirchhoff and
23 RTM) in imaging hardrock environment still need to be explored with effort and case studies. Though Kirchhoff prestack
24 depth imaging algorithms have been attempted with a few good illustrating results (Bellefleur et al., 2018; Bräunig et al.,
25 2020), direct targeting deep mineral deposits using the RTM methods has rarely been applied to mineral exploration data
26 examples.

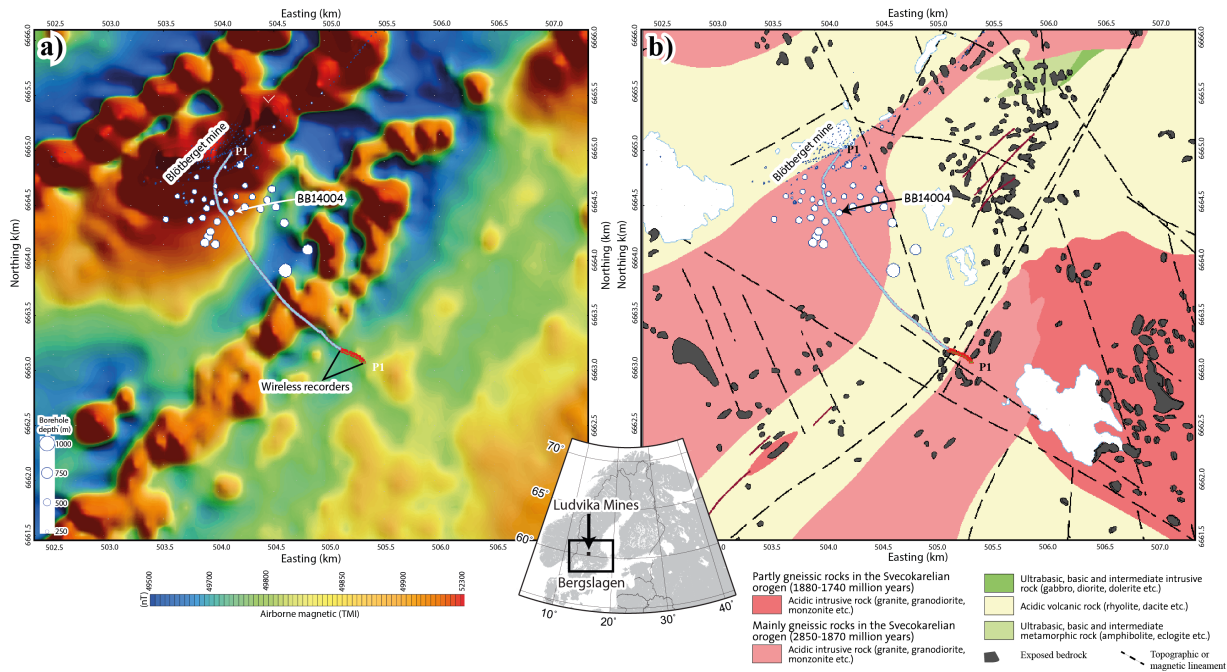

27 In this study, our main goal is to demonstrate the usefulness of the seismic methods in deep-targeting of iron-oxide deposits
28 by applying the RTM imaging algorithm (Baysal et al., 1983; Zhou et al., 2018) to a field dataset. The dataset was acquired in
29 the Ludvika mining area (Blötberget), in central Sweden in 2016. Although there have been several studies (Balestrini et al.,
30 2020; Bräunig et al., 2020; Markovic et al., 2020; Maries et al., 2020) on this 2D dataset, RTM as a method honouring the
31 two-way wave equation has not been applied to it yet. In this work, we show that advanced imaging methods such as RTM
32 can produce images to aid better understanding of the deposits and other geological features in the host rocks.

1 This paper covers three key parts. First, we provide a brief review of the study area. Second, we apply the RTM imaging
2 method to the dataset after a comprehensive data pre-processing. Third, we study and interpret the resultant RTM image by
3 integrating with other geological and geophysical datasets.

4 **2 Study area**

5 The Ludvika mining area belongs to the Paleoproterozoic Bergslagen mineral district (Figure 1), which has a long history of
6 iron ore mining (Magnusson, 1970). The ore deposits are primarily magnetite and hematite as sheet-like bodies. At the
7 Blötberget site where this study focuses, the sheet-like mineral horizons show a moderate dip (around $30 - 45^\circ$) towards the
8 south-southwest based on the core logging data (Maries et al., 2017) and a recent 3D reflection survey in the area (Malehmir
9 et al., 2020b).

10 Due to the dropping steel prices on the global market, the mining operations had to be stopped in 1979. However, because of
11 recent feasibility studies and more available resources, as well as the growing iron ore market, Nordic Iron Ore (NIO) plans to
12 reopen the mine and exploit the deposits at depth level of 400-420 m in the near future. Relevant to this study is the work by
13 Maries et al. (2017) on a downhole logging study of the iron-oxide deposits at the site. As shown in the logging data, the strong
14 density contrast between the iron-oxide deposits ($\sim 4500 \text{ kg m}^{-3}$) and their igneous host rocks ($\sim 2500 \text{ kg m}^{-3}$) should produce
15 a strong impedance contrast as a good target for the seismic methods. However, the resistivity of the deposits is not as strong
16 as normally expected for base metals (it is only on the order of 1000 ohm.m) and very similar to that of the host rocks (around
17 3000-5000 ohm.m) to make the resistivity-based methods (such as EM) suitable for depth delineation of deposits.

2 **Figure 1.** (a) Total-field aeromagnetic and (b) geological maps of Blötberget within the Ludvika Mines of Bergslagen mineral district in
 3 central Sweden. 2D seismic survey (blue line) and borehole BB14004 are used in this study. Magnetic data were provided by the
 4 Geological Survey of Sweden.

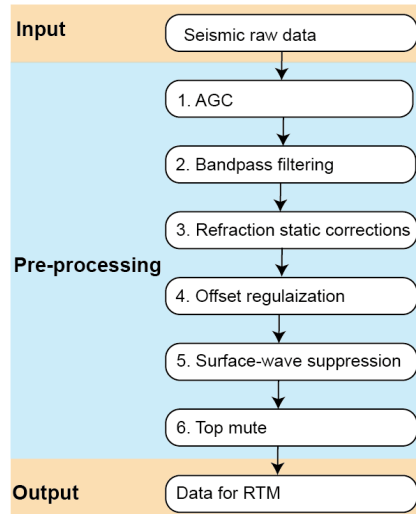

5 3 RTM imaging on the Blötberget dataset

6 3.1 Review of the seismic data acquisition

7 The seismic survey was conducted along a 2D profile in 2016 (e.g., Markovic et al., 2020) following a feasibility study of a
 8 seismic landstreamer survey (Malehmir et al., 2017). In order to better image the deposits, the seismic profile was designed to
 9 run approximately perpendicular to the strike of the known mineralized sheets. In the survey, 451 receivers were deployed
 10 (Figure 1) of which 427 were cable-connected geophones (blue line) and 24 were wireless recorders (red line) deployed at the
 11 southern end of the profile. A 10-Hz spike-type geophone was used as the sensor. The cabled receivers were deployed at every
 12 5 m approximately while the wireless recorders at every 10 m approximately. The source used was a 500-kg Bobcat-mounted
 13 drophammer. The source locations were collocated with the receiver locations. The sampling rate was set as 1 ms and recording
 14 time to 2 s. To avoid violating the 2D assumption of the subsurface below the seismic profile, we only use 369 receivers and
 15 sources that form a rather straight line in this study. The remaining 82 receivers and sources are not used due to the fact that
 16 they make a strong bend towards the northern-west end of the profile. Details of the survey can be found in Markovic et al.
 17 (2020) and Maries et al. (2020).

