16 **Abstract**

17 Porosity reduction in rocks from a fault core can cause elevated pore fluid pressures, and consequently influence the
18 recurrence time of earthquakes. We investigated the porosity distribution in the New Zealand's Alpine Fault core in
19 samples recovered during the first phase of the Deep Fault Drilling Project (DFDP-1B) by using two-dimensional
20 nanoscale and three-dimensional microscale imaging. Synchrotron X-ray microtomography-derived analyses of
21 open pore spaces show total microscale porosities in the range of 0.1 to 0.24%. These pores have mainly non-
22 spherical, elongated, flat shapes and show subtle bipolar orientation. Transmission electron microscopy reveals that
23 nanoscale pores ornament grain boundaries of the gouge material, especially clay minerals. Our data implies that: (i)
24 the distribution of clay minerals controls the shape and orientation of the associated pores; (ii) porosity was reduced
25 due to pressure solution processes; and (iii) mineral precipitation in fluid-filled pores can affect the mechanical
26 behaviour of the Alpine Fault by decreasing the already critically low total porosity of the fault core, causing
27 elevated pore fluid pressures, and/or introducing weak mineral phases, and thus lowering the overall fault frictional
28 strength. We conclude that the current state of porosity in the Alpine Fault core is likely to play a key role in the
29 initiation of the next fault rupture.

30 **1. Introduction**

31 Fault mechanics, fault structure and fluid flow properties of damaged fault rocks are intimately related (Gratier and
32 Gueydan, 2007; Faulkner et al., 2010). Fault rupture is associated with intense brittle fracturing that enhances

33 porosity, and thus permeability, and therefore also possible rates and directions of fluid propagation within fault
34 zones (Girault et al., 2018). Conversely, post seismic recovery mechanisms (gouge compaction and pressure
35 solution processes) result in porosity, permeability and fluid flow propagation reductions (Renard et al, 2000;
36 Faulkner et al., 2010; Sutherland et al., 2012). These processes may cause elevated pore fluid pressures within fault
37 cores, and trigger frictional failure (Sibson, 1990; Gratier et al., 2003). Therefore, the state of porosity within rocks
38 from fault cores can play a key role in fault slip.

39 The Alpine Fault of New Zealand is late in its seismic cycle (Cochran et al., 2017), so studying it allows us to
40 investigate pre-earthquake conditions that may influence earthquake nucleation and rupture processes. Recently,
41 drilling operations were undertaken in this fault zone to investigate the *in situ* conditions (Sutherland et al, 2012,
42 2017). Slug tests in the DFDP-1B borehole (Sutherland et al., 2012) and laboratory permeability measurements of
43 core samples (Carpenter et al., 2014) indicate permeability decreases by six orders of magnitude with increasing
44 proximity to the fault. Furthermore, Sutherland et al. (2012) documented a 0.53 MPa fluid pressure difference across
45 the principal slip zone (PSZ) of the fault, which suggests that the fault core has significantly lower permeability than
46 the surrounding cataclasite units. It is therefore interpreted to act as a fault seal that limits fluid circulation within its
47 hanging wall (Sutherland et al., 2012). Permeability variations like this are closely associated with the porosity
48 evolution of fault cores, and thus are likely to affect the fault strength and seismic properties (Sibson, 1990; Renard
49 et al., 2000; Gratier and Gueydan, 2007).

50 In this study, we investigate the porosity distribution in rocks from the Alpine Fault core and consider the potential
51 effects of this porosity on fault strength. We have measured open pore spaces in these rocks from X-ray computed
52 tomography (XCT) datasets and examined pore morphology by implementing quantitative shape analyses and using
53 transmission electron microscopy (TEM).

