17 **Abstract**

18 Porosity reduction in rocks from a fault core can cause elevated pore fluid pressures, and consequently influence the
19 recurrence time of earthquakes. We investigated the porosity distribution in the New Zealand's Alpine Fault core in
20 samples recovered during the first phase of the Deep Fault Drilling Project (DFDP-1B) by using two-dimensional
21 nanoscale and three-dimensional microscale imaging. Synchrotron X-ray microtomography-derived analyses of
22 open pore spaces show total microscale porosities in the range of 0.1-0.24%. These pores have mainly non-
23 spherical, elongated, flat shapes and show subtle bipolar orientation. Scanning and transmission electron microscopy
24 reveal the samples' microstructural organization, where nanoscale pores ornament grain boundaries of the gouge
25 material, especially clay minerals. Our data imply that: (i) the porosity of the fault core is very small and not
26 connected, (ii) the distribution of clay minerals controls the shape and orientation of the associated pores; (iii)
27 porosity was reduced due to pressure solution processes; and (iv) mineral precipitation in fluid-filled pores can
28 affect the mechanical behaviour of the Alpine Fault by decreasing the already critically low total porosity of the
29 fault core, causing elevated pore fluid pressures, and/or introducing weak mineral phases, and thus lowering the
30 overall fault frictional strength. We conclude that the current state of very low porosity in the Alpine Fault core is
31 likely to play a key role in the initiation of the next fault rupture.

32 **1. Introduction**

33 Fault mechanics, fault structure and fluid flow properties of damaged fault rocks are intimately related (e.g. Gratier
34 and Gueydan, 2007; Faulkner et al., 2010). Fault rupture is associated with intense brittle fracturing that enhances
35 porosity, and thus permeability, and therefore also possible rates and directions of fluid propagation within fault
36 zones (e.g. Girault et al., 2018). Conversely, post seismic recovery mechanisms (gouge compaction and pressure

37 solution processes) result in reductions of porosity, permeability and fluid flow (Renard et al., 2000; Faulkner et al.,
38 2010; Sutherland et al., 2012). These processes may cause elevated pore fluid pressures within fault cores, and
39 trigger frictional failure (e.g. Sibson, 1990; Gratier et al., 2003; Zhu et al., 2020). Therefore, the state of porosity
40 within rocks from fault cores can play a key role in fault slip.

41 The Alpine Fault of New Zealand is late in its seismic cycle (Cochran et al., 2017), so studying it allows us to
42 investigate pre-earthquake conditions that may influence earthquake nucleation and rupture processes. Recently,
43 drilling operations were undertaken in this fault zone to investigate the *in situ* conditions (Sutherland et al., 2012,
44 2017). Slug tests in the DFDP-1B borehole (Sutherland et al., 2012) and laboratory permeability measurements of
45 core samples (Carpenter et al., 2014) indicate permeability decreases by six orders of magnitude with increasing
46 proximity to the fault. Furthermore, Sutherland et al. (2012) documented a 0.53 MPa pressure difference across
47 the principal slip zone (PSZ) of the fault, which suggests that the fault core has significantly lower permeability than
48 the surrounding cataclasite units. It is therefore interpreted to act as a fault seal that limits fluid circulation within its
49 hanging wall (Sutherland et al., 2012). Permeability variations like this are closely associated with the porosity
50 evolution of fault cores, and thus are likely to affect the fault strength and seismic properties (Sibson, 1990; Renard
51 et al., 2000; Gratier and Gueydan, 2007).

52 In this study, we investigate the porosity distribution in rocks from the Alpine Fault core and consider the potential
53 effects of this porosity on fault strength. We have measured open pore spaces in these rocks from X-ray computed
54 tomography (XCT) datasets and examined pore morphology by implementing quantitative shape analyses.
55 Lithological and microstructural characteristics of these samples were performed by using scanning electron
56 microscopy (SEM) and transmission electron microscopy (TEM).