1 3.2 Data Pre-processing

2 The aim of data pre-processing is to strengthen the reflected events in terms of amplitudes and continuity. For the pre-
3 processing of the seismic data, we designed a 6-step workflow as shown in Figure 2.

4

5 **Figure 2.** The six-step data pre-processing workflow for the RTM imaging. In this study, offset regularization and surface-wave suppression
6 had the most significant roles.

7

8 **Step 1.** We applied automatic gain control (AGC) (e.g., Yilmaz, 2001) to balance the amplitudes at different offsets and
9 different arrival times. The amplitudes of the raw data are more balanced after AGC (Figure 3a). This step was necessary to
10 reduce the strong amplitude of the surface-waves relative to the weak reflection signals.

11

12 **Step 2.** We used a bandpass filter (10-35-150-200 Hz) to maintain data in this frequency band based on the analysis of the
13 frequency band in the first breaks (Figure 3b).

14 **Step 3.** We performed surface-consistent refraction static corrections to compensate for the near surface effects due to the
15 different surface topography and the low-velocity glacial covers. The irregularity in time of the first arrivals is mitigated after
16 the refraction static corrections (Figure 3c).

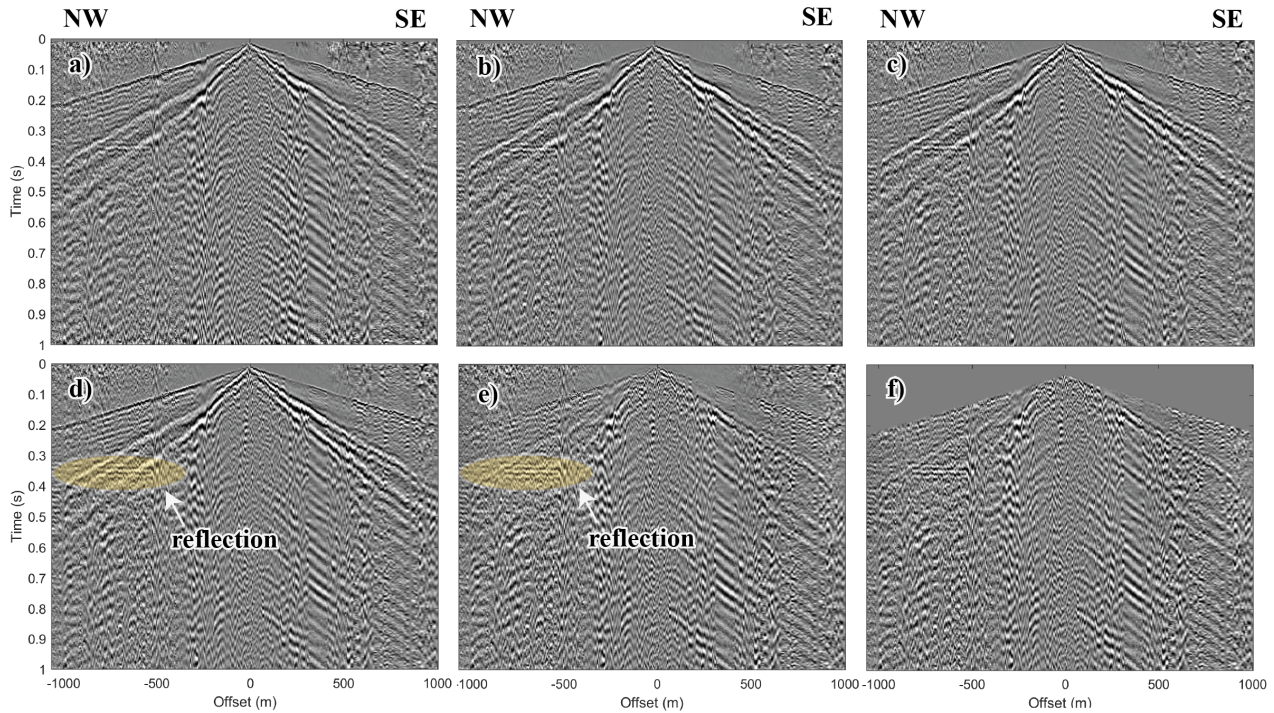

17 **Step 4.** We practiced offset regularization of the dataset along a 1D smooth-curved line and obtain a regularized dataset (Figure
18 3d). The original locations of sources and receivers (Figure 4a) were projected onto the 1D curve which was defined by a
19 polynomial of degree 3 (Figure 4b). Based on the projected receiver locations (Figure 4c), we regularized the receiver spacing
20 to a constant interval (i.e., 5 m) along the 1D curve (Figure 4d). The seismic traces at those regularized receiver locations were

1 obtained by a cubic interpolation using the traces at the projected receiver locations. Similarly, we regularized the source
2 locations along the 1D curve and obtained the seismic traces at every 5 m by a cubic interpolation which was performed in the
3 common receiver domain. After data regularization, we acquired a more even fold coverage required for RTM imaging. As a
4 result, the total number of shot points (or receiver points) was regularized to 415 from the original 369. Such even fold coverage
5 should contribute to an amplitude-balanced image, although one needs to use and inspect the interpolated seismic traces with
6 care.

7 **Step 5.** We suppressed the surface-waves (Figure 3e) using the curvelet filtering method (Candès et al., 2006) on the
8 regularized dataset. The geometrical difference of surface waves (almost linear events) and reflections (non-linear events)
9 provides a feasibility to separate them using curvelet filtering. After removing the strong surface-waves with large amplitudes,
10 the relative weaker reflection events show up clearly in the dataset. In this shown shot gather, the obvious reflection signal
11 (yellow ellipse in Figure 3e) has a small moveout across offsets due to the specific source location relative to the dipping
12 mineralization sheets.