54 **2. Geological setting**

55 New Zealand's Alpine Fault (Fig. 1a) is a major active crustal-scale structure that ruptures in a large earthquake
56 every 291 ± 23 years, the last one of which occurred in 1717 (Cochran et al., 2017). The fault is the main constituent
57 of the oblique transform boundary between the Australian Plate and the Pacific Plate, accommodating around 75%
58 of the relative plate motion. Ongoing dextral strike-slip at 27 ± 5 mm yr⁻¹ along the fault has resulted in a total
59 strike-separation of ~ 480 km over the last 25 Ma (Norris and Cooper, 1995, 2001; Norris and Toy, 2014). In
60 Neogene time, a dip-slip component added to the fault motion has resulted in more than 20 km of vertical uplift of
61 the hanging wall (Norris and Cooper, 1995, 2001; Norris and Toy, 2014). Consequently, rocks comprising the
62 hanging wall of the fault have been exposed in various outcrops, where they can be studied in detail. The
63 amphibolite facies Alpine Schist is the metamorphic protolith of a ~ 1 km thick mylonite zone, which has been
64 exhumed from depth and now structurally overlies an up to 50 m thick zone of brittlely deformed cataclasites and
65 gouges (e.g. Norris and Cooper, 1995, 2001; Norris and Toy, 2014). These rocks have been investigated in outcrops
66 and from samples collected in three boreholes during the two phases of the Deep Fault Drilling Project (DFDP-1A,
67 DFDP-1B and DFDP-2B; Fig. 1a) along the Alpine Fault (Sutherland et al., 2012; Toy et al., 2015; Toy et al., 2017).

68 Most of the brittle shear displacement along the fault has been accommodated within the fault core, which includes
69 Principal Slip Zone (PSZ) gouges and cataclasite-series rocks (Toy et al., 2015). Both in surface outcrops and drill
70 core samples, the Alpine Fault manifests as a thin (5 to 20 cm thick) gouge zone with a predominantly random fabric
71 of clay-rich material (Toy et al., 2015; Schuck et al., 2020). This cohesive but uncemented layer has a significantly
72 finer grain size than the surrounding cataclasite units, which shows that the material was reworked only within this
73 layer, most probably as a result of ultracomminution due to multiple shear events under brittle conditions (Boulton
74 et al., 2012; Toy et al., 2015). The local presence of authigenic smectite clays (Schleicher et al., 2015) and calcite
75 and/or chlorite mineralization within sealed fractures and in the gouge matrix (Williams et al, 2017) indicate that
76 mineral reactions are restricted to an alteration zone within the fault core (Sutherland et al., 2012; Schuck et al.,
77 2020). The Alpine Fault core has been interpreted to have formed during a cyclical history of mineralization, shear,
78 and fragmentation (Toy et al., 2015). In addition, in the DFDP-1B borehole (Fig. 1b, Sutherland et al., 2012) fault
79 gouges occur at two distinct depths: 128.1 m (PSZ-1) and 143.85 m (PSZ-2), which shows that the slip was not
80 localized within a single gouge layer (Toy et al., 2015).

81 **3. Sample description and analytical methods**

82 **3.1 Samples**

83 Porosity analyses were performed on four samples representing PSZ gouges and cataclasites of the Alpine Fault
84 core, which were recovered from the DFDP-1B borehole (Fig. 1b, c; Sutherland et al., 2012). These are DFDP-1B
85 58_1.9, DFDP-1B 69_2.48, DFDP-1B 69_2.54 and DFDP-1B 69_2.57. Sample nomenclature includes drill core run
86 number, section number, and centimeters measured from the top of each section. These samples were recovered
87 from drilled depth of 126.94 m, 143.82 m, 143.88 m and 143.91 m, respectively.

88 Detailed lithological and microstructural descriptions of the DFDP-1B drill core were carried out simultaneously
89 with, and after the drilling operations by the DFDP-1 Science Team, and these data were later summarized by Toy et
90 al. (2015). Samples DFDP-1B 58_1.9 and DFDP-1B 69_2.48 belong to the upper foliated cataclasite units (Fig. 1b,
91 c; Toy et al., 2015). These were described as ultracataclasites with gouge-filled shears located above PSZ-1 and
92 PSZ-2 respectively. Sample DFDP-1B 69_2.54 represents the gouge layer that defines PSZ-2, whereas sample
93 DFDP-1B 69_2.57 is composed of brown ultracataclasites that belong to the lower cataclasite unit (Fig. 1b, c; Toy et
94 al., 2015).

