13

14 **Abstract**

15 Joint systems in the eastern portion of the Ebro Basin of the eastern Pyrenees enjoy near
16 continuous exposure from the frontal portion of the belt up to the external portion of its
17 associated foredeep. Utilizing orthophoto mosaics of these world class exposures, we have
18 manually digitized over 30000 joints within a 16x50 km study area. The mapped traces
19 exhibit orientations that are dominantly perpendicular to the trend of the belt (transverse) and,
20 subordinately, parallel to the belt (longitudinal). In particular, joints systematically orient
21 perpendicular to the trend of the belt both in the frontal folds and in the inner and central
22 portion of the foredeep basin. Longitudinal joints occur rarely, with a disordered spatial
23 distribution, exhibiting null difference in abundance between the belt and the foredeep. Joint
24 orientations in the external portion of the foredeep become less clustered, with adjacent areas
25 dominated by either transverse or oblique joints. Our data indicates that joints in the studied
26 area formed in the foredeep in response to a foredeep-parallel stretching, which becomes
27 progressively less intense within the external portion of the foredeep. There, the minimum
28 stress direction becomes more variable, evidencing poor contribution of the forebulge-
29 perpendicular stretching on stress organization.

30

1 Introduction

2 Fractures can be effective pathways for fluid flow (e.g. Laubach et al., 2019), thus
3 impacting production of hydrocarbons (Barr et al., 2007; Engelder et al., 2009; Questiaux et
4 al., 2010) and geothermal water (Haffen et al., 2013; Vidal et al., 2017), the pathways and
5 fates of contaminants released from deep geological radioactive waste repositories
6 (Berkowitz et al., 1988; Iding and Ringrose, 2010) and the sustainable management of
7 groundwater (Masciopinto and Palmiotta, 2013). Associated with crustal tension, joints are
8 ubiquitous open-mode fractures occurring in a range of tectonic settings, including collisional
9 belts. In collisional settings, layer bending and stretching during the growth of thrust-related
10 anticlines has conventionally been invoked as the principal causative process for the
11 development of joints oriented approximately parallel (e.g. Ramsay, 1967; Murray, 1968) and
12 perpendicular (e.g. Dietrich, 1989; Lemiszki et al., 1994) to the trend of the belt and of the
13 thrust related anticlines. However, the frequently observed obliquity between joints (and
14 other meso-scale structures) and the trend of the hosting anticlines (e.g. Tavani et al., 2019;
15 Beaudoin et al., 2020), along with the documented occurrence of joints in exposed forelands
16 (e.g. Dunne and North, 1990; Zhao and Jacobi, 1997; Billi and Salvini, 2003; Whitaker and
17 Engelder, 2006), has more recently led to the conclusion that, in many cases, joints and other
18 kinds of extensional fractures exposed in thrust and fold belts have developed prior to folding
19 and thrusting, within the foreland region (e.g. Doglioni, 1995; Zhao and Jacobi, 1997;
20 Tavarnelli and Peacock, 1999; Lash and Engelder, 2007; Branellec et al., 2015; Basa et al.,
21 2019; Giuffrida et al., 2019; Martinelli et al., 2019; Carrillo et al., 2020), where joints are
22 layer-perpendicular and commonly oriented parallel (longitudinal) and perpendicular
23 (transverse) to the belt-foredeep-forebulge trend (Tavani et al., 2015).

24 A partially unresolved question in foreland deformation relates to the development of
25 transverse joints, which requires a tensile minimum stress oriented parallel to the foredeep.
26 Even in arched systems, the forebulge, the foredeep, and the belt tend to be nearly parallel to
27 each other locally (e.g. the Hellenic arc, the Apennines-Calabrian arc, the Betic-Rif arc). The
28 shortening direction in the inner portion of the foredeep (subjected to layer parallel
29 shortening) and the stretching direction in the forebulge (where bulge-perpendicular
30 stretching induced by lithospheric outer arc extension operates) are nearly parallel in a belt-
31 perpendicular transect (Fig. 1). In addition, in the innermost portion of the foredeep, where
32 layer parallel shortening operates, the σ_2 is typically vertical and the σ_3 is positive,