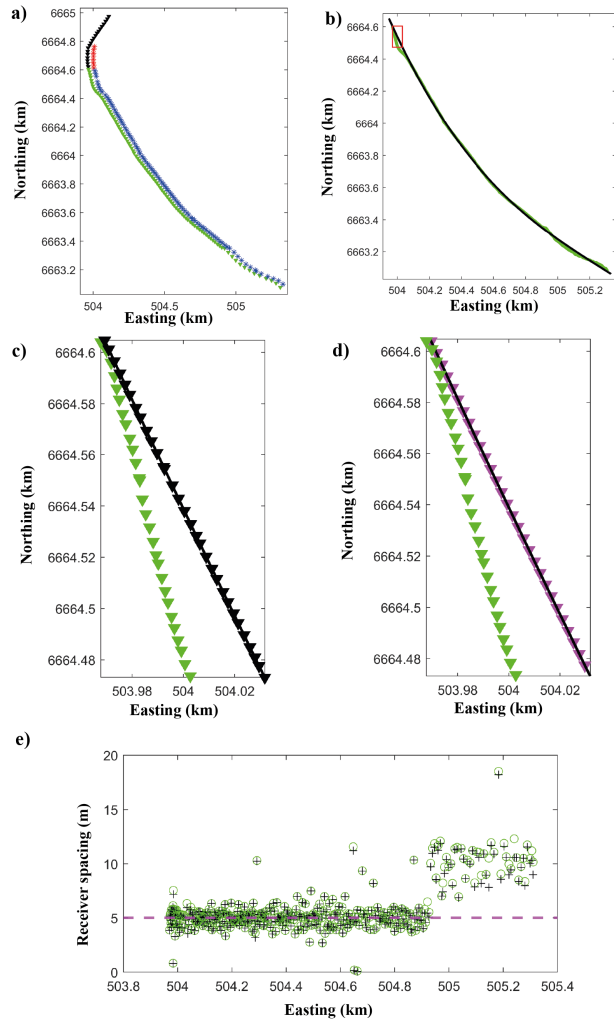

13 **Step 6.** We muted the direct arrivals and the ambient noise above the first breaks (Figure 3f) to reduce artefacts in the final
14 seismic section.

15

16

17 **Figure 3.** (a) Example raw shot gather after AGC application (Step 1). (b) After bandpass filtering (Step 2). (c) After refraction static
18 corrections (Step 3). (d) After data regularization (Step 4). (e) After surface-wave suppression (Step 5) and (f) after top muting (Step 6).
19 The yellow ellipses mark a clear reflection, which we interpret to be from the iron-oxide deposits.

1

2 **Figure 4.** a) Original source (blue and red stars) and receiver (green and black triangles) locations. The blue sources and the green
 3 receivers were selected for RTM imaging. b) The 1D smooth-curved line (black) based on a line fitting method using the positions of
 4 green receivers. c) The receivers (black triangles) projected along the 1D curve from their original locations (green triangles), zoomed in
 5 the red triangle in Figure 4b. d) The receivers (magenta triangles) regularized along the 1D curve from the projected receivers (black
 6 triangles) in Figure 4c. e) The spacing of receivers in their original locations (green circles), their projected locations (black crosses), and
 7 regularized locations (magenta dashed line).

8

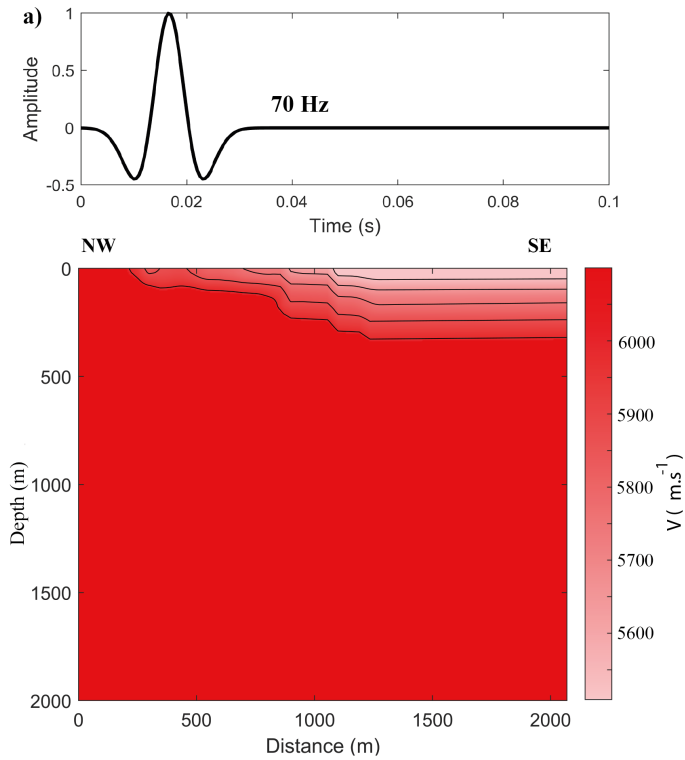

9 Note that we only used a bandpass filter to suppress parts of the noise. When forming an RTM image using the field data in the
 10 next section, the random noise in the data tends to be cancelled because of the cross-correlation imaging condition.

1 3.3 RTM imaging

2 The RTM imaging algorithm requires three ingredients (1) a source wavelet, (2) a shot gather, and (3) a smooth but reasonable
3 velocity model. Using the source wavelet and the migration velocity model, one can then forward propagate wavefields from
4 the source side. Using the shot gather and the migration velocity model, the backward-propagating wavefields from the receiver
5 side can then be modelled. Cross-correlation between the forward-propagating wavefields and the backward-propagating
6 wavefields forms a partial RTM image from a single shot gather. During the cross-correlation, an illumination compensation
7 using source-side wavefields is done to balance the amplitudes in the seismic section (e.g., Valenciano and Biondi, 2003).
8 Such a deconvolution imaging condition (Claerbout, 1971) removes the source wavelet approximately and hence improves the
9 resolution of the image. The final RTM section is obtained by summing all the partial RTM images of all the shot gathers.