57 2. Geological setting

58 New Zealand's Alpine Fault (Fig. 1a) is a major active crustal-scale structure that ruptures in a large earthquake
59 every 291 ± 23 years, the last one of which occurred in 1717 (Cochran et al., 2017). The fault is the main constituent
60 of the oblique transform boundary between the Australian Plate and the Pacific Plate, accommodating around 75%
61 of the relative plate motion. Ongoing dextral strike-slip at 27 ± 5 mm yr⁻¹ along the fault has resulted in a total
62 strike-separation of ~ 480 km over the last 25 Ma (Norris and Cooper, 1995, 2001; Norris and Toy, 2014). In
63 Neogene time, a dip-slip component added to the fault motion has resulted in more than 20 km of vertical uplift of
64 the hanging wall (Norris and Cooper, 1995, 2001; Norris and Toy, 2014). Consequently, rocks comprising the
65 hanging wall of the fault have been exposed in various outcrops, where they can be studied in detail. The
66 amphibolite facies Alpine Schist is the metamorphic protolith of a ~ 1 km thick mylonite zone, which has been
67 exhumed from depth and now structurally overlies an up to 50 m thick zone of brittlely deformed cataclasites and
68 gouges (e.g. Norris and Cooper, 1995, 2001; Norris and Toy, 2014). These rocks have been investigated in outcrops
69 and from samples collected in three boreholes during the two phases of the Deep Fault Drilling Project (DFDP-1A,
70 DFDP-1B and DFDP-2B; Fig. 1a) along the Alpine Fault (Sutherland et al., 2012; Toy et al., 2015; Toy et al., 2017).

71 Most of the brittle shear displacement along the fault has been accommodated within the fault core, which includes
72 Principal Slip Zone (PSZ) gouges and cataclasite-series rocks (Toy et al., 2015). Both in surface outcrops and drill
73 core samples, the Alpine Fault manifests as a thin (5 to 20 cm thick) gouge zone with a predominantly random fabric
74 of clay-rich material (Toy et al., 2015; Schuck et al., 2020). This cohesive but uncemented layer has a grain size
75 significantly finer than the surrounding cataclasite units, which shows that the material was reworked only within
76 this layer, most probably as a result of ultra-comminution due to multiple shear events under brittle conditions
77 (Boulton et al., 2012; Toy et al., 2015). The local presence of authigenic smectite clays (Schleicher et al., 2015) and
78 calcite and/or chlorite mineralization within sealed fractures and in the gouge matrix (Williams et al., 2017) indicate
79 that mineral reactions are restricted to an alteration zone within the fault core (Sutherland et al., 2012; Schuck et al.,
80 2020). The Alpine Fault core has been interpreted to have formed during a cyclical history of mineralization, shear,
81 and fragmentation (Toy et al., 2015). In addition, in the DFDP-1B borehole (Fig. 1b, Sutherland et al., 2012) fault

82 gouges occur at two distinct depths: 128.1 m (PSZ-1) and 143.85 m (PSZ-2), which shows that the slip was not
83 localized within a single gouge layer (Toy et al., 2015).

84 **3. Sample description and analytical methods**

85 **3.1 Samples**

86 Porosity analyses were performed on four samples representing PSZ gouges and cataclasites of the Alpine Fault
87 core, which were recovered from the DFDP-1B borehole (Fig. 1b, c; Sutherland et al., 2012). These are DFDP-1B
88 58_1.9, DFDP-1B 69_2.48, DFDP-1B 69_2.54 and DFDP-1B 69_2.57. Sample nomenclature includes drill core run
89 number, section number, and centimeters measured from the top of each section. These samples were recovered
90 from drilled depth of 126.94 m, 143.82 m, 143.88 m and 143.91 m, respectively.

91 Detailed lithological and microstructural descriptions of the DFDP-1B drill core were carried out simultaneously
92 with, and after the drilling operations by the DFDP-1 Science Team, and these data were later summarized by Toy et
93 al. (2015). Samples DFDP-1B 58_1.9 and DFDP-1B 69_2.48 belong to foliated cataclasite units (Fig. 1b, c; Toy et
94 al., 2015), described as ultracataclasites with gouge-filled shear zones located above PSZ-1 and PSZ-2 respectively.
95 Sample DFDP-1B 69_2.54 represents the gouge layer that defines PSZ-2, whereas sample DFDP-1B 69_2.57 is
96 composed of brown ultracataclasites that belong to the lower cataclasite unit (Fig. 1b, c; Toy et al., 2015).