95 **3.2 X-ray computed tomography (XCT)**

96 We imaged the samples using absorption tomography, where the signal intensity depends on how electron density
97 and bulk density attenuate a monochromatic X-ray along its path through the material (e.g. Füsseis et al. 2014). We
98 acquired the X-ray microtomography data for this study at the 2-BM beamline of the Advanced Photon Source,
99 Argonne National Laboratories USA in December 2012. The non-cylindrical samples of ~7 mm height and ~4 mm
100 diameter were drilled parallel to the foliation and mounted on a rotary stage and imaged with a beam energy of 20
101 keV. A charge-couple device camera collected images at 0.25° rotation steps over 180° at sample detector distance

102 of 70 mm and FoV 2.81 mm. The voxel size was 1.3 μm . We have reconstructed the datasets with a filtered back-
103 projection parallel beam reconstruction into 32-bit gray level volumes consisting of 2083 * 2083 * 2083 voxels
104 using X-TRACT (Gureyev et al., 2011).

105 **3.3 Analyses of XCT datasets**

106 Data analyses and image processing were performed using the commercial software package Avizo 9.1 (Fig. 2).
107 Initially, the datasets were rescaled to 8-bit grey scale volumes for enhanced computer performance. In addition,
108 small volumes of interest were cropped from the whole volume before a non-local means filter was applied to
109 reduce noise (Buades et al., 2005). On the filtered gray-scale images, porosity was identified as the darkest phase
110 (Fig. 2a). The corresponding gray-scale values were thresholded, and the datasets were converted into binary form.
111 However, this threshold range also captured cracks within a sample, which are likely to result from depressurization
112 during core recovery (Fig. 2b). To omit the cracks, thresholded components with volumes larger than the volume of
113 200 face connected voxels ($439.4 \mu\text{m}^3$) were excluded from the binary label images by using the morphological
114 operation ‘connected components’ built in software Avizo 9.1. Clusters of connected components were then created
115 to visualize 3D volumes of segmented pore spaces (Fig. 2c).

116 Unfortunately, this methodology results in either loss of larger pores or inclusion of small cracks depending on the
117 implemented limit of connected components, and thus calculating total porosities includes significant bias.
118 Therefore, “connected components” limited up to 200 connected voxels were used only for visualization purposes.
119 Instead, the volumes and shape characteristics of segmented materials (including cracks) were exported from Avizo
120 software in numerical format, and volume distributions within a sample were plotted on a logarithmic scale in
121 Matlab (Fig. 3). Data up to a specific volume size were fit to a polynomial curve, and then the curve was
122 extrapolated to the X intercept, which is the expected maximum pore size (Fig. 3). Total porosities were then
123 estimated by integrating the curve, which excludes all volumes on the right side of the curve. Total porosities are
124 presented as a percentage of the whole sample volume (Fig. 3). The implemented equations are presented in
125 Supplementary material 1.

126 Pore shapes were analyzed on bivariate histograms plotted on Matlab by using the numerical pore characteristics,
127 previously extracted from Avizo software. Only pore volumes between $21.97 \mu\text{m}^3$ (10 voxels) and $878.8 \mu\text{m}^3$ (400
128 voxels) were included to avoid bias in the data due to insufficient voxel count and presence of cracks, respectively.
129 Individual pores in our dataset are separated (Fig. 2c), thus the covariance matrix of each pore was calculated, and
130 the three eigenvalues of this covariance matrix were extracted. These three values correspond to the three main
131 orthogonal directions in each pore (i.e. the longest, medium and shortest axes) and we use them as proxies to
132 describe pore geometry. Thus, their amplitudes provide information on the spatial extension of the pore and its
133 shape. The ratio between the medium and largest eigenvalues of each pore defines its elongation (Fig. 4), the ratio
134 between the smallest to the largest – its sphericity (Fig. 5), and the ratio of the smallest to the medium – its flatness
135 (Fig. 6).