1 horizontal, and parallel to the trend of the belt (Tavani et al., 2015). Given the above, there
2 should be an area in between the inner portion of the foredeep and the peripheral bulge where
3 σ_1 becomes vertical and where σ_3 is still horizontal and parallel to the belt (Fig. 1a). This
4 scenario could explain the development of layer-perpendicular transverse extensional
5 structures, with transverse extensional faults or veins expected to develop where σ_3 is
6 positive. In this scenario, transverse joints occurring in this zone of localized tension could
7 only develop as cross-joints (e.g. Gross, 1993) of the longitudinal set formed in the forebulge.
8 This simplified model does not explain the documented occurrence of transverse joints in
9 areas where longitudinal joints do not occur or represent the cross-joint set (e.g. Zhao and
10 Jacobi, 1997; Quintà and Tavani, 2012). This framework does not admit a simple stress
11 permutation in the foredeep and requires a negative σ_3 connected to a foredeep-parallel
12 stretching component (Fig. 1b). Lithospheric bending of the foredeep, both along the
13 horizontal plane (e.g. Doglioni, 1995) and along the vertical plane parallel to the trench
14 (Quintà and Tavani, 2012), has been invoked as a process able to produce foredeep-parallel
15 stretching.

16 Continuous exposures across the entire foreland region of the eastern Pyrenees allows
17 investigation of the primary mechanism responsible for transverse joint development
18 described above. Tens to hundreds of meters long joints affect the sedimentary sequence of
19 the Ebro foredeep basin (Fig. 2a), and are found tilted within the frontal structures of the
20 Pyrenean belt (Fig. 2b). These pre-folding joints are exceptionally exposed and mappable
21 from orthophotos (Fig. 2c-f), from which they can be traced almost continuously from the
22 external portion of the foredeep until the thrust belt. We have remotely mapped 30059 joints
23 traces from the aforementioned orthophoto dataset and obtained their azimuthal distributions
24 across the study area. Subsequently, this extended lineament database has been used to
25 constrain the causative mechanism behind transverse jointing in the Ebro foredeep basin.

26

27 **Geological framework**

28 The study area is situated in the eastern Ebro foreland basin within an area connecting
29 the eastern Pyrenees with the Catalan Coastal Ranges (Fig. 3a). The Pyrenees is an EW-
30 striking orogenic system that formed as the Iberian and European plates collided from Late
31 Cretaceous to Miocene times (Roest and Srivastava, 1991; Rosenbaum et al., 2002; Muñoz,
32 1992, 2002), and constitutes an asymmetric, doubly vergent orogenic wedge above the

1 northward subduction of the Iberian lithosphere beneath the European plate (Chevrot et al.,
2 2018). As a result, the Ebro basin formed as a flexural foreland developed on the downgoing
3 Iberian plate at the southern margin of the chain (Beaumont et al., 2000). In the study area, to
4 the south of the Ebro Basin (Fig. 3a), the Catalan Coastal Ranges developed as a Paleogene
5 intraplate left-lateral transpressional system (López-Blanco, 2002; Santanach et al., 2011).
6 The low-displacement character of thrusts and the absence of an associated foredeep both
7 evidence the limited importance of this range. A series of NE-SW and NW-SE trending
8 extensional faults strike parallel and perpendicular to the Catalan Coastal Range respectively,
9 which are a result of the late Oligocene-Miocene opening of the NW Mediterranean basin
10 (Vegas, 1992; Sàbat et al., 1995; Granado et al., 2016a).

11 The study area where joint traces have been digitized is delimited to the north by the
12 frontal Pyrenean thrusts and by the Eocene Bellmunt anticline (Figs. 3a,b). This anticline
13 comprises the Paleocene to upper Eocene foredeep infill. Immediately to the south of the
14 anticline (i.e. < 5 km), this multilayer becomes sub-horizontal and thins southward where the
15 Paleozoic to Mesozoic foredeep floor gently rises up and becomes exposed (Fig. 3a). There,
16 this pre-orogenic succession is slightly tilted to the north by uplift in the footwall of NW-SE
17 striking E-late Oligocene to Neogene extensional faults. Further to the southwest, this
18 succession is affected by the Paleogene contractional structures of the Catalan Coastal
19 Ranges (Fig. 3b).