97 **3.2 X-ray computed tomography (XCT)**

98 We imaged the samples using X-ray absorption tomography, where the signal intensity depends on how electron
99 density and bulk density attenuate a monochromatic X-ray along its path through the material (e.g. Fuisseis et al.
100 2014). We acquired the X-ray microtomography data for this study at the 2-BM beamline of the Advanced Photon
101 Source, Argonne National Laboratories USA in December 2012. The non-cylindrical samples of ~7 mm height and
102 ~ 4 mm diameter were mostly drilled parallel to the foliation, mounted on a rotary stage, and imaged with a beam
103 energy of 22.5 keV. A charge-couple device camera collected images at 0.25° rotation steps over 180°. A sample-
104 detector distance of 70 mm yielded a field-of-view of 2.81 mm. The voxel size (i.e. spatial sampling) was 1.3 μm
105 and the spatial resolution ranged from two to three times the voxel size. We have reconstructed the datasets with a
106 filtered back-projection parallel beam reconstruction into 32-bit gray level volumes consisting of 2048 * 2048 *
107 2048 voxels using X-TRACT (Gureyev et al., 2011).

108 **3.3 Analyses of XCT datasets**

109 Data analyses and image processing were performed using the commercial software Avizo 9.1™ (Fig. 2). Initially,
110 the datasets were rescaled to 8-bit grey scale volumes for enhanced computer performance. In addition, small
111 volumes of interest were cropped from the whole volume before a non-local means filter was applied to reduce noise
112 (Buades et al., 2005). For each voxel, this filter compares the value of this voxel with all neighboring voxels in a
113 given search window. A similarity between the neighbors determines a correction applied to each voxel (e.g.
114 Thomson et al., 2018).

115 On the filtered gray-scale images, pores were identified as disconnected materials of the darkest grey-scale range
116 (Fig. 2a). The corresponding gray-scale values were thresholded, and the datasets were converted into binary form.
117 This step is called segmentation. Several segmentation techniques exist, from thresholding at a given gray scale
118 value (e.g. Ianossov et al., 2009; Andrew et al., 2013) to deep learning algorithms (Ma et al., 2020). It is up to the
119 user to choose the segmentation technique that is most appropriate to analyze a given dataset. To our knowledge, no
120 single segmentation technique can be generalized and universally used independently of the nature of the samples.
121 In the present study, we have chosen a simple segmentation technique by applying a threshold to the gray scale
122 images to separate the void space from the solid. This technique has been used in many studies in the last two
123 decades to characterize porosity in rocks, including some very recent studies in rock physics (Macente et al., 2019;
124 Renard et al., 2019). The segmented porosity volume depends strongly on the choice of the threshold and some

125 studies have demonstrated that the final porosity estimated by different segmentation methods can vary by 20%
126 (Andrä et al., 2013). However, when the level of noise in the data is low, the differences in porosities estimated by
127 different segmentation techniques is negligible (Andrew, 2018). Our data were acquired at a synchrotron where the
128 parallel beam and high photon flux ensured a low level of the noise in the images. In addition, application of a non-
129 local-means filter applied to our data reduced the noise level. For these reasons, we consider that it was robust to
130 apply a simple thresholding technique to this dataset but acknowledge that the porosity values we estimate could
131 differ by <20% from the ‘true’ porosity of the rock (cf. Andrä et al., 2013; Hapca et al., 2013).

132 However, our segmentation procedure also captured cracks within a sample, which are likely to result from
133 depressurization during core recovery (Fig. 2b). To omit the cracks, we utilized the morphological operation
134 ‘connected components’ available in the software Avizo 9.1, which allows volumes larger than selected number of
135 connected voxels to be excluded from the binary label images. To each sample we applied upper limits of 20 (43.94
136 μm^3), 50 (109.85 μm^3), 100 (219.7 μm^3) and 200 (439.4 μm^3) face connected voxels. Total porosities estimates
137 based on these operations are presented as percentages of the sample volume in Supplementary material 1.
138 Unfortunately, this methodology results in either loss of larger pores or inclusion of small cracks depending on the
139 implemented limit of connected components, and thus the calculated porosities include significant bias. Therefore,
140 the operation ‘connected components’ was used only for visualization purposes, and clusters of 200 face connected
141 voxels were created to show the 3D volumes of segmented pore spaces (Fig. 2c)

142 Instead, the volumes and shape characteristics of segmented materials (including cracks i.e. without any data
143 limitation) were exported from Avizo software in numerical format, and volume distributions within a sample were
144 plotted on a logarithmic scale (Fig. 3). Data up to a specific volume size were fit to a polynomial curve, and then the
145 curve was extrapolated to the X-axis intercept, which is the expected maximum pore size (Fig. 3). For each sample
146 the total porosity was then estimated by integrating the curve, which excludes all volumes on the right side of the
147 curve. Total porosities are presented as a percentage of the whole sample volume (Fig. 3). The implemented
148 equations are given in Supplementary material 1.