136 The angles θ and ϕ that describe the orientation of the longest axis of each pore with respect to the main axis of the
137 3D scan were calculated. These angles were translated into trend and plunge and then plotted on a lower hemisphere
138 equal area stereographic projection with a probability density contour to display the distribution of pore unit
139 orientations (Fig. 7).

140 **3.4 Transmission electron microscopy (TEM)**

141 TEM images were collected on a FEI Tecnai G2 F20 X-Twin transmission electron microscope, located at the
142 German Research Centre for Geosciences (GFZ), Potsdam, Germany (Fig. 8). The instrument is equipped with field-
143 emission gun (FEG) electron source and high-angle annular dark-field (HAADF) Detector. Images were collected
144 from samples placed on a Gatan double-tilt holder at 200kV. TEM sample preparation was performed with focused
145 ion beam (FIB) milling at GFZ Potsdam using a HELIOS system operated at 30 kV.

146 **4. Results**

147 **4.1 XCT-derived characteristics of porosity**

148 All samples contain low total porosities, ranging from 0.1% to 0.24% (Fig. 3). However, it should be noted that the
149 lower cataclasite sample (DFDP-1B 69_2.57) has twice as much pore space (Fig. 3d) as any of the other samples.
150 The characterized pore size distributions range over almost three orders of magnitude for all samples (Fig. 3).
151 Furthermore, the expected maximum pore size volume was estimated to be largest in the PSZ-2 sample (DFDP-1B
152 69_2.54), reaching $862 \mu\text{m}^3$ (Fig. 3c).

153 In all samples, shape analyses of pores with volumes between $21.97 \mu\text{m}^3$ (10 voxels) and $878.8 \mu\text{m}^3$ (400 voxels)
154 demonstrate predominantly elongated (Fig. 4), non-spherical (Fig. 5) and flat pore shapes (Fig. 6). This is
155 particularly pronounced for the smaller pore volumes. The number of elongated pores per sample is increasing in the
156 upper foliated cataclasites (Fig. 4a and b) with increasing proximity to PSZ-2, where most elongated pores occur
157 (Fig. 4c). Conversely, the lower cataclasite sample demonstrates proportionally fewer elongated pores within the
158 sample (Fig. 4d). The degree of sphericity is uniform for all samples, and pores appear as mainly non-spherical (Fig.
159 5). Few isolated spherical pores are manifested only by small pore volumes (Fig. 5). A trend of increasing the
160 number of flat pores is observed with increasing sample depth (Fig. 6), and most flat pores are detected in the lower
161 cataclasite (Fig. 6d).

162 The orientations of the individual pore units show two distinctive peaks with opposite vergence, defining bipolar
163 distributions of pore orientations (Fig. 7). The observed bipolarity is subtle in samples DFDP-1B 58_1.9 (Fig. 7a)
164 and DFDP-1B 69_2.48 (Fig. 7b), and more obvious in samples DFDP-1B 69_2.54 (Fig. 7c) and DFDP-1B 69_2.57
165 (Fig. 7d).

166 **4.2 Microstructural characteristics of porosity**

167 TEM characterization of the gouge material from PSZ-2 (sample DFDP-1B 69_2.54) reveals that the Alpine Fault
168 gouges are composed of angular quartz and/or feldspar fragments (~200 nm in size), wrapped by smaller
169 phyllosilicates (< 100 nm long). This random fabric is ornamented by nanoscale pores (< 50 nm), distributed along
170 all grain and phase boundaries, especially abundant along clay minerals (Fig. 8a).

171 The gouge material also demonstrates phyllosilicate-rich areas, defined by an increase in the clay/clast ratio. In these
172 zones, fine (< 100 nm long) and coarser (few μm long) clay grains coexist and are aligned in wavy fabric that
173 surrounds sporadic protolith fragments (Fig. 8b). Pore spaces are again distributed along the boundaries of the
174 constituent mineral grains but some of them are larger (~0.5 μm) with thin ellipsoidal or elongated shapes (Fig. 8b,
175 c). These pores are commonly associated with inter-clay layer porosity. Large size pores are also observed along
176 quartz-feldspar grains, where pores are associated with multiple grains and occasionally disrupt grain boundaries,
177 thus were labelled as fracture porosity (Fig. 8d).