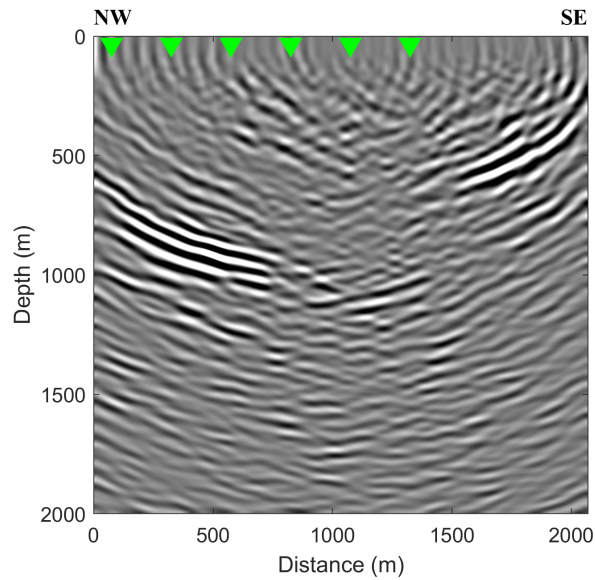

10 For the Blötberget seismic dataset, we used a staggered finite-difference modelling method (2nd order in time, 4th order in
11 space) to realize the RTM. The source signal was chosen to be a Ricker wavelet (Figure 5a) with a peak frequency of 70 Hz
12 and with a time step of $dt = 5 * 10^{-4}$ s. The dt used in RTM is half of the sampling rate in the data. Hence, our data was up-
13 sampled to dt by a linear interpolation before it was back propagated. The 2D migration velocity consists of grids (Figure 5b)
14 of 401 (vertical) by 415 (horizontal). The grid interval was set to 5 m along both directions ($dx = dz = 5$ m). To obtain a good
15 migration velocity model using this dataset, we performed the semblance velocity analysis (e.g., Zhou, 2014). In doing this,
16 the reflected signal from the deposits was the main constraint. Thus, the velocity above the deposits were well constrained
17 while the other areas are less. To mitigate the numerical artefacts from the boundaries of the velocity model, we added the
18 perfectly matched layers (PML) (e.g., Komatitsch and Martin, 2007) on the four edges of the velocity model. Each PML has
19 a thickness of 50 grid points. The wavefield modelling had no free-surface effects due to the implemented PML.

20 We ran the RTM for all the 415 shot gathers to obtain 415 partial images. Then, we applied a Gaussian smoothing filter to
21 suppress noise with small wavelengths ($\lambda < \sim 10$ m, i.e., 2-grid size) in the partial images. Summing the smoothed 415 partial
22 images, we obtained the final RTM image (Figure 6). Using the dominant frequency (70 Hz) in the field data and the migration
23 velocity (~ 6000 m/s) at depth, we estimated that the vertical resolution based on major wavelength as 100 m approximately.

1

2 **Figure 5** (a) Ricker wavelet (70 Hz) was chosen as the source wavelet, which generates forward propagating wavefields. (b) Migration
 3 velocity model used for the forward and backward propagations. The black lines are contour lines of the velocity values.

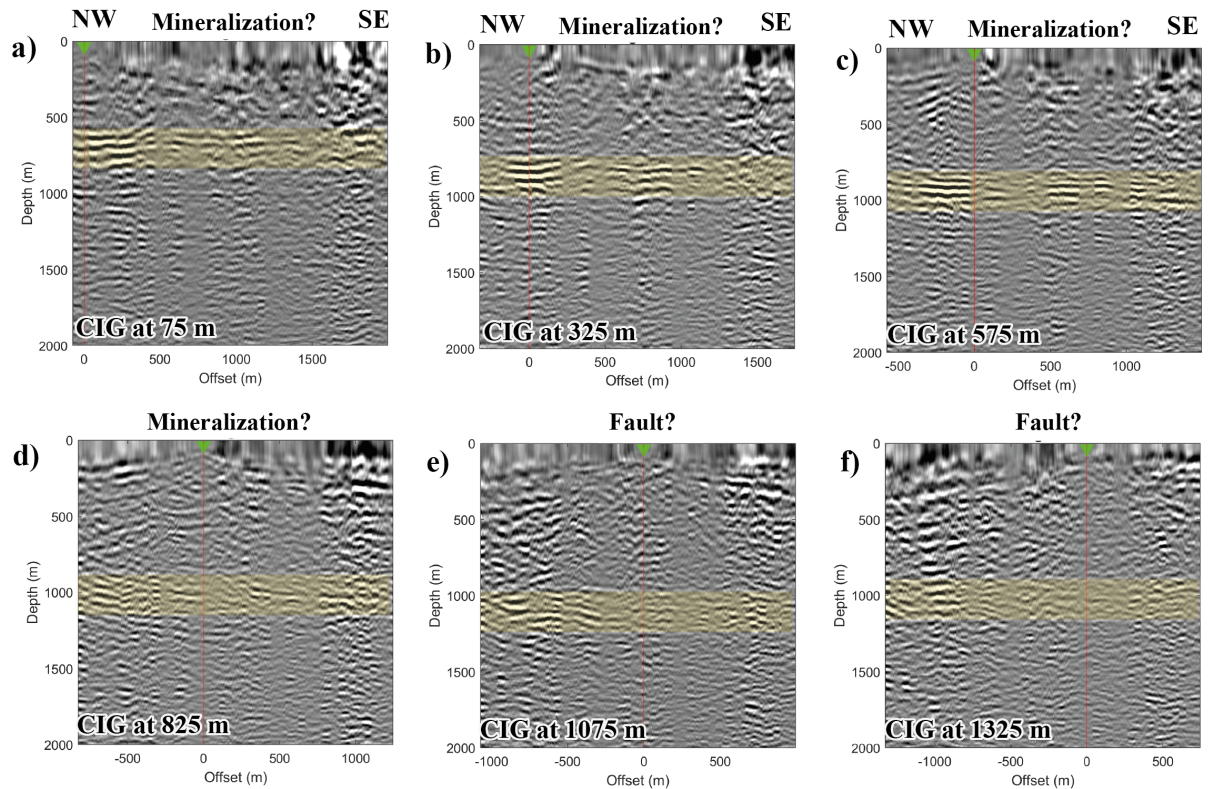

4

5 **Figure 6.** Final RTM section of the Blötberget dataset. The green triangles are where common image gathers (CIG) are shown later in the
 6 article.

1 **4 RTM results, their interpretations and comparisons**

2 Compared to the previous studies (Balestrini et al., 2020; Bräunig et al., 2020; Maries et al., 2020; Markovic et al., 2020) using
3 the same dataset, the RTM image (Figure 6) is much more promising in terms of imaging the crosscutting features and rock
4 contacts. We validated the trustworthiness of the imaged reflectors in the RTM image in two ways. First, we analysed six
5 common image gathers (CIG) (e.g., Yan and Xie, 2011) from the image. Second, we integrated the results with other available
6 geological and geophysical data to verify our interpretation of the reflectors in the section.