149 Pore shapes were analyzed on bivariate histograms plotted by using the numerical pore characteristics, previously
150 extracted from Avizo software. Only pore volumes between 21.97 μm^3 (10 voxels) and 878.8 μm^3 (400 voxels) were
151 included to avoid bias in the data due to insufficient voxel count and presence of cracks, respectively. Individual
152 pores in our dataset are separated (Fig. 2c). The covariance matrix of each pore was calculated, and the three
153 eigenvalues of this covariance matrix were extracted. These three values correspond to the three main orthogonal
154 directions in each pore (i.e. the longest, medium and shortest axes) and we use them as proxies to describe pore
155 geometry. Thus, their amplitudes provide information on the spatial extension of a given pore and its shape. The
156 ratio between the medium and largest eigenvalues of each pore defines its elongation (Fig. 4), the ratio between the
157 smallest and the largest eigenvalues defines its sphericity (Fig. 5), and the ratio of the smallest and the medium
158 eigenvalues defines its flatness (Fig. 6).

159 The angles θ and φ that describe the orientation of the longest eigenvalue (i.e. axis) of each pore with respect to the
160 global orthogonal axes system of the 3D scan were calculated. These angles were translated into trend and plunge
161 and then plotted on a lower hemisphere equal area stereographic projection with a probability density contour to
162 display the distribution of pore unit orientations (Fig. 7).

163 3.4 Scanning electron microscopy (SEM)

164 SEM images were collected on Zeiss Sigma-FF-SEM at the University of Otago's Centre for Electron Microscopy.
165 The SEM was operated at a working distance of 8.5 mm, an **accelerating** voltage of 10 keV and a 120 μm aperture
166 with dwell time of 100 μs . EDS maps were created by using Aztec Software ([https://www.oxford-](https://www.oxford-instruments.com/products/microanalysis/energy-dispersive-x-ray-systems-eds-edx/eds-for-sem/eds-software-aztec)
167 [instruments.com/products/microanalysis/energy-dispersive-x-ray-systems-eds-edx/eds-for-sem/eds-software-aztec](https://www.oxford-instruments.com/products/microanalysis/energy-dispersive-x-ray-systems-eds-edx/eds-for-sem/eds-software-aztec)).

168 3.5 Transmission electron microscopy (TEM)

169 TEM images were collected on a FEI Tecnai G2 F20 X-Twin transmission electron microscope, located at the
170 German Research Centre for Geosciences (GFZ), Potsdam, Germany (Fig. 9). The instrument is equipped with field-
171 emission gun (FEG) electron source and high-angle annular dark-field (HAADF) Detector. Images were collected
172 from samples placed on a Gatan double-tilt holder at an accelerating voltage of 200kV. These TEM samples were
173 prepared by focused ion beam (FIB) milling at GFZ Potsdam using a HELIOS system operated at an accelerating
174 voltage of 30 kV.

175 **4 Results**

176 **4.1 XCT-derived characteristics of porosity**

177 All samples contain low total porosities, ranging from 0.1% to 0.24% (Fig. 3). If different segmentation techniques
178 were applied, a variability in the range that Andrew (2018) demonstrated is reasonable, from nearly 0% to 20%,
179 would correspond to porosities between 0.08% and 0.29% in our samples. It can be noted that the lower cataclasite
180 sample (DFDP-1B 69_2.57) has twice as much pore space (Fig. 3d) as any of the other samples. The characterized
181 pore volume distributions range over almost three orders of magnitude for all samples (Fig. 3). Furthermore, the
182 expected maximum pore volume was estimated to be largest in the PSZ-2 sample (DFDP-1B 69_2.54), reaching 862
183 μm^3 (Fig. 3c).