20 In the field, joints are constantly bedding-perpendicular, regardless of the bedding dip
21 (Fig. 2a,b), and they are characterized by the occurrence of either a single set (Fig. 2c) or by a
22 ladder pattern (Fig. 2d,e). In the latter case, the few E-W striking joints are almost
23 everywhere perpendicular to the N-S striking set and abut on it (Fig. 2e). This indicates that
24 E-W striking joints are cross-joints formed perpendicular to, and about synchronously with,
25 the N-S striking joint set.

26

27

28 **Data and Methods**

29 Joints have been digitized within the 16.4x49.2 km area displayed on Figure 3, on 25 and 50
30 cm/px orthophotos provided by the Spanish Instituto Geográfico Nacional via the PNOA
31 (Plan Nacional de Ortofotografía Aérea) project (<https://pnoa.ign.es/>). The open source
32 geographical information system QGIS 3.4 has been used to manually digitize 30059 joint

1 traces. A collection of these traces seen on orthophotos is provided in Figure 2c-f. Joints have
2 been digitized in Bartonian and, subordinately, in Lutetian and Priabonian sedimentary rocks
3 (Fig. 3c). The NE and SE portions of the study area are highly vegetated (Fig. 3d,e) and only
4 a few joint traces have been mapped there. Quaternary sediments unaffected by joints crop
5 out in the central portion of the study area (Fig. 3d).

6 Digitized traces have lengths ranging from 2 to 100 m, with an average of ~20 m (Fig.
7 3f). The frequency distribution of trace trend shows that the vast majority of the mapped
8 joints are approximately N-S striking (Fig. 3f). A second subordinate set corresponds to E-W
9 striking joints, which in the field occur as cross-joints (Fig. 2d). The frequency distribution of
10 trace trend is not symmetrical around these orthogonal sets, due to the presence of a third less
11 abundant set composed of NW-SE oriented joints (Fig. 2e,f). The NW-SE striking joints are
12 mostly seen in the southern portion of the study area, in exposures where the N-S striking set
13 is not occurring. As mentioned above, exposures are frequently characterized by a single set
14 (Fig. 2c,d). At many locations, the dominant set is accompanied by associated cross-joints
15 (Fig. 2d). Very rarely, two mutually oblique sets occur in the same exposure (Fig. 2f).

16 In order to evaluate the variability of joint traces, the 16.4x49.2 km study area has
17 been divided into meshes of equilateral triangular elements with edge lengths of 1025m
18 (Mesh 1) and 1640m (Mesh 2). At each node, mean value and variance of trace trends has
19 been computed using a circular moving window with a radius of 1200m (Mesh 1) and 1900m
20 (Mesh 2). The radius of the circular moving window is set to these values for two reasons: 1)
21 it is two orders of magnitude longer than the average length of joints; 2) it is large enough to
22 ensure that most of the nodes have data number >20, as only nodes with data number > 20
23 have been analyzed. Since trace trends are circular data with an angle (α) over a period of
24 180° , in agreement with Mardia (1975) we used equations 1 to 4 to derive at each node the
25 circular mean value (M_{V_π}), the circular variance (V_π) and the resultant length (R_π ; $V_\pi = 1-R_\pi$),
26 the latter spanning from 0 (unclustered distribution) to 1 (perfectly clustered distribution). In
27 the presence of cross-orthogonal joint sets, it is also useful using a period of $\pi/2$, thus
28 modifying Mardia's equations and introducing the $M_{V_{\pi/2}}$ and $R_{\pi/2}$ parameters, which are
29 computed using Equations 5 to 8.

