10 **Abstract.** This paper presents selected results of a broader research project pertaining to the hydraulic fracturing of oil reservoirs hosted in the siltstones and fine grained sandstones of the Bakken Formation in southeast Saskatchewan, Canada. The Bakken Formation contains significant volumes of hydrocarbon, but large-scale hydraulic fracturing is required to achieve economic production rates. The performance of hydraulic fractures is strongly dependent on fracture attributes such as length and width, which in turn are dependent on in-situ stresses.

15 This paper reviews methods for estimating changes to the in-situ stress field (stress shadow) resulting from mechanical effects (fracture opening), poro-elastic effects, and thermo-elastic effects associated with fluid injection for hydraulic fracturing. The application of this method is illustrated for a multi-stage hydraulic fracturing operation, to predict principal horizontal stress magnitudes and orientations at each stage. A methodology is also presented for using stress shadow models to assess the potential for inducing shear failure on natural fractures.

20 The results obtained in this work suggest that thermo and poro-elastic stresses are negligible for hydraulic fracturing in the Bakken Formation of southeast Saskatchewan, hence a mechanical stress shadow formulation is used for analyzing multistage hydraulic fracture treatments. This formulation (and a simplified version of the formulation) predicts an increase in instantaneous shut-in pressure (ISIP) that is consistent with field observations (i.e., ISIP increasing from roughly 21.6 MPa to values slightly greater than 26 MPa) for a 30-stage fracture treatment. The size of predicted zones of shear failure on natural  
25 fractures are comparable with the event clouds observed in microseismic monitoring when assumed values of 115°/65° are used for natural fracture strike/dip; however, more data on natural fracture attributes and more microseismic monitoring data for the area are required before rigorous assessment of the model is possible.

## 30 1 Introduction

During fracturing operations, the changes in principal stress magnitudes and orientations induced in the reservoir during a given fracture stage may alter the conditions for the subsequent stages, giving rise to the so-called “stress shadow” effect (see Figure 1). Stress shadows can impact the effectiveness of fracturing operations by increasing the injection pressures required to create and propagate fractures, reducing fracture width, and potentially altering fracture trajectory (Nagel et al., 2013; Zangeneh et al., 2015; Gorjian & Hawkes, 2017; Patterson, 2017; Roussel, 2017). The design of effective fracture stimulation treatments in a reservoir requires analysis of the geomechanical attributes of the reservoir and the prediction of stress shadow effects (Smith & Montgomery, 2015; Suppachoknirun and Tutuncu, 2017).

Analytical solutions exist for modeling stress shadows under idealized conditions (e.g., homogeneous and isotropic rock properties; linear elastic material behaviour; 2-dimensional, plane strain geometry). The following is a summary of stress shadow mechanisms and the corresponding references for available analytical solutions. The equations drawn from literature and used in this work are presented in Section 2.

- Mechanical stress shadow; i.e., the stress increase caused by a fracture as it “pushes” outwards on the rock mass on either side of the fracture plane. A conceptual model for the mechanical stress shadow is given in Figure 2. General expressions for the resulting induced stress field were presented by Warpinski (1989), Pollard and Segall (1987), and can also be found in Ge and Ghassemi (2008). The Gohfer software also calculates stress shadow by using a 1-D analytical solution for the point-load stress shadow presented by Boussinesq (1885).
- Poro-elastic stress shadow; i.e., increasing pore pressure due to fluid leak-off into the reservoir rock matrix causing dilation of the reservoir and consequently a reduction in fracture width. Equations for the resulting induced stress field were presented by Koning (1985), Perkins and Gonzalez (1985) and Ge and Ghassemi (2008).
- Thermo-elastic stress shadow; i.e., the stress reduction caused by reservoir contraction associated with temperature drop due to the use of a fracture fluid with temperature that is cooler ( $T_f$ ) than the native reservoir temperature ( $T_R$ ). Equations for the resulting induced stress field were presented by Perkins and Gonzalez (1985), and can also be found in Ge and Ghassemi (2008).

The main objective of this research was to develop a better understanding of the combined effects of mechanical, thermos- and poro-elastic stress shadows during the process of hydraulic fracturing, with application to the Bakken Formation (a tight oil reservoir) in western Canada.

Pursuit of this objective was achieved by undertaking the following tasks:

- Developing analytical models for quantifying the effects of stress shadows, and using these models to analyse thermo-hydro-mechanical stress perturbation (stress shadow) around hydraulic fractures as a function of the reservoir depth, in-situ stress ratio, wellbore spacing and injection rate.
- Testing the thermo-hydro-mechanical stress shadow model by comparing its results with field data.

The relatively simple stress shadow formulation developed in this project can be used easily on site to assess the effects of stage spacing on fracture pressure and (potentially) fracture orientation, improving fracture stimulation design.