178 **5. Discussion**

179 **5.1 Characteristics of porosity within the Alpine Fault core**

180 Porosity analyses of samples from, or in close proximity to the two PSZs encountered in the DFDP-1B drill core
181 reveal total pore volumes between ~ 0.1 and 0.24% (Fig. 3). These values are significantly lower than the porosity
182 estimates from other active faults in the world, such as: 0.2 to 5.7% total porosity in the core of the Nojima Fault,
183 Japan (Surma et al., 2003) and 0 to 18% in the San Andreas Fault core (Blackburn et al., 2009). The Alpine Fault
184 core contains total pore space volumes, comparable only with the lower porosities in these previous studies. It
185 should be noted that the smallest pore spaces captured in the XCT datasets are 1.3 μm in size due to acquisition
186 constrains, whereas nanoscale porosity was identified on the TEM images. Therefore, the estimated total porosities
187 represent only minimum values of the open pore spaces in the Alpine Fault core.

188 TEM images presented here mainly focus on nano-scale materials (Fig. 8a, c, d) but were also used to describe the
189 distribution of micro-porosity in these rocks (Figure 8b). The pores visible on grain and phase boundaries in figure
190 8b have similar sizes to the pores segmented on XCT images (> 1.3 μm in diameter), thus we conclude that this is
191 the typical habit of both nano- and micro-pores within the Alpine Fault core (Fig. 8). In addition, both quantitative
192 micro-porosity shape analyses (Fig. 4, 5 and 6) and nano-pores identified on TEM images (Fig. 8) reveal that a
193 significant population of pores are predominantly non-spherical with elongated, flat shapes. We attribute this
194 observation to the tendency of these pores to ornament clay minerals where pores are attained and elongated along
195 their (001) planes (Fig. 8b, c and d).

196 Foliation in the upper cataclasites is defined by clay-sized phyllosilicates, that become more abundant with
197 proximity to the PSZ (Toy et al., 2015), where weak clay fabric is developed (Schleicher et al., 2015). This gradual
198 enrichment in clay minerals coincides with the subtle development of bipolar distributions of pore orientations with
199 increasing sample depth (Fig. 7). This observation and the fact that pores are mainly attained along grain boundaries

200 of clays (Fig. 8) suggest that the distribution of clay minerals also controls pore orientations within the Alpine Fault
201 core. Previously, the phyllosilicate foliation in the Alpine Fault cataclasites has been used to define shear direction
202 (Toy et al., 2015). Thus, we speculate that pore orientations in these rocks are also systematically related to the
203 kinematic framework of the shear zone. If these pores represent remnants of fluid channels, their spatial orientation
204 is likely to reflect the fluid flow directions during deformation. To address this possibility more data for systematic
205 analyses of pore orientations are needed.

206 **5.2 Porosity reduction within the Alpine Fault core**

207 The comparatively lower porosity estimates of the Alpine Fault core than other active faults (e.g. the Nojima Fault,
208 Surma et al., 2003, and the San Andreas Fault, Blackburn et al., 2009) can be attributed to the fact that the Alpine
209 Fault is late in its seismic cycle and the last seismic event occurred in 1717 (Cochran et al., 2017). Porosity of the
210 fault core is considered to evolve during the seismic cycle when fault rupture can cause porosity increase up to 10%
211 (Marone et al., 1990), and the consequent healing mechanisms lead to porosity decrease over time due to mechanical
212 compaction of the fault gouge and/or elimination of pore spaces within the fault core due to pressure solution
213 processes (Sibson, 1990; Renard et al., 2000; Faulkner et al., 2010). TEM data presented here show abundance of
214 newly precipitated authigenic clays, wrapped around coarser clay minerals (Fig. 8b). Furthermore, delicate clay
215 minerals form fringe structures (Fig. 8a), and strain shadows (Fig. 8c) around larger quartz-feldspar grains. These
216 microstructural observations demonstrate that pressure solution processes operated within these rocks (Toy et al.,
217 2015).