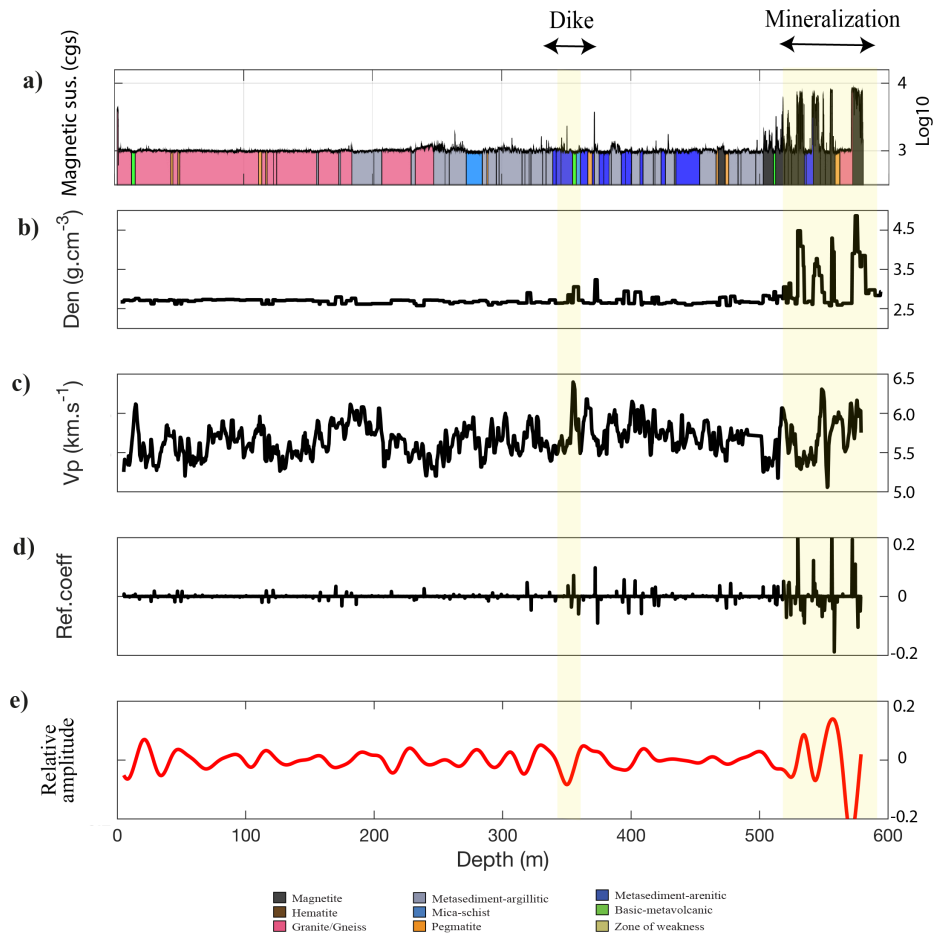

7 For a trace in the final image (Figure 6) at a specific spatial location (75, 325, 575, 825, 1075, and 1325 m distances along the
8 profile), its corresponding common image gather (CIG) was formed by extracting the seismic traces from different partial
9 images at the same spatial location. In our case, the CIG was composed of seismic traces extracted at those specific image
10 locations from 415 single-shot partial images. In a single CIG gather, the traces were indexed by the offset between a source
11 location and its specific CIG location in the RTM image. The flatness of continuous events in the CIG provided a qualitative
12 evaluation of the fidelity of imaged reflectors. We extracted six CIGs from the RTM image (Figure 6) at 75, 325, 575, 825,
13 1075, and 1325 m (Figure 7). In the CIGs, the events reflected from the iron-oxide deposits are quite continuous and flat
14 (Figure 7a-d) from zero offset to the far offset (~ 900 m), while events reflected from the inferred faults (Markovic et al., 2020)
15 do not show continuity across the whole section (Figure 7e & 6f). The less continuous flattened events in the CIG
16 corresponding to the inferred fault planes are likely due to the inaccuracy of the velocity model in the area of the inferred
17 faults.

1

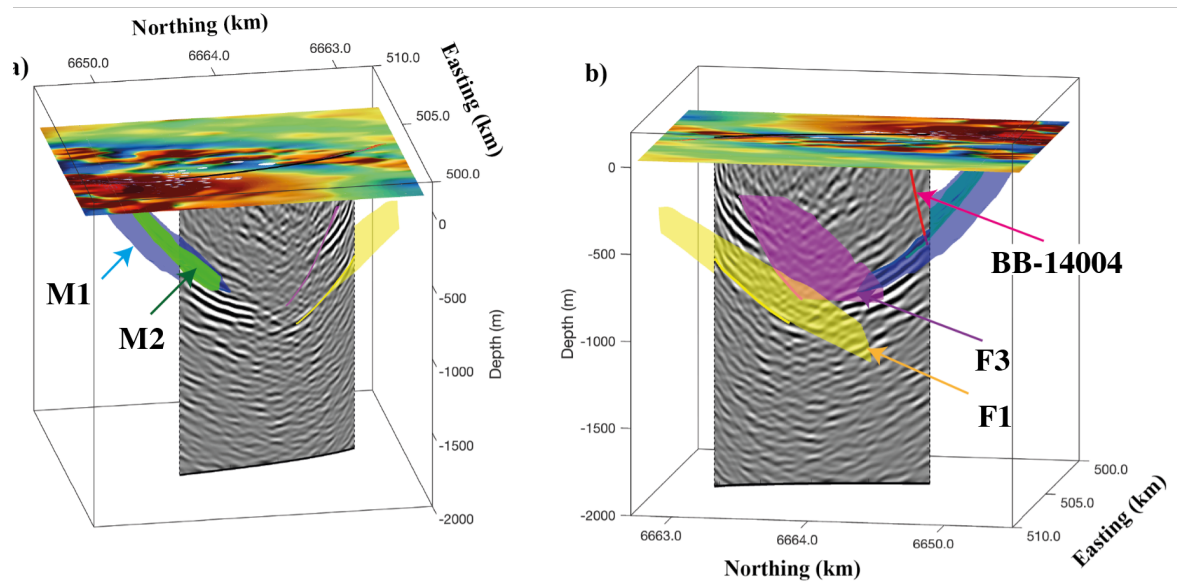

2 **Figure 7.** Six CIG gathers (a) 75 m, (b) 325 m, (c) 575 m, (d) 825 m, I 1075 m and (f) 1325 m distances along the RTM section extracted
 3 to present the quality of the RTM section (see Figure 5). The green receiver in each CIG collocates with their CIG positions in the original
 4 image. The yellow boxes highlight where the flat events are present.

5 The CIGs only show the trustworthiness of the final seismic image in an image-wise sense. However, one should integrate
 6 these results with other geological and/or geophysical data to assist the interpretation of the seismic image. In our study area,
 7 four other datasets are available for this purpose. First, we have an existing 3D ore block model from boreholes. Second, two
 8 inferred 3D fault planes have recently been imaged and picked from the recent 3D survey (Malehmir et al., 2020b). Third, one
 9 borehole (BB-14004) near the seismic acquisition line has the natural gamma, core logging, density and sonic logging data
 10 (Figure 8) (Maries et al., 2017). Using the density data and P-wave sonic data, we calculated their reflection coefficients
 11 (Figure 8d) along the wellbore trajectories. Convolving the calculated reflection coefficients (Figure 8d) with a 70-Hz Ricker
 12 wavelet, we obtained a synthetic seismic trace along the wellbore trajectory (Figure 8e). Fourth, there is a high-resolution (200
 13 m flight spacing) aeromagnetic data (Figure 9) available in this study area. The calculated magnetic anomaly data from the
 14 aeromagnetic data were used as well for the interpretation. Treating the RTM image as a dataset, we have 5 datasets in total.
 15 Assembling these 5 different datasets in 3D (Figure 9), we can note their spatial relationships and correlations.