65 The methodology developed in this work can also be extended to predict zones of possible rock failure (due to shearing) around a hydraulic fracture. If there is a large-scale discontinuity around the wellbore, failure on that discontinuity due to hydraulic fracture can be assessed and that assessment can mitigate the potential for operational problems due to reactivation. Predicting the failure zone associated with slip on smaller natural fractures around a hydraulic fracture is also valuable for predicting stimulated reservoir volume. As such, the following task was additional undertaken in this work:

- 70 • Using stress shadow modeling results to assess the potential for induced shear failure on natural fractures, as a means of predicting the dimensions of the microseismic cloud area around a hydraulic fracture.

## 2 Analytical Models for Stress Shadow Distribution

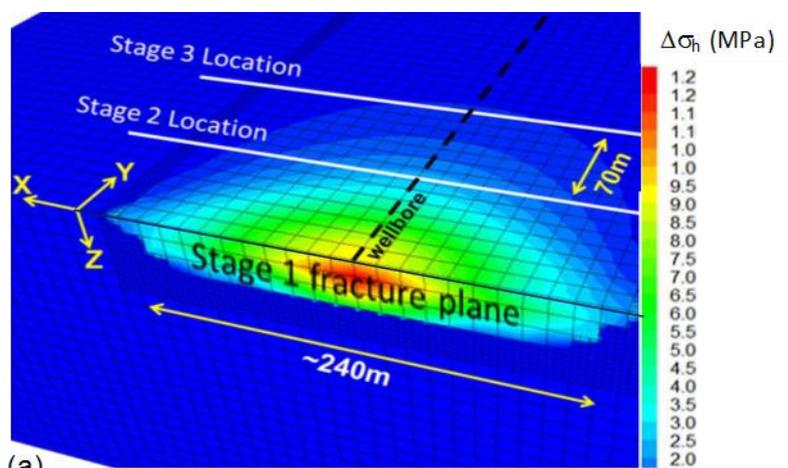

### 2.1 Workflow for Using Analytical Stress Shadow Models in Tandem with a Numerical Fracture Simulator

75 This section presents equations to analyze and calculate the stress shadow existing at each stage of hydraulic fracturing due to the cumulative effects of the previous stages. The workflow used to implement these stress shown models in combination with a numerical fracture simulator is shown in Figure 3. In this work, hydraulic fracture dimensions and pressures were predicted using the commercial fracture simulator GOHFER (Barree and associates, 2016).

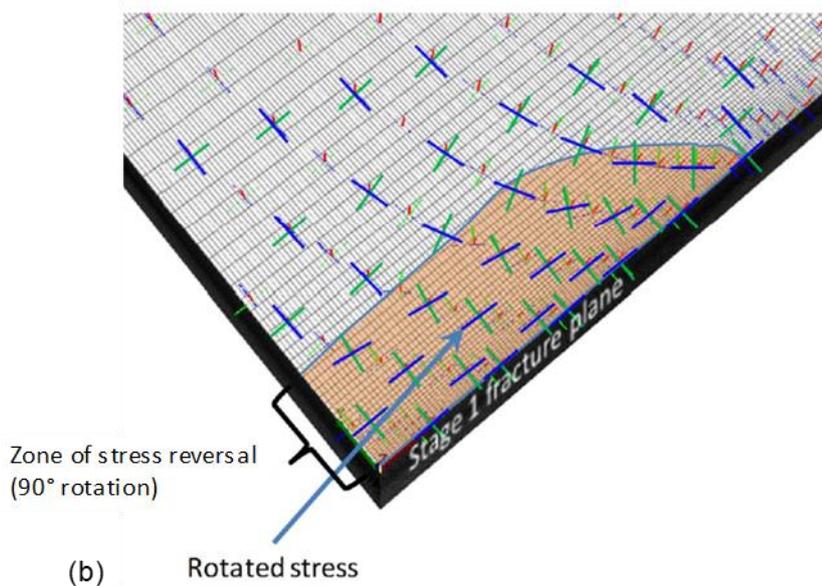

80 The process begins by simulating the first fracture stage with GOHFER using the initial in-situ stress state as model input. The time interval simulated includes the injection period as well as the ensuing pressure falloff, up to the point in time when the second fracture stage is undertaken. At this point, key attributes of the fracture (length, average width, average pressure) are taken and used as inputs for the stress shadow equations. In turn, these equations provide estimates of stress changes induced at the location of the second fracturing stage, which are superimposed on the original in-situ stress state to yield a revised stress state. This revised stress state is used as input for a GOHFER simulation of the second fracture stage. The workflow is then repeated for each subsequent fracture stage, with the stress shadow effects of all preceding stages accounted for.