30

$$C_{\pi} = \frac{\sum_{i=1}^n \cos(2\alpha_i)}{n} \quad (1); S_{\pi} = \frac{\sum_{i=1}^n \sin(2\alpha_i)}{n} \quad (2); V_{\pi} = 1 - R_{\pi} = 1 - \sqrt{C_{\pi}^2 + S_{\pi}^2} \quad (3); Mv_{\pi} = \frac{\text{Arctan}(S_{\pi}/C_{\pi})}{2} \quad (4)$$

$$C_{\pi/2} = \frac{\sum_{i=1}^n \cos(4\alpha_i)}{n} \quad (5); S_{\pi/2} = \frac{\sum_{i=1}^n \sin(4\alpha_i)}{n} \quad (6); V_{\pi/2} = 1 - R_{\pi/2} = 1 - \sqrt{C_{\pi/2}^2 + S_{\pi/2}^2} \quad (7); Mv_{\pi/2} = \frac{\text{Arctan}(S_{\pi/2}/C_{\pi/2})}{4} \quad (8)$$

1
2

3 By using these four parameters together, instead for example of the classical k-means
4 clustering analysis, it is possible to derive important considerations on the distribution of
5 polymodal distributions in which two mutually orthogonal sets do occur, as illustrated in
6 Figure 4. We compare the Mv and the R parameters computed using the π and $\pi/2$ periods. In
7 the first example two parallel traces are analyzed, resulting in $Mv_{\pi/2} = Mv_{\pi}$, and $R_{\pi/2} = R_{\pi} = 1$
8 (i.e. circular variance = 0). When data dispersion is slightly increased (Example 2), $Mv_{\pi/2}$ is
9 still equal to Mv_{π} , whereas $R_{\pi/2}$ decreases faster than R_{π} . Further increase of data dispersion
10 (Example 3), in an asymmetric distribution (i.e. non-orthogonal sets), causes additional
11 decrease of $R_{\pi/2}$ with respect to R_{π} , and slight divergence between $Mv_{\pi/2}$ and Mv_{π} . In the
12 presence of a cross-orthogonal subset, the statistical usefulness of $R_{\pi/2}$ becomes evident, as
13 illustrated in Example 4. In this case, R_{π} rapidly approaches zero, suggesting high dispersion
14 (i.e. unrepresentative Mv_{π}), whereas $R_{\pi/2}$ is essentially unaffected with respect to Example 2,
15 indicating low dispersion and a representative $Mv_{\pi/2}$. However, the use of the $\pi/2$ period only
16 returns results in the 0 to $\pi/2$ range, so that NW-SE trending traces result in a NE-SW
17 trending mean value ($Mv_{\pi/2}$), as shown in the Example 5. In summary, Mv_{π} is useful to derive
18 the mean direction, whereas $R_{\pi/2}$ and R_{π} should be used in conjunction to discriminate
19 between populations in which oblique sets occur ($R_{\pi/2} < R_{\pi}$) from those in which two
20 perpendicular sets occur ($R_{\pi/2} > R_{\pi}$).

21

22 Results

23 Figure 5 displays attribute maps generated from Mesh 1 and Mesh 2 using the trace
24 orientation parameters described above. Both Mesh 1 and Mesh 2 have $R_{\pi} > 0.5$ across almost
25 the entire study area, with the only exception being in its NW corner. For $R_{\pi/2}$, in addition to
26 the NW corner, the central portion of the study area has $R_{\pi/2} < 0.5$. Noteworthy differences
27 between R_{π} and $R_{\pi/2}$ occur: (1) in the NW corner ($R_{\pi} \ll R_{\pi/2}$) and (2) in the central area ($R_{\pi} \gg$
28 $R_{\pi/2}$). The first area corresponds to a vegetated folded and faulted zone (Fig 3b-e).
29 Consequently, we consider the dataset poorly reliable in this location. In the central portion of
30 the study area, the difference between R_{π} and $R_{\pi/2}$ (which increases as data dispersion

1 increases) is less pronounced in Mesh 1 than Mesh 2. Thus, data dispersion increases with
2 increasing the search window size (1200m for Mesh 1 and 1900m for Mesh 2), evidencing
3 that joint orientation is changing in this area. In the rest of the analyzed foreland, $R_{\pi/2}$ has
4 values similar to R_{π} , indicating approximately unimodal data distribution within this region,
5 and poor spatial organization of the longitudinal cross-joints.