184 In all samples, shape analyses of pores with volumes between $21.97 \mu\text{m}^3$ (10 voxels) and $878.8 \mu\text{m}^3$ (400 voxels)
185 demonstrate predominantly elongated (Fig. 4), non-spherical (Fig. 5) and flat pore shapes (Fig. 6). This is
186 particularly pronounced for the smaller pore volumes. The number of elongated pores per sample increases in the
187 upper foliated cataclasites (Fig. 4a and b) with increasing proximity to PSZ-2, where most elongated pores occur
188 (Fig. 4c). Conversely, the lower cataclasite sample demonstrates proportionally fewer elongated pores within the
189 sample (Fig. 4d). The degree of sphericity is uniform for all samples, and pores appear as mainly non-spherical (Fig.
190 5). Few isolated spherical pores are manifested only by small pore volumes (Fig. 5). A trend of increasing the
191 number of flat pores is observed with increasing sample depth (Fig. 6), and most flat pores are detected in the lower
192 cataclasite (Fig. 6d).

193 The orientations of the individual pore units show two distinctive peaks with opposite vergence, defining bipolar
194 distributions of pore orientations (Fig. 7). The observed bipolarity is subtle in samples DFDP-1B 58_1.9 (Fig. 7a)
195 and DFDP-1B 69_2.48 (Fig. 7b), and more obvious in samples DFDP-1B 69_2.54 (Fig. 7c) and DFDP-1B 69_2.57
196 (Fig. 7d).

197 **4.2 Microstructural characteristics of porosity**

198 To demonstrate the microstructural arrangement of the cataclasites, we show representative SEM images from
199 sample DFDP-1B 69_248 (Fig. 8), previously described as a ‘lower foliated cataclasite’ by Toy et al., 2015. SEM
200 images presented here reveal rounded to sub-rounded crystalline clasts up to $100 \mu\text{m}$ in diameter (Fig. 8a, b), which
201 consist of ~50 % plagioclase, ~40 % K-feldspar, and ~10 % quartz and are elongated at angles of 0-30° to the
202 foliation. The surrounding matrix material is composed of finer grains (< $30 \mu\text{m}$ in diameter) of white micas,
203 chlorite, K-feldspar, calcite and Ti-oxide (Fig. 8c). Numerous quartz clasts contain microfractures, filled by calcite
204 and/or chlorite.

205 TEM characterization of the gouge material from PSZ-2 (sample DFDP-1B 69_2.54) reveals that the Alpine Fault
206 gouges are composed of angular quartz and/or feldspar fragments (~200 nm in size), wrapped by smaller
207 phyllosilicates (< 100 nm long). This random fabric is ornamented by nanoscale pores (< 50 nm), distributed along
208 all grain and phase boundaries, but especially abundant within/around clay minerals (Fig. 9a).

209 The gouge material also demonstrates phyllosilicate-rich areas, defined by an increase in the clay/clast ratio. In these
210 zones, fine (< 100 nm long) and coarser (few μm long) clay grains coexist and are aligned in wavy fabric that

211 surrounds sporadic protolith fragments (Fig. 9b). Pore spaces are again distributed along the boundaries of the
212 constituent mineral grains but some of them are larger ($\sim 0.5 \mu\text{m}$) with thin ellipsoidal or elongated shapes (Fig. 9b,
213 c). These pores are commonly associated with inter-clay layer porosity. Large size pores are also observed along
214 quartz-feldspar phase boundaries. These latter pores are associated with multiple grains and occasionally disrupt the
215 boundaries, thus were labelled as fracture porosity (Fig. 9d).

216 **5 Discussion**

217 **5.1 Characteristics of porosity within the Alpine Fault core**

218 Porosity analyses of samples from, or in close proximity to the two PSZs encountered in the DFDP-1B drill core
219 reveal total pore volumes between 0.1% and 0.24% (Fig. 3). These values are significantly lower than the porosity
220 estimates from other active faults in the world, such as: 0.2 to 5.7% total porosity in the core of the Nojima Fault,
221 Japan (Surma et al., 2003) and 0 to 18% in the San Andreas Fault core (Blackburn et al., 2009). The Alpine Fault
222 core contains total pore space volumes comparable only with the lower porosities in these previous studies. It should
223 be noted that the smallest pore spaces captured in the XCT datasets are $1.3 \mu\text{m}$ in size due to acquisition constraints,
224 whereas nanoscale porosity was identified on the TEM images. Therefore, the estimated total porosities from XCT
225 data represent only minimum values of the open pore spaces in the Alpine Fault core.