85 GOHFER was chosen for this work as a simulator. The rationale for this choice was based on the fact that this modeling tool strikes a balance between being physically robust (in terms of physical processes directly associated with hydraulic fracture behaviour) while being sufficiently practical and accessible to be widely used in the petroleum industry. As such, the results of this work would be reliable in form and content to industry personnel, and new insights and methods would have greater potential for being adopted in practice.

90 The following sections present the equations that have been identified to enable prediction of stress shadow are based on mechanical, thermal and poro-elastic mechanisms.

(a)

(b)

Figure 1: Scenarios Examples illustrating the stress shadow effect resulting from the creation of a hydraulic fracture: (a) Change in minimum horizontal stress magnitude ( $\Delta\sigma_h$ ) resulting from the first fracture stage; and (b) orientations of maximum horizontal (green lines) and minimum horizontal (dark blue lines) stresses, for an extreme case in which stress reversal ( $90^\circ$  stress rotation) occurs near the hydraulic fracture. (After Oilfield Geomechanics, 2015)

95

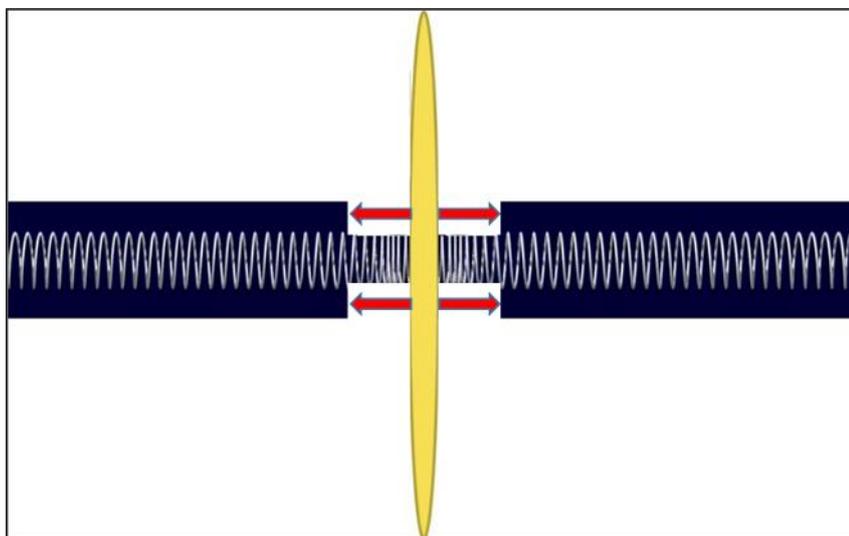

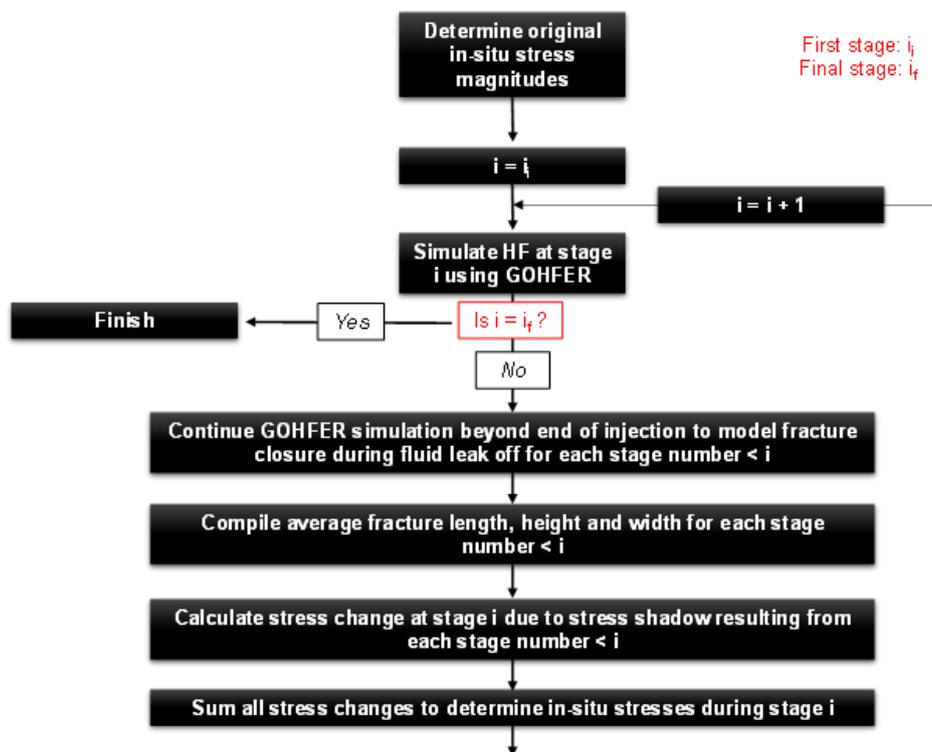

Figure 2: Conceptual model for mechanical stress shadow. As the fracture opens, it pushes outwards on rock mass on either side of the fracture plane and it may increase stress (Gorjian & Hawkes, 2017).