218 Evidence for pressure solution processes has been previously documented in all units, comprising the Alpine Fault
219 core (Toy et al., 2015). Abundant precipitation of alteration minerals (Sutherland et al., 2012), calcite filled
220 intragranular and cross-cutting veins (Williams et al., 2017), and the occurrence of newly formed smectite clays
221 (Schleicher et al., 2015) indicate extensive fluid-rock reactions. In addition, anastomosing networks of opaque
222 minerals (such as graphite; Kirilova et al., 2017), which define foliation in the upper cataclasites (Toy et al., 2015),
223 have been interpreted to be concentrated by pressure solution processes during aseismic creep (Toy et al., 2015;
224 Gratier et al., 2011). The petrological characteristics of the Alpine Fault core lithologies identify solution transfer
225 mechanisms likely were the dominant mechanism for pore closure within these rocks.

226 Post-rupture porosity reduction is known to operate three to four times faster within fine-grained fault gouges than in
227 coarser-grained cataclasites (Walder and Nur, 1984; Sleep and Blanpied, 1992; Renard et al., 2000), which may
228 explain the differences in total porosity between the gouge-containing samples and the footwall ultracataclasite –
229 DFDP-1B 69-2.57 (Fig. 3). Furthermore, previous studies documented less carbonate and phyllosilicate filling of
230 cracks in the Alpine Fault footwall cataclasites as compared to the hanging wall cataclasites (Sutherland et al., 2012;
231 Toy et al., 2015), suggesting more reactive fluids are present and isolated within the hanging wall of the Alpine
232 Fault. Thus, more intense dissolution-precipitation processes took place in the fault's hanging wall, which very
233 likely resulted in more efficient porosity reduction, as demonstrated by our porosity estimates (Fig. 3).

234

235 **5.3 Effects of porosity on the Alpine Fault strength**

236 The extremely low porosity estimates presented here (Fig. 3) are consistent with the low permeabilities of 10^{-18} m²
237 measured experimentally in clay-rich cataclasites and gouges from the Alpine Fault zone (Carpenter et al., 2014). In
238 addition, the documented difference of total porosities between the hanging wall and footwall samples (Fig. 3)
239 implies different intensity of pressure solution processes, and thus compartmented fluid propagation. Our data is
240 comparable with the permeability measurements in that study (Carpenter et al., 2014) and yields increased
241 confidence in their interpretation of a permeability gradient with distance from the PSZ, which itself acts as a
242 hydraulic seal (Sutherland, et al., 2012). The existence of such a barrier to flow is characteristic for faults
243 undergoing creep and locked faults (Rice, 1992; Labaume et al., 1997; Wiersberg and Erzinger, 2008). However,
244 much higher permeabilities in the surrounding damaged rocks (Carpenter et al., 2014) allow fast propagation of
245 fluids within them and can cause localization of high fluid pressures on one side or the other of a hydraulic seal
246 (Sibson, 1990). Such fluid pressures can enhance gouge compaction and pressure solution processes within the fault
247 core, which will eventually introduce zones of weakness and thus may trigger fault slip (Faulkner et al., 2010).

248 Previous studies and the observations presented here show that fluids were present in the Alpine Fault rocks. Fluid-
249 filled pores represent a favorable environment for mineral precipitation, which can affect the fault strength in two
250 ways: (i) Very small decrease of these critically low total porosities due to mineral precipitation would cause fluid
251 pressurization, which is a well-known fault weakening mechanism described by Byerlee, 1990 and Sibson, 1990.
252 However, this pressure increase will be slightly offset by inclusion of fluids into new hydrous minerals; (ii)
253 deposition of frictionally weak phases (such as clay minerals and graphite), especially if they decorate grain contacts
254 and/or form interlinked weak layers, would lower the overall frictional strength (Rutter et al., 1976; Niemeijer et al.,
255 2010).