1

2 **Figure 8.** Logging data from BB14004. (a) Natural gamma and rock types, (b) Density, (c) P-wave velocity values and (d) Calculated
 3 reflection coefficients. (e) The synthetic trace using a 70-Hz Ricker wavelet. The iron-oxide deposits (530-570 m) produced strong seismic
 4 signal in the synthetic trace.

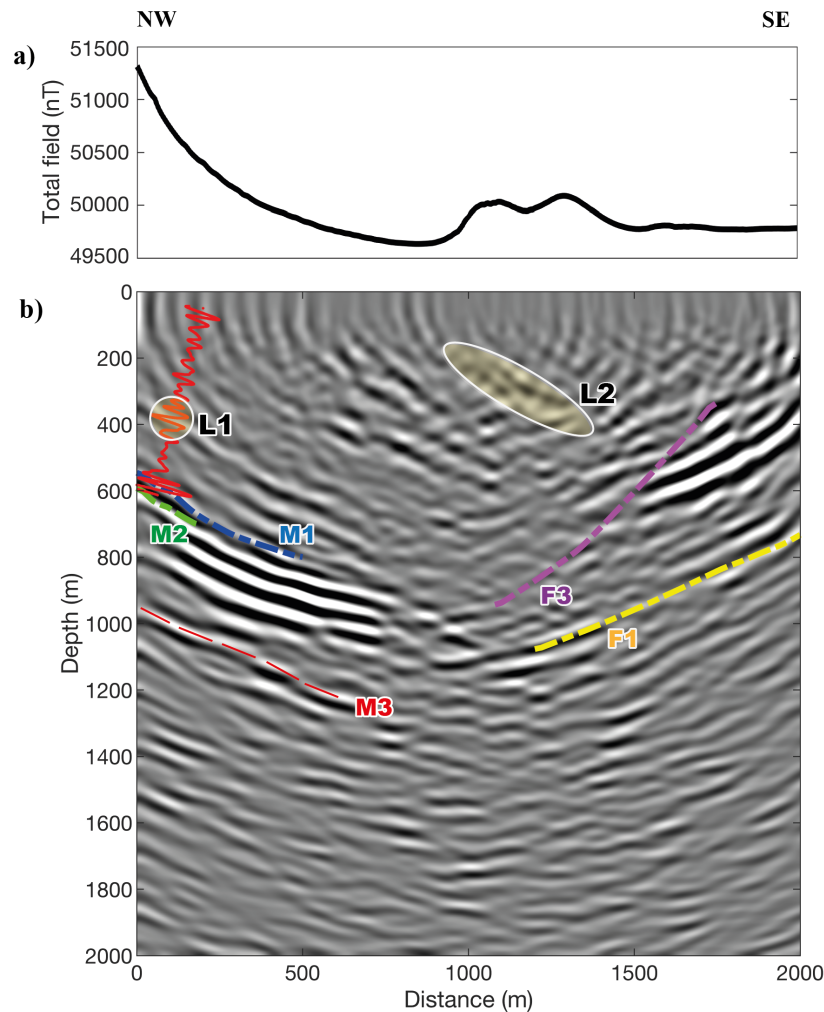

1

2 **Figure 9.** 3D view integrating the RTM section with other geophysical data. (a) M1 and M2 are 3D ore block models intersecting the
 3 strong reflectors in the seismic section. These imaged strong reflectors also correlate well with the high magnetic anomaly seen on the
 4 northern part of the profile in the overlaid magnetic map. (b) Two inferred fault planes (F1 and F3) as mapped by the recent 3D seismic
 5 data in the area and borehole BB-14004 (solid red line) intersecting the deposits. A small discrepancy between the imaged reflectors and
 6 the inferred fault planes (F1 and F3) might be due to the out-of-the-plane nature of these features producing a biased dip in the 2D RTM
 7 plane.

8 We interpreted the seismic image in the contexts of the four different datasets as above-mentioned. For a better illustration,
 9 we also show the integrated datasets along the 2D seismic section (Figure 10). First, we extracted the magnetic anomaly data
 10 along the seismic acquisition line (Figure 10a). Based on the high values of the magnetic anomaly data in the northern east
 11 part along the profile, the position of the deposits is indicated well. From 1000 m to 1500 m distance along the profile, the
 12 magnetic anomaly bulges up again, which we related to a shallow reflector (L2 in Figure 10b) in the seismic section. Second,
 13 we plotted the intersections between the two mineralized sheets and the RTM image (M1 and M2 in Figure 10b). The two
 14 intersection lines match well with the negative peaks in the seismic section. Based on the continuity of the reflectors at the
 15 deposit depths, it is highly reasonable that the mineralised sheets extend down to approximately 1000 m compared to the ore
 16 block model. We also marked M3 (Figure 10b) as a potential mineralization below M1 and M2. Third, we marked out the
 17 intersections between the two inferred fault planes and the RTM image (F1 and F3 in Figure 10b). The intersection due to the
 18 deeper fault (F1) matches well with the reflector, which is cross-cutting the deposit reflectors. However, the intersection due
 19 to the shallow fault (F3) only matches well a reflector at the deeper part cutting through the deposits. Fourth, we projected the
 20 1D synthetic seismic trace from BB-14004 on the 2D image (Figure 10b). The large amplitudes in the synthetic seismic trace
 21 at a depth interval of 500-600 m matches well with the reflectors in the image. Additionally, the reflector imaged above the
 22 deposits also matches well with weak amplitude in the synthetic seismic trace at a depth interval of approximately 350-370 m
 23 (L1 in Figure 10b). We attributed this reflector to a dike (Figure 8) based on the borehole core logging information. There are

1 other reflectors clearly shown up in the RTM image. However, we did not interpret them due to the lack of other geological
2 and geophysical data at their locations.