100

Figure 3: Algorithm which is applied for calculating stress shadow in multi-stage hydraulic fracturing (HF) treatment.  $i$  denotes stage number (varying from 1 to  $n$ ), and HF denotes hydraulic fracture.

## 2.2 Mechanical Stress Shadow

105 For the calculation of mechanical stress shadow around a fracture, an improved version of the Pollard and Segall (1987) method was used (Figure 4). Ge and Ghassemi (2008) have also used this technique. The hydraulic fracture is assumed to be a 2-D crack with an average propped width of  $\varpi$ . The equations from Pollard and Segall (1987) are given in equations 1 to 9, as follows.

$$\Delta\sigma_X = -\frac{2E'\varpi}{\pi h} \left[ Rr^{-1} * \cos(\theta - \theta_{ave}) - 1 - (L/2)^2 Rr^{-3} \sin(\theta) \sin(3\theta_{ave}) \right] + (\tau_{XY} - \tau_{XY}^c) \left[ (L/2)^2 Rr^{-3} \sin(\theta) \sin(3\theta_{ave}) \right] \quad (1)$$

$$\Delta\sigma_Y = -\frac{2E'\varpi}{\pi h} \left[ Rr^{-1} * \cos(\theta - \theta_{ave}) - 1 + (L/2)^2 Rr^{-3} \sin(\theta) \sin(3\theta_{ave}) \right] + (\tau_{XY} - \tau_{XY}^c) \left[ (L/2)^2 Rr^{-3} \sin(\theta) \cos(3\theta_{ave}) \right] \quad (2)$$

$$\Delta\tau_{XY} = (\tau_{XY} - \tau_{XY}^c) \left[ Rr^{-1} * \cos(\theta - \theta_{ave}) - 1 - (L/2)^2 Rr^{-3} \sin(\theta) \sin(3\theta_{ave}) \right] - \frac{2E'\varpi}{\pi h} \left[ (L/2)^2 Rr^{-3} \sin(\theta) \cos(3\theta_{ave}) \right] \quad (3)$$

$$\text{And } \Delta\sigma_Z = \nu(\Delta\sigma_X + \Delta\sigma_Y) \quad (4)$$

$$\text{Where } R = \sqrt{X^2 + Y^2}, \theta = \tan^{-1}(Y/X) \quad (5)$$

$$R_1 = \sqrt{Y^2 + (L/2 - X)^2}, \theta_1 = \tan^{-1}[Y/(X - L/2)] \quad (6)$$

$$R_2 = \sqrt{Y^2 + (X + L/2)^2}, \theta_2 = \tan^{-1}[Y/(X + L/2)] \quad (7)$$

$$r = \sqrt{R_1 R_2}, \theta_{ave} = \frac{\theta_1 + \theta_2}{2} \quad (8)$$

$\tau_{xy}$  and  $\tau_{xy}^c$  = in-situ shear stress and shear stress on the crack surface (assumed zero because hydrostatic pressure of fracture fluid, inside of the crack, doesn't create shear stress on the crack surface)