6 Distribution of Mv_{π} relates to the prevalence of NS-striking joints in the northern and
7 central portion of the study area. Towards the south, patches characterized by both N-S and
8 NW-SE-striking joints occur. High values of R_{π} and $R_{\pi/2}$ are characteristic of such subareas,
9 which as previously mentioned, is indicative of unimodal joint trace distributions.

10

11 **Discussion**

12 Remotely sensed and mapped joint traces in the eastern portion of the Pyrenees-Ebro
13 system show systematic distributions of azimuthal orientations. In the frontal portion of the
14 belt and within the foredeep, joints are mostly transverse (i.e. N-S-striking), with limited
15 occurrence of E-W-striking longitudinal cross-joints. Approaching the southern border of the
16 foredeep, joints exhibit both N-S and NW-SE orientations where the pre-Cenozoic floor of the
17 foredeep is exposed. Joints affect the Lutetian to Priabonian foredeep infill, and are found
18 tilted together with strata within the Bellmunt anticline (Fig. 2b), which is Priabonian in age
19 (Burbank et al., 1992). Given the above, jointing in the study area must have taken place
20 during or before the Priabonian. The occurrence of the N-S striking joints within the Ebro
21 foredeep is documented also to the west of the study area (e.g. Turner and Hancock, 1990),
22 where joint emplacement affects up to the Miocene (Arlegui and Simon, 2001). Transverse
23 joints, striking approximately NNE-SSW occur also to the SW in Bartonian to Priabonian
24 strata cropping out at the boundary between the Ebro basin and the Catalan Coastal Ranges
25 (Alsaker et al., 1996). These data indicate that transverse joints systematically developed in
26 the foredeep basin of the E-W oriented Pyrenean belt. Locally, the process of transverse
27 jointing occurred until the early Miocene (i.e. until the end of mountain building). Also, pre-
28 thrusting transverse extensional faults of upper Paleocene to lower Eocene age occur a few
29 tens of km to the NE of the study area (Carrillo et al., 2020), being presently incorporated
30 into the Pyrenean belt. Thus, we conclude that foredeep-parallel extension has occurred in the
31 foredeep of the Pyrenean belt since the Paleocene and until the end of convergence.
32 Transverse joints documented in this work clearly represent foredeep-related structures,

1 which can develop by (i) N-S oriented layer-parallel shortening (LPS) or (ii) E-W oriented
2 along foredeep stretching (Tavani et al., 2015). LPS is to be excluded, as the state of stress in
3 this case would include a positive minimum stress (Fig. 1). In agreement, LPS-related
4 extensional structures can form only due to fluid pressure contribution and they include mm-
5 to cm-long fractures filled with calcite (which is removed from pressure solution seams, Fig.
6 1; Tavani et al., 2015 and references therein). The type (joints with no calcite infill) and size
7 (tens of m-long) of transverse extensional structures described here are incompatible with the
8 layer-parallel shortening mechanism.

9 The relatively constant orientation of joints along the strike of the foredeep, the
10 occurrence of appreciable dispersion at the outer border of the foredeep, and the remarkably
11 poor abundance of longitudinal joints allow us to derive two major conclusions:

12 (1) The almost linear trend of the eastern Pyrenees facilitates the exclusion of planar arching
13 (e.g. Doglioni, 1995; Zhao and Jacobi, 1997) as the causative process for generating
14 foredeep-parallel stretching (i.e. required to establish the negative σ_3 responsible for
15 transverse jointing). Arching along the vertical plane parallel to the trench (Quintà and
16 Tavani, 2012) represents instead a viable mechanism for generating along-foredeep
17 stretching. This is analogous, albeit at a larger scale to the process of release faulting
18 described by Destro (1995). The basic concept behind this mechanism is the following: when
19 a straight line joining two fixed points - the tips of a fault in the case of Destro (1995) or the
20 edges of the foredeep in the case of Quintà and Tavani (2012) – becomes an arch, there is
21 stretching (Fig. 1b), which causes extensional stress parallel to the direction of elongation. In
22 essence, this mechanism is expected to operate in any doubly plunging foredeep, particularly
23 at its lateral edges, such as in the study area (Fig. 3a).