226 TEM images presented here mainly focus on nano-scale materials (Fig. 9a, c, d) but were also used to describe the
227 distribution of micro-porosity in these rocks (Figure 9b). The pores visible on grain and phase boundaries in figure
228 9b have similar sizes to the pores segmented on XCT images ($> 1.3 \mu\text{m}$ in diameter), thus we conclude that this is
229 the typical habit of both nano- and micro-pores within the Alpine Fault core (Fig. 9). In addition, both quantitative
230 micro-porosity shape analyses (Fig. 4, 5 and 6) and nano-pores identified on TEM images (Fig. 9) reveal that a
231 significant population of pores are predominantly non-spherical with elongated, flat shapes. We attribute this
232 observation to the tendency of these pores to ornament clay minerals where pores are distributed and elongated
233 along their (001) planes (Fig. 9b, c and d).

234 Foliation in the upper cataclasites is defined by clay-sized phyllosilicates, that become more abundant with
235 proximity to the PSZ (Toy et al., 2015), where a weak clay fabric is developed (Schleicher et al., 2015). This gradual
236 enrichment in clay minerals coincides with the subtle development of bipolar distributions of pore orientations with
237 increasing sample depth (Fig. 7). This observation and the fact that pores are mainly distributed along grain
238 boundaries of clays (Fig. 9) suggest that the distribution of clay minerals also controls pore orientations within the
239 Alpine Fault core. Previously, the phyllosilicate foliation in the Alpine Fault cataclasites has been used to define
240 shear direction (Toy et al., 2015). Thus, we speculate that pore orientations in these rocks are also systematically
241 related to the kinematic framework of the shear zone. If these pores represent remnants of fluid channels, their
242 spatial orientation is likely to reflect the fluid flow directions during deformation. To address this possibility more
243 data for systematic analyses of pore orientations are needed.

244 **5.2 Porosity reduction within the Alpine Fault core**

245 The comparatively lower porosity estimates of the Alpine Fault core than other active faults (e.g. the Nojima Fault,
246 Surma et al., 2003, and the San Andreas Fault, Blackburn et al., 2009) could be attributed to the fact that the Alpine
247 Fault is late in its c. 300 year seismic cycle and the last seismic event occurred in 1717 (Cochran et al., 2017). Thus,
248 we propose that the fault has almost completely sealed. Porosity of fault cores is believed to evolve during the
249 seismic cycle, since fault rupture can cause porosities to increase up to 10% (Marone et al., 1990), and subsequent
250 healing mechanisms (such as mechanical compaction of the fault gouge and/or elimination of pore spaces within the
251 fault core due to pressure solution processes) cause porosity to decrease over time (Sibson, 1990; Renard et al.,
252 2000; Faulkner et al., 2010). SEM data presented here show that fine-grained chlorite and muscovite grains formed
253 as a cement in the cataclastic matrix (Fig. 8c). Our TEM data reveal the abundance of newly precipitated authigenic
254 clays, wrapped around coarser clay minerals (Fig. 9b). Furthermore, delicate clay minerals form fringe structures

255 (Fig. 9a), and strain shadows (Fig. 9c) around larger quartz-feldspar grains. These microstructural observations
256 demonstrate that pressure solution processes operated within these rocks (Toy et al., 2015).

257 Evidence for pressure solution processes has been previously documented in all units, comprising the Alpine Fault
258 core (Toy et al., 2015). Abundant precipitation of alteration minerals (Sutherland et al., 2012), calcite filled
259 intragranular and cross-cutting veins (Williams et al., 2017), and the occurrence of newly formed smectite clays
260 (Schleicher et al., 2015) indicate extensive fluid-rock reactions. In addition, anastomosing networks of opaque
261 minerals (such as graphite; Kirilova et al., 2017), which define foliation in the upper cataclasites (Toy et al., 2015),
262 have been interpreted to be concentrated by pressure solution processes during aseismic creep (Toy et al., 2015;
263 Gratier et al., 2011). The petrological characteristics of the Alpine Fault core lithologies indicate that solution
264 transfer was likely the dominant mechanism for pore closure within these rocks.