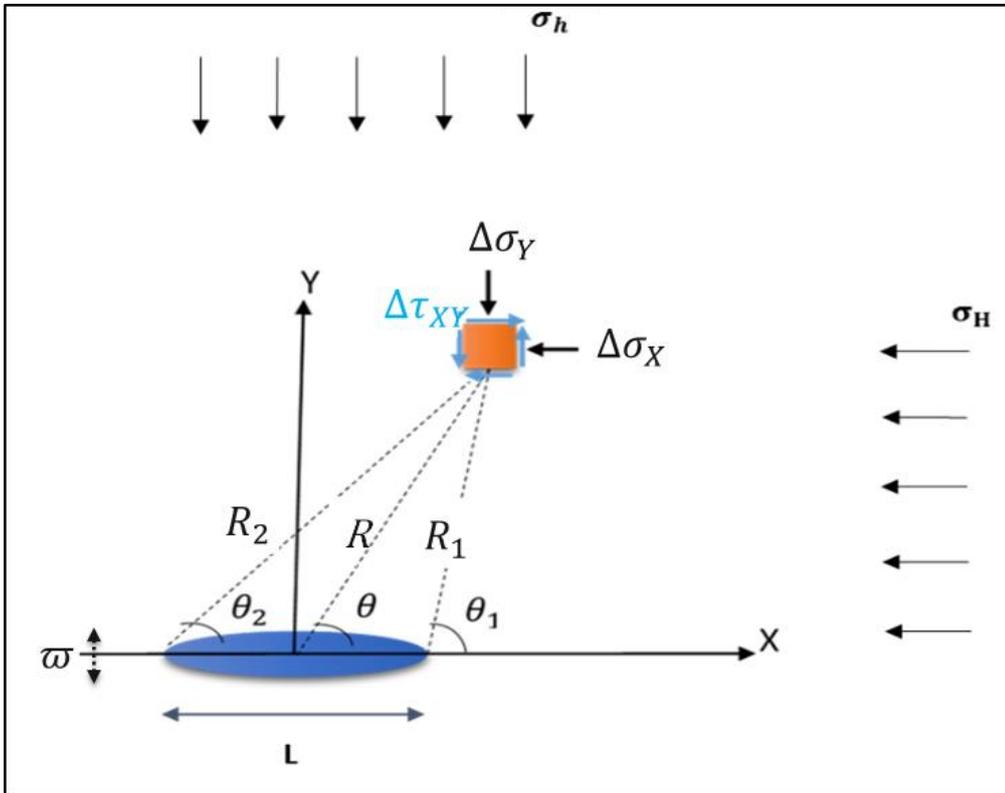

$\Delta\sigma_X, \Delta\sigma_Y$  and  $\Delta\sigma_Z$  = induced stress in X, Y and Z directions.

$\Delta\tau_{XY}$  = induced shear stress in X-Y plane

$$E' = \frac{E}{(1-\nu^2)} \quad (9)$$

Negative values of angles  $\theta$ ,  $\theta_1$  and  $\theta_2$  (shown in Figure 3) should be corrected by adding  $180^\circ$  ( $\pi$  radians). Values for  $L$  and  $w$  are taken from Gohfer simulation output for the prior hydraulic fracture stages.

110

Figure 4: Induced mechanical stress around the fracture. The orange square represents an element volume of the formation and is exaggerated in dimensions for the purpose of stress visualization (after Ge & Ghassemi, 2008).

### 2.3 Thermo-elastic Stress Shadow

115

In Most studies in thermo-elastic stresses have been conducted in the field of geothermal production (Ge & Ghassemi, 2008). In the petroleum industry, the thermo-elastic stress shadow is often considered to be insignificant due to the small difference in temperature between the injected fluid and in-situ rock. As a result, it is assumed that temperature is distributed uniformly and elliptically around the fracture and that the rock temperature increases outwards as a fracture propagates and injection

continues. The cool region (i.e., rock within the ellipse of semi-axes  $a_0$  and  $b_0$  in Figure 5) is assumed to have the same  
 120 temperature as the injected fluid, and the unaffected region (i.e., rock exterior to the ellipse of semi-axes  $a_0$  and  $b_0$ ) remains  
 constant at the in-situ reservoir temperature.

For the cool region, thermo-elastic stresses perpendicular ( $\Delta\sigma_{1T}$ ) and parallel ( $\Delta\sigma_{2T}$ ) to the fracture surface are calculated as  
 follows (Perkins and Gonzales, 1985):

$$\frac{(1-\nu)\Delta\sigma_{1T}}{E\alpha\Delta T} = \frac{(b_0/a_0)}{1+(b_0/a_0)} \quad (10)$$

$$+ \left[ \frac{1}{1+(b_0/a_0)} \right] \left( \frac{1}{\left\{ 1 + 1/2 \left[ 1.45 \left( \frac{h}{2b_0} \right)^{0.9} + 0.35 \left( \frac{h}{2b_0} \right)^2 \right] \left[ 1 + \left( \frac{b_0}{a_0} \right)^{0.774} \right] \right\}} \right)$$

$$\frac{(1-\nu)\Delta\sigma_{2T}}{E\alpha\Delta T} = \frac{(b_0/a_0)}{1+(b_0/a_0)} \quad (11)$$

$$+ \left[ \frac{(b_0/a_0)}{1+(b_0/a_0)} \right] \left( \frac{1}{\left\{ 1 + \left[ 1.45 \left( \frac{h}{2b_0} \right)^{0.9} + 0.35 \left( \frac{h}{2b_0} \right)^2 \right] \left[ 1 + \left( 1 - \frac{b_0}{a_0} \right)^{1.36} \right] \right\}} \right)$$

125

Where  $\nu$  = Poisson's ratio

$E$  = Young's modulus

$\alpha_T$  = linear coefficient of thermal expansion

$\Delta T$  = the difference between fluid temperature ( $T_f$ ) and reservoir temperature ( $T_R$ )