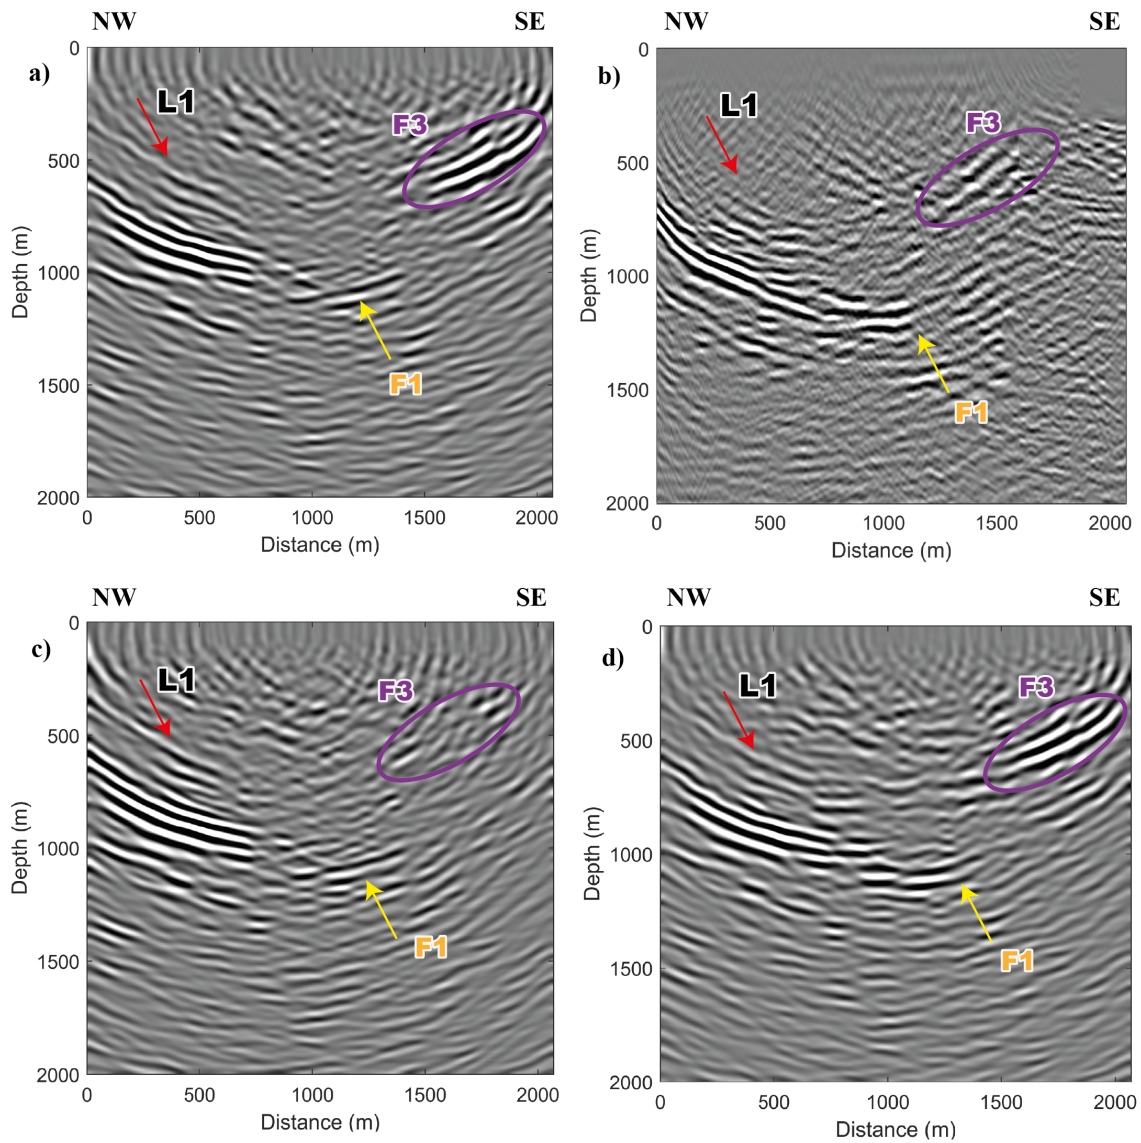

3
4 **Figure 10.** (a) Total-field magnetic anomaly along the seismic section. (b) The intersections of two deposit surfaces (M1 & M2) and the
5 intersection of the two fault planes (F1 & F2) are plotted. The synthetic trace is plotted along the well trajectory. R1 is interpreted to be
6 from a lithological contact (see Figure 8). R2 may be a weak iron-oxide mineralization as it appears in a region with slightly higher
7 magnetic properties than the neighbouring areas.

8
9 A specific comparison was made between the produced RTM image (Figure 11a) and the image (Figure 11b) obtained by
10 running a poststack Kirchhoff migration using two datasets acquired in 2015 and 2016 in the same area (Markovic et al., 2020).
11 Though the main features of the mineralization are similar in the two images, the RTM section imaged one reflector (L1 in
12 Figure 11a) clearly above the mineralization and indicated well the two possible crosscutting features (F1 and F3 in Figure

1 11a). Even though the RTM image was obtained by using dataset acquired in 2016 only, it showed more details because of the
2 RTM imaging algorithm.

3 We also made comparisons of the RTM images produced from different datasets which were pre-processed using different
4 methods in the pre-processing flow. In this way, we demonstrated the influences of different pre-processing methods on the
5 final RTM image results. To show the influence of the offset regularization (Step 4 in Figure 2), we relocated the seismic
6 traces in the original dataset to be at the points of 5-meter grids along the 1D curve without trace interpolation. The relocation
7 of any seismic trace was accomplished by moving the trace to the nearest point of the 5-meter grids relative to its true receiver
8 location. Keeping other pre-processing steps unchanged, the resultant RTM image (Figure 11c) without offset regularization
9 provided similar information as compared to the RTM image (Figure 11a) obtained with offset regularization. However, the
10 offset-regularized data improved fault imaging (ellipse in Figure 11a) in the 10 m receiver spacing designed area since the
11 trace density were doubled in this area. To show the effects of different methods for surface-wave suppression (Step 5 in Figure
12 2), we tested the widely used median filter to suppress the surface waves without changing other pre-processing steps. We
13 found that the RTM section (Figure 11d) obtained by using the data pre-processed with median filter did not present the
14 obvious crosscutting feature F1 which was shown in the RTM section (Figure 11a) with the curvelet filter in the pre-processing.

2 **Figure 11.** Comparisons of different image results. (a) The RTM image (same as Figure 10). (b) Image produced by a poststack Kirchhoff
 3 migration in Markovic et al. (2020). (c) RTM image obtained from data without offset regularization in the pre-processing, step 4. (d)
 4 RTM image obtained from data with median filter applied in the pre-processing, step5.