256 Precipitation of authigenic clay minerals was identified on our TEM data (Fig. 8) and also documented by previous
257 studies (Schleicher et al., 2015). As well as having low frictional strengths (Moore and Lockner, 2004), clay
258 minerals may also contribute to the formation of an impermeable seal if they form an aligned fabric, and thus can
259 enhance the likelihood of fluid-pressurization in the fault rocks (Rice, 1992; Faulkner et al., 2010). In addition,
260 graphite, which was previously documented in these rocks by previous studies (Kirilova et. al., 2017), may
261 effectively weaken the fault due to mechanical smearing (Rutter et al., 2013) and/or localized precipitation within
262 strained areas (Upton and Craw, 2008). Such graphite precipitation within shear surfaces was previously
263 documented by Kirilova et al. (2017).

264 In summary, the presence of trapped fluids in the low porosity rocks of the Alpine Fault core possibly controls the
265 mechanical behavior of the fault and could be responsible for future rupture initiation due to fluid pressurization
266 and/or precipitation of weak mineral phases. This hypothesis is further supported by an experimental study showing
267 that the DFDP-1 gouges are frictionally strong in the absence of elevated fluid pressure (Boulton et al., 2014).

268 **6. Conclusions**

269 Analyses of XCT-datasets and TEM images of borehole samples from the core of the Alpine Fault reveal micro- and
270 nanoscale pores, distributed along grain boundaries of the constituent mineral phases, especially clay minerals. The
271 tendency of these pores to ornament clays defines their predominantly non-spherical, elongated, flat shapes and the
272 bipolar distribution of pore orientations. The documented extremely low total porosities (from 0.1 to 0.24 %) in
273 these rocks suggest effective porosity reduction. Microstructural observations presented here and documented in
274 previous studies indicate that pressure solution processes were the dominant healing mechanism, and that fluids
275 were present in these rocks. Therefore, fluid-filled pores may be places where elevated pore fluid pressures develop,
276 due to further mineral precipitation that decreases the already critically low total porosities. Alternatively, they may
277 also facilitate deposition of weak mineral phases (such as clay minerals and graphite) that may very effectively
278 weaken the fault. We conclude that the current state of the fault core porosity is possibly a controlling factor on the
279 mechanical behaviour of the Alpine Fault and will likely play a key role in the initiation of the next fault rupture.

280 **Data availability.**

281 Matlab code and numerical data of pore volumes can be found in Supplementary material 1.

282 **Authors contribution**

283 Kirilova reconstructed, processed, and analysed the XCT datasets presented here, interpreted the TEM data and
284 prepared the manuscript. Most of this work was performed during Kirilova's PhD under the academic guidance of
285 Toy. Toy and Gessner collected the XCT data with technical support by Xiao. Renard and Sauer contributed with
286 valuable discussion about XCT data analyses. Wirth enabled TEM data acquisition and provided his expertise on
287 TEM data interpretation. The final version of this manuscript benefits from collective intellectual input.

288 **Competing interests**

289 The authors declare that they have no conflict of interest.

290 **Acknowledgments**

291 We gratefully acknowledge funding from the Advances Photon Source (GUP 31177). This research used resources
292 of the Advanced Photon Source, a U.S. Department of Energy (DOE) Office of Science User Facility operated for
293 the DOE Office of Science by Argonne National Laboratory under Contract No. DE-AC02-06CH11357. Avizo
294 workstation was built at the University of Otago with financial support provided by Nvidia, Corporation Royal
295 Society of New Zealand's Rutherford fellowships (16-UOO-001), the Ministry of Business and Innovation's
296 Endeavor Fund (C05X1605/GNS-MBIE00056), and a subcontract to the Tectonics and Structure of Zealandia
297 Program at GNS Science (GNS-DCF00020). Publishing bursary funding provided by the University of Otago is
298 greatly appreciated. We thank Sherry Mayo for helping with the reconstruction process of XCT data and Andrew
299 Squelch for providing use of the Avizo workstation, located at CSIRO, Perth, Australia during the initial data

300 analyses. Special thanks to Reed Debaets for assistance with the development of Matlab code. Klaus Gessner
301 publishes with permission of the Executive Director, Geological Survey of Western Australia.