130

$b_0$  and  $a_0$  = minor and major semi-axes of the cool region, respectively

$h$  = height of fracture

$\Delta\sigma_{1T}$  and  $\Delta\sigma_{2T}$  = thermo-elastic stress change perpendicular and parallel to fracture surface at any point around the  
 fracture

135

For calculating the semi-axes of the cool region, the following equations are used:

$$W_i = Qt \quad (12)$$

$$V_{wt} = \frac{W_i}{(Phie(1 - S_{or} - S_{wi}))} \quad (13)$$

$$V_c = \frac{\rho_w C_w W_i}{\rho_{gr} C_{gr} (1 - Phie) + \rho_w C_w Phie (1 - S_{or}) + \rho_o C_o Phie S_{or}} \quad (14)$$

$$F_1 = 2 * V_c / (\pi * h * L_f^2) + 0.5 * \sqrt{\left(\frac{4V_c}{\pi L_f^2 h}\right)^2 + 4} \quad (15)$$

$$a_0 = \frac{L_f * (\sqrt{F_1} + \frac{1}{\sqrt{F_1}})}{2} \quad (16)$$

$$b_0 = \frac{L_f * (\sqrt{F_1} - \frac{1}{\sqrt{F_1}})}{2} \quad (17)$$

Where  $t$  = time of injection

$Q$  = rate of injection

$W_i$  = cumulative volume of fluid injected

140  $V_c$  = volume of rock formation cooled by the injected fluid

$F_1$  = an intermediate calculation parameter

$L_f$  = fracture half length

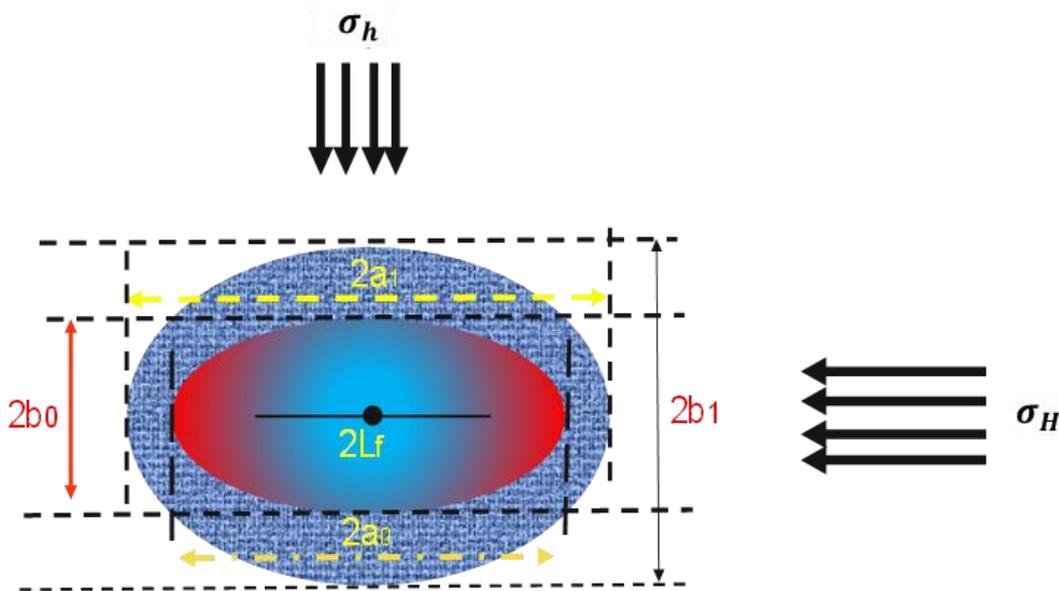

$Phie$  = effective porosity

$S_{or}$  = residual oil saturation

145  $S_{wi}$  = initial water saturation

$\rho_{gr}$ ,  $\rho_w$  and  $\rho_o$  = density of mineral grains, water and oil, respectively

$C_{gr}$ ,  $C_w$  and  $C_o$  = specific heat of mineral grains, water and oil, respectively

150 **Figure 5:** Cool region (ellipse of semi-axes  $a_0$  and  $b_0$ ) and flood region (semi-axes  $a_1$  and  $b_1$ ) around the fracture with half-length of  $L_f$

#### 2.4 Poro-elastic Stress Shadow

For the flood region zone (i.e., the rock within the ellipse of semi-axes of  $a_1$  and  $b_1$  in Figure 5), poro-elastic stresses perpendicular ( $\Delta\sigma_{1p}$ ) and parallel ( $\Delta\sigma_{2p}$ ) to the fracture surface are calculated as follows (Perkins and Gonzales, 1985):