5

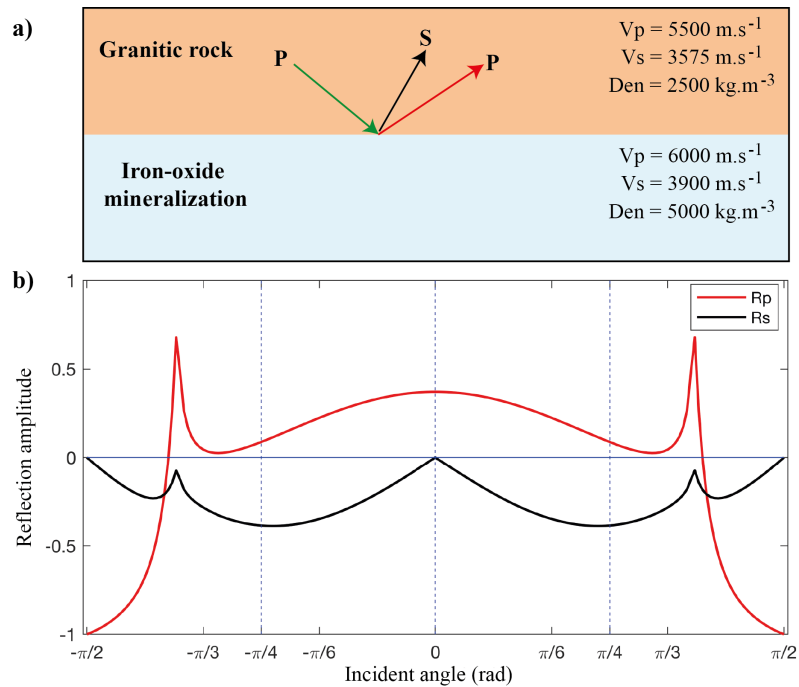

6

1 **5 Discussion**

2 In the current 2D case, when considering the sheet-like targets having a dip at certain depth, one needs to set up the orientation
3 and the length of the seismic line accordingly. The proper orientation (i.e., perpendicular to the strike of the targeted dipping
4 layer) of the profile ensures obtaining a nearly true dip of the target in the image. The proper length of the profile allows
5 receiving the reflected signal from the target at depth.

6 In our study, the six-step pre-processing workflow was essential in preconditioning the data and hence obtaining a good RTM
7 seismic section. This pre-processing workflow is recommended for future studies of RTM on hardrock seismic data, though
8 different methods could be used to preprocess the data as well. The migration velocity model is another factor that influences
9 the accuracy of the resultant RTM image. If the data itself lacks reflection events to be used for a good velocity analysis across
10 the whole velocity model, one needs to be careful with the interpretation of the reflectors in the final image. With the CIG
11 analysis (e.g., Schleicher et al., 2008), it is possible to refine the velocity model in the future studies. Based on the flatness of
12 those events in CIG images, we argue that the current velocity model works well for imaging the mineral deposits at the site,
13 though the migration velocity needs to be updated for better imaging other subsurface structures. An accurate 2D velocity
14 model using VSP surveys could likely improve the RTM imaging results. However, the current study already supports the use
15 of RTM imaging methods for hardrock seismic datasets and for mineral exploration purposes.

16 A remaining topic that one should also consider is that if there is strong AVO/AVA (amplitude-versus-offset/angle) effect
17 (Castagna and Backus, 1993; Hilterman et al., 2000) in the CIG images. Using Zoeppritz equations (Zoeppritz, 1919; Sheriff
18 and Geldart, 1995), we calculated the AVA (amplitude-versus-angle) effect using a simple isotropic two-layer model (Figure
19 12a), which simulates the physical properties of crystalline rocks. The amplitudes of P- and S-waves reflected from the
20 horizontal contact between the granite and the iron-oxide mineralization show a strong variation (Figure 12b) versus the
21 incident angles of the plane waves (P). Relevant to this specific dataset, the dipping angle and the thickness of the mineralized
22 sheets need further to be accounted for when studying their AVO effects. Since the CIGs produced from the RTM partial
23 images are ideal for studying the AVO effect relative to the CIG locations (Yan and Xie, 2012), future studies should exploit
24 this potential for better scrutinizing and extracting physical property information from seismic data. Additionally, crystalline
25 environment with a high degree of metamorphism may even show strong anisotropic AVO response (Asaka, 2018). Utilizing
26 the isotropic/anisotropic AVO analysis as a supplementary tool to characterise various rocks and mineral deposits from the
27 seismic data is ideal in mineral exploration (Harrison and Urosevic, 2012).

2 **Figure 12.** (a) A two-layer model with rock properties of granitic rock in the top layer and that of iron-oxide mineralization in the bottom
 3 layer. (b) The amplitude versus incident angle (AVA) response of the reflected P- and S-waves. The incident plane wave is P-wave with
 4 amplitude 1.

5 6 Conclusions

6 We have studied the application of the RTM imaging method on a hardrock seismic dataset acquired for deep-targeting iron-
 7 oxide deposits in the Ludvika mining area of central Sweden. Using a 6-step pre-processing workflow, we suppressed the
 8 unwanted noise and improved the signal-to-noise ratio. Consequently, the reflected events from the deposits and other
 9 geological features were remarkably strengthened. The resultant RTM image shows several reflectors, which are consistent
 10 when compared with four other independent datasets. From the known deposit model constrained by existing boreholes, two
 11 sets of strong seismic reflectors match well with the two iron-oxide mineralised bearing horizons. Two oppositely dipping
 12 reflectors, interpreted to be from fault planes, intersect the two strong reflectors from the mineralization implying possibly a
 13 geological control on the extension or termination of these deposits at depth. Integrating the seismic image with the high-
 14 resolution magnetic anomaly data, a weak zone of iron-oxide mineralization can be interpreted at shallow depth. Using P-wave
 15 sonic data, density and core logging data, we identified one continuous reflector as the dike formation.

16 AVO effect was also studied using a simple two-layer model since we speculated a possible AVO response in the CIGs. There
 17 may be opportunities for detailed AVO studies of dense metallic deposits in either theoretical modelling or real field

1 applications. In summary and exemplified with the Ludvika seismic dataset, we demonstrate the usefulness of advanced
2 imaging methods such as RTM for deep targeting and imaging mineral deposits and their host rock structures.

4 *Code Availability.* This work has benefited from the open-source software ‘CREWES’.

5
6 *Data Availability.* Original data underlying the material presented are available by contacting the corresponding author.
7 However, as the dataset is the subject of other PhD studies, there is a period of 3 years embargo on their availability.

8
9 *Author contributions.* AM contributed to the data acquisition. YD worked on the data processing, and wrote the paper, with
10 contributions from AM.

11 *Competing interests.* The authors declare that they have no conflict of interest.

12 *Special issue statement.* This article is part of the special issue “State of the art in mineral exploration”. It is a result of the
13 EGU General Assembly 2020, 3–8 May 2020.

14 *Financial support.* This research has been supported by the European Commission, Executive Agency for Small and
15 Medium-sized Enterprises (Smart Exploration grant no. 775971).

16 *Acknowledgements.* **This work was performed within the Smart Exploration project. The Smart Exploration was funded**
17 **by European Union’s Horizon 2020 research and innovation program with the grant agreement no. 775971. We thank**
18 **Nordic Iron Ore (NIO) AB for their collaboration in this study. Georgiana Maries is thanked for providing the density**
19 **and sonic logs. We thank four anonymous reviewers and the editor Ramon Carbonell for providing their helpful**
20 **comments to improve the original version of the manuscript.**