265 Porosity estimates presented here are so low that presumably negligible variations in between samples can represent
266 significant gradients in porosity. For example, the increase of total porosity in sample DFDP-1B 69-2.57 with only
267 0.14%, manifests as twice as many open pore spaces in comparison to the rest of the analyzed samples (Fig. 3). In
268 addition, this is the only footwall sample analyzed here and as already mentioned in section 3.1 does not contain any
269 gouge material. Post-rupture porosity reduction is known to operate three to four times faster within fine-grained
270 fault gouges than in coarser-grained cataclasites (Walder and Nur, 1984; Sleep and Blanpied, 1992; Renard et al.,
271 2000) which may explain the porosity differences demonstrated above. Furthermore, previous studies documented
272 less carbonate and phyllosilicate filling of cracks in the Alpine Fault footwall cataclasites than in the hanging wall
273 cataclasites (Sutherland et al., 2012; Toy et al., 2015), suggesting more reactive fluids are present and isolated
274 within the hanging wall of the Alpine Fault. Thus, more intense dissolution-precipitation processes took place in the
275 fault's hanging wall, which very likely resulted in more efficient porosity reduction, as demonstrated by our porosity
276 estimates (Fig. 3).

277 **5.3 Effects of porosity on the Alpine Fault strength**

278 Very low porosity estimates are presented here (Fig. 3). Very low permeabilities of 10^{-18} m² were also measured
279 experimentally in clay-rich cataclasites and gouges from the Alpine Fault zone (Carpenter et al., 2014). In addition,
280 the documented difference of total porosities between the hanging wall and footwall samples (Fig. 3) may be
281 interpreted to reflect different intensities of pressure solution processes, and thus compartmentalization of
282 percolating fluids. Our porosity data show a spatial trend similar to the permeability measurements of Carpenter et
283 al. (2014). This observation yields increased confidence in the interpretation of Carpenter et al. (2014) of a
284 permeability gradient with distance from the PSZ, which itself acts as a hydraulic seal (Sutherland, et al., 2012). The
285 existence of such a barrier to flow is characteristic for faults undergoing creep and locked faults (Rice, 1992;
286 Labaume et al., 1997; Wiersberg and Erzinger, 2008). However, much higher permeabilities in the surrounding
287 damaged rocks (Carpenter et al., 2014) allow fast propagation of fluids within them and can cause localization of
288 high fluid pressures on one side or the other of a hydraulic seal (Sibson, 1990). Such fluid pressures can enhance
289 gouge compaction and pressure solution processes, which will eventually introduce zones of weakness and thus may
290 trigger fault slip (Faulkner et al., 2010).

291 Previous studies and the observations presented here show that fluids were present in the Alpine Fault rocks. Fluid-
292 filled pores represent a favorable environment for mineral precipitation, which can affect the fault strength in two
293 ways: (i) Very small decrease of these critically low total porosities due to mineral precipitation would cause fluid
294 pressurization, which is a well-known fault weakening mechanism described by Byerlee (1990) and Sibson (1990);
295 however, this pressure increase could be slightly offset by inclusion of fluids into new hydrous minerals; (ii)
296 deposition of frictionally weak phases (such as clay minerals and graphite), especially if they decorate grain contacts
297 and/or form interlinked weak layers, would lower the overall frictional strength (Rutter et al., 1976; Niemeijer et al.,
298 2010).

299 Precipitated authigenic clay minerals were identified in our TEM data (Fig. 9) and also documented by previous
300 studies (Schleicher et al., 2015). As well as having low frictional strengths (Moore and Lockner, 2004), clay
301 minerals may also contribute to the formation of an impermeable seal if they form an aligned fabric, which can
302 enhance the likelihood of fluid-pressurization in the fault rocks (Rice, 1992; Faulkner et al., 2010). In addition,
303 graphite, which was previously documented in these rocks (Kirilova et al., 2017), may effectively weaken the fault
304 due to mechanical smearing (Rutter et al., 2013) and/or localized precipitation within strained areas (Upton and
305 Craw, 2008). Such graphite precipitation within shear surfaces was previously documented by Kirilova et al. (2017).

306 In summary, the presence of trapped fluids in the low porosity rocks of the Alpine Fault core possibly controls the
307 mechanical behavior of the fault and could be responsible for future rupture initiation due to fluid pressurization
308 and/or precipitation of weak mineral phases. This hypothesis is further supported by an experimental study showing
309 that the DFDP-1 gouges are frictionally strong in the absence of elevated fluid pressure (Boulton et al., 2014).