155

$$\frac{(1 - \nu)\Delta\sigma_{1p}}{EJ\Delta p} = \frac{\left(\frac{b_1}{a_1}\right)}{1 + \left(\frac{b_1}{a_1}\right)} \quad (18)$$

$$+ \left[ \frac{1}{1 + \left(\frac{b_1}{a_1}\right)} \right] \left( \frac{1}{\left\{ 1 + \frac{1}{2} \left[ 1.45 \left(\frac{h}{2b_1}\right)^{0.9} + 0.35 \left(\frac{h}{2b_1}\right)^2 \right] \left[ 1 + \left(\frac{b_1}{a_1}\right)^{0.774} \right] \right\}} \right)$$

$$\frac{(1 - \nu)\Delta\sigma_{2p}}{EJ\Delta p} = \frac{\left(\frac{b_1}{a_1}\right)}{1 + \left(\frac{b_1}{a_1}\right)} \quad (19)$$

$$+ \left[ \frac{\left(\frac{b_1}{a_1}\right)}{1 + \left(\frac{b_1}{a_1}\right)} \right] \left( \frac{1}{\left\{ 1 + \left[ 1.45 \left(\frac{h}{2b_1}\right)^{0.9} + 0.35 \left(\frac{h}{2b_1}\right)^2 \right] \left[ 1 + \left(1 - \frac{b_1}{a_1}\right)^{1.36} \right] \right\}} \right)$$

For calculating the semi-axes of the flood region  $a_1$  and  $b_1$  within the ellipse, the following equations are used:

$$V_{wt} = W_i / (Phie * (1 - S_{or} - S_{wi})) \quad (20)$$

$$F_2 = 2 * V_{wt} / (\pi * h * L_f^2) + 0.5 * \sqrt{\left(\frac{4V_{wt}}{\pi * h * L_f^2}\right)^2 + 4} \quad (21)$$

$$a_1 = \frac{L_f * (\sqrt{F_2} + \frac{1}{\sqrt{F_2}})}{2} \quad (22)$$

$$b_1 = \frac{L_f * (\sqrt{F_2} - \frac{1}{\sqrt{F_2}})}{2} \quad (23)$$

160

Where  $V_{wt}$  = total volume of the flooded region

$F_2$  = an intermediate calculation parameter

And all other parameters are the same as those defined in Section 2.2.

165

Pore pressure distribution can be obtained by using equations 24 to 27 (Koning, 1985; Ge & Ghassemi, 2008; Perkins and Gonzalez, 1985):

$$P(\xi, \eta, t) = P_p + \Delta P(\xi) \quad (24)$$

$$\Delta P_1(\xi) = \frac{q}{2\pi h \lambda_1} \ln\left(\frac{3.0\sqrt{\kappa t}}{L \cosh \xi + L \sinh \xi}\right) \quad \xi_1 \leq \xi \leq \xi_2 \quad (25)$$

$$\Delta P_2(\xi) = \frac{q}{2\pi h \lambda_2} \ln\left(\frac{a_1 + b_1}{L \cosh \xi + L \sinh \xi}\right) + \Delta P_1 \quad \xi_0 \leq \xi \leq \xi_1 \quad (26)$$

$$\Delta P_3(\xi) = \frac{q}{2\pi h \lambda_3} \ln \left( \frac{a_0 + b_0}{L \cosh \xi + L \sinh \xi} \right) + \Delta P_1 + \Delta P_2 \quad (27)$$

$$0 \leq \varepsilon \leq \varepsilon_0$$

Where  $\Delta P_1$  = pore pressure increase at the elliptical boundary of the flood front

$$= \frac{q}{2\pi h \lambda_1} \ln \left( \frac{3.0\sqrt{\kappa t}}{a_1 + b_1} \right)$$

$P_p$  = native pore pressure of the reservoir

$\Delta P_2$  = pore pressure increase between the flood front and the thermal front (compressibility effect is assumed negligible) =  $\frac{q}{2\pi h \lambda_2} \ln \left( \frac{a_1 + b_1}{a_0 + b_0} \right)$

$\lambda_1 = k k_{rw} / \mu_0$ ,  $\lambda_2 = k k_{rw} / \mu_{hot}$  and  $\lambda_3 = k k_{rw} / \mu_{cold}$  = reservoir, flood region and cool region fluid mobilities, respectively

$K = \frac{k}{\phi h e \mu_0 c_f}$  = reservoir diffusivity constant

$J$  = linear coefficient of pore pressure expansion =  $\frac{1-2\nu}{E} - \frac{c_{gr}}{3}$

$c_{gr}$ ,  $c_w$  and  $c_f$  = grain, water and formation compressibility, respectively

$k$  = reservoir permeability

$k_{rw}$  = relative permeability to “water” (i.e., injected fracture fluid filtrate) at residual oil saturation

$\mu_0$  = viscosity of oil at reservoir temperature

$\mu_{hot}$  = viscosity of fracture fluid filtrate at reservoir temperature

$\mu_{cold}$  = viscosity of fracture fluid filtrate at cool temperature

$\xi$  and  $\eta$  = axial parameters for an elliptical coordinate system, as shown in Figure 6.