24 (2) Extension in the peripheral bulge, which is documented from many active and fossil
25 foredeep basins (e.g. Bradley and Kidd, 1991; Ranero et al., 2003; Tavani et al., 2015;
26 Granado et al., 2016b), including the lower Eocene foredeep basin presently incorporated into
27 the Pyrenees (e.g. Martinez et al., 1989; Pujadas et al., 1989) appears to be weakly influential
28 at the southern border of the study area (i.e. the upper Eocene peripheral bulge). Indeed, the
29 observed longitudinal joints are characteristically subordered, forming locally as cross-joints
30 to the identified transverse set within the study area (Fig. 2d). The transverse set becomes less
31 organized at the southern margin of the foredeep, where patches of N-S and NW-SE

1 dominated domains do occur. This evidences the absence of a major forebulge-perpendicular
2 extension capable of systematically reorienting σ_3 at the external foredeep edge.

3

4 **Conclusions**

5 Analysis of remotely sensed and mapped joints in the eastern Pyrenees and in the
6 adjacent Ebro foreland basin indicates that the emplacement of the dominant joint set within
7 the area, which strikes perpendicular to the trend of the foredeep occurred prior to folding and
8 developed in response to along-strike stretching caused by the plunging shape of the
9 foredeep. Joints developed in response to flexuring of the lithosphere at the peripheral bulge
10 do not occur in the area, suggesting that this mechanism has limited relevance to the observed
11 joint system. This is confirmed by the variability of joint orientations observed at the
12 foredeep external edge, negating the occurrence of a major forebulge-perpendicular extension
13 able to systematically orient the stress field at the foredeep edge.

2 Figure 1

3 Scheme showing the architecture of a foreland fold-and-thrust belt and adjacent foredeep
4 basin, with syn-orogenic fracture patterns in the different structural domains of the orogenic
5 system. (A) The foredeep state of stress is governed by the permutation between the state of
6 stress in the layer-parallel shortening and peripheral bulge domains. (B) The foredeep state of
7 stress is controlled by the along-strike stretching of the foredeep.

8

9 Figure 2

10 Examples of pre-folding joints within the studied area. (A) N-S striking joint with plumose
11 structures in the foredeep sediments (42°02'39.7"N; 2°13'54.9"E). (B) Tilted N-S and E-W
12 striking joints in the southern limb of the Bellmunt anticline, with the red arrow indicating an
13 E-W striking joint abutting on a N-S striking joint (42°05'39"N; 2°17'41.5"E). The density
14 contours of poles to bedding and joints (in their present day orientation and after unfolding)
15 refer to data collected in the Bellmunt anticline area. (C to F) Examples of joints seen on
16 orthophotos. (C) Transverse joints. (D) N-S striking transverse joints with subordinate E-W
17 striking cross-orthogonal joints. (E) NW-SE striking joints. (F) Rare example of multiple
18 oblique sets occurring at the same exposure. Orthophotos are available from the Spanish
19 Instituto Geográfico Nacional (<https://pnoa.ign.es/>).

20

21 Figure 3

22 (A) Simplified geological map of the western Pyrenees and Catalan Coastal Ranges (based on
23 the Geological Map of Catalunya scale 1:250'000; <https://www.icgc.cat/en/Downloads>), with
24 N-S geological cross-section (modified from Parés et al., 1999). (B) Detailed geological map
25 of the study area, with digitized joints (C). (D) Orthophoto (<https://pnoa.ign.es/>) of the study
26 area, with digitized joints (E). (F) Frequency distribution of joint traces trend and length.

27

28 Figure 4

29 Examples of joint patterns and resultant M_v and R parameters calculated for the π and $\pi/2$
30 periods. For the five examples, we show the map view of the joints, the azimuthal frequency,
31 and the sin-cos coordinates of the resultant values of M_v and R . Note that the distance from
32 the center is proportional to R .