310 **6 Conclusions**

311 Analyses of XCT-datasets and TEM images of borehole samples from the core of the Alpine Fault reveal micro- and
312 nanoscale pores, distributed along grain boundaries of the constituent mineral phases, especially clay minerals. The
313 tendency of these pores to ornament clays defines their predominantly non-spherical, elongated, flat shapes and the
314 bipolar distribution of pore orientations. The documented extremely low total porosities (in the range 0.1-0.24 %) in
315 these rocks suggest effective porosity reduction and fault healing. Microstructural observations presented here and
316 documented in previous studies indicate that pressure solution processes were the dominant healing mechanism, and
317 that fluids were present in these rocks. Therefore, fluid-filled pores may be places where elevated pore fluid
318 pressures develop, due to further mineral precipitation that decreases the already critically low total porosities.
319 Alternatively, these pores may also facilitate the deposition of weak mineral phases (such as clay minerals and
320 graphite) that may very effectively weaken the fault. We conclude that the current state of the fault core porosity is
321 possibly a controlling factor on the mechanical behaviour of the Alpine Fault and will likely play a key role in the
322 initiation of the next fault rupture.

323 **Data availability.**

324 Matlab scripts and numerical data of pore volumes can be found in Supplementary material 1.

325 **Authors contribution**

326 Kirilova reconstructed, processed, and analysed the XCT datasets presented here, interpreted the TEM data and
327 prepared the manuscript. Most of this work was performed during Kirilova's PhD under the academic guidance of
328 Toy. Toy and Gessner collected the XCT data with technical support by Xiao. Renard and Sauer contributed with
329 valuable discussion about XCT data analyses and edited the manuscript. Wirth enabled TEM data acquisition and
330 provided his expertise on TEM data interpretation. Matsumura collected and analyzed the presented SEM data. The
331 final version of this manuscript benefits from collective intellectual input.

332 **Competing interests**

333 The authors declare that they have no conflict of interest.

334 **Acknowledgments**

335 We gratefully acknowledge funding from the Advances Photon Source (GUP 31177). This research used resources
336 of the Advanced Photon Source, a U.S. Department of Energy (DOE) Office of Science User Facility operated for
337 the DOE Office of Science by Argonne National Laboratory under Contract No. DE-AC02-06CH11357. Avizo
338 workstation was built at the University of Otago with financial support provided by Nvidia Corporation, Royal

339 Society of New Zealand`s Rutherford fellowships (16-UOO-001), the Ministry of Business and Innovation`s
340 Endeavor Fund (C05X1605/GNS-MBIE00056), and a subcontract to the Tectonics and Structure of Zealandia
341 Program at GNS Science (GNS-DCF00020). Publishing bursary funding provided by the University of Otago is
342 greatly appreciated. We thank Sherry Mayo for helping with the reconstruction process of XCT data and Andrew
343 Squelch for providing use of the Avizo workstation, located at CSIRO, Perth, Australia during the initial data
344 analyses. Special thanks to Reed Debaets for assistance with the development of Matlab code. Klaus Gessner
345 publishes with permission of the Executive Director, Geological Survey of Western Australia.

503

504

Figure 7. Distribution of pore unit orientations plotted on a lower hemisphere equal area stereographic projection with a probability density contour.

505

506 **Figure 8.** Scanning electron images collected from sample DFDP 1B 69-2.48 showing the existing mineral
507 associations. (a) Sub-rounded and intensely fractured quartz and white mica clasts, within fine matrix material. (b)
508 Reworked cataclasite clasts in phyllosilicate-rich matrix. (c) Fine chlorite and white mica aggregates between quartz
509 clasts. (Qtz = quartz, Wm = white mica, Chl = chlorite).

510
 511 **Figure 9.** Transmission electron microscopy images collected from the gouge sample DFDP-1B 69_2.54 (PSZ-2).
 512 (a) and (c) are bright-field (BF) images, where porosity appears as bright contrast areas. (b) and (d) are high-angle
 513 annular dark field (HAADF) images, where pores appear as dark contrast areas. (a) TEM bright-field image of
 514 homogeneous fault gouge area. Quartz/feldspar grains, wrapped by fine authigenic clays, displaying fringe
 515 morphologies. Pores with sub-angular shape distributed along grain boundaries. (b) HAADF image of phyllosilicate-
 516 rich gouge area. Co-existence of fine authigenic clays with coarser clay mineral grains. Elongated pores and
 517 interlayer porosity. (c) TEM bright-field image of ellipsoidal pores in phyllosilicate-rich areas. Examples of strain
 518 shadows along quartz/feldspar grains. (d) HAADF image of fracture porosity along grain boundaries of
 519 quartz/feldspar grains.