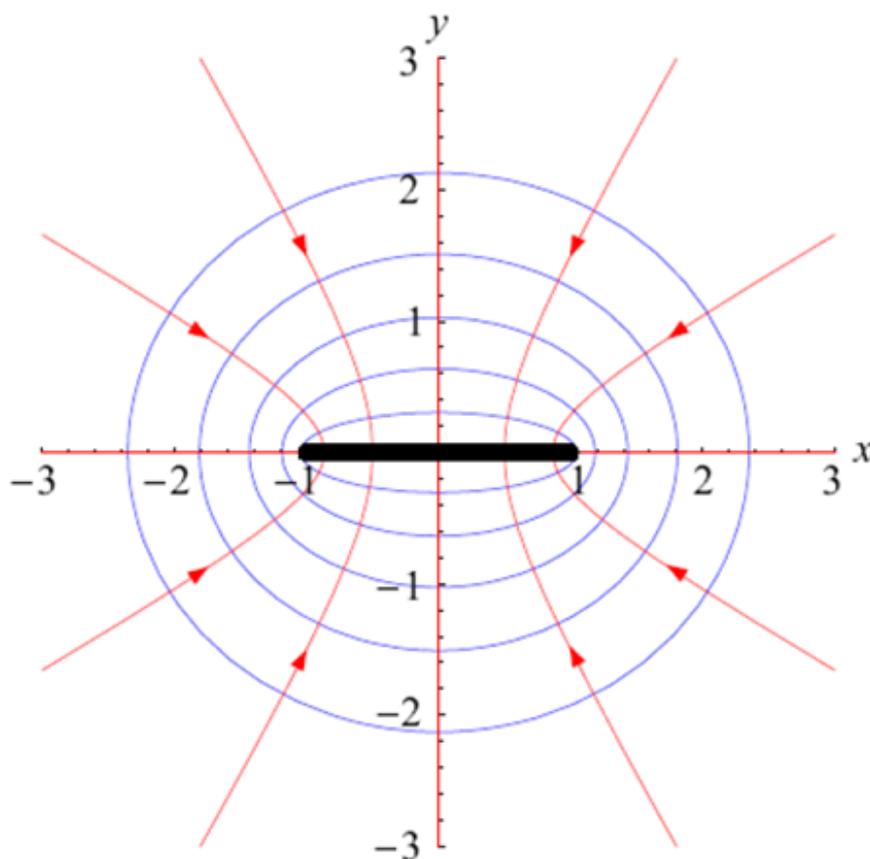

$\xi_0$ ,  $\xi_1$  and  $\xi_2$  = the boundaries of cool region, flood region, and pressure front, respectively

For convenience of analysis and visualization, it is beneficial to use an elliptical coordinate system for this type of analysis. An elliptical coordinate system ( $\xi - \eta$ ) is shown in Figure 6. Confocal ellipses and hyperbolae create two-dimensional orthogonal elliptical coordinates. Two foci are located at fixed positions of  $-L_f$  and  $L_f$  on the X-axis of the Cartesian coordinate system (X-Y). For any point around the fracture in an X-Y coordinate, the elliptical coordinate can be set as (Ge & Ghassemi, 2008):

$$X = L_f \cosh \xi \cos \eta \quad (28)$$

$$Y = L_f \sinh \xi \sin \eta \quad (29)$$

195 **Figure 6: Elliptical coordinate, blue lines are  $\xi$  and red lines are  $\eta$  (Ge & Ghassemi, 2008)**

### 2.5 Analysis of Stress Rotation Due to Stress Shadows

The induced stress changes due to stress shadow effects will generally result in principal stresses that are rotated with respect to the in-situ principal stresses. For analyzing stress rotation around a fracture, principal stress magnitudes are calculated using  
200 equations 30 and 31.

$$\sigma_1 = \frac{\sigma_X + \sigma_Y}{2} + \sqrt{\left(\frac{\sigma_X - \sigma_Y}{2}\right)^2 + \tau_{XY}^2} \quad (30)$$

$$\sigma_3 = \frac{\sigma_X + \sigma_Y}{2} - \sqrt{\left(\frac{\sigma_X - \sigma_Y}{2}\right)^2 + \tau_{XY}^2} \quad (31)$$

Where  $\sigma_1$  and  $\sigma_3$  = principal stresses in the X-Y plane

$\sigma_X$  = stress in the X direction =  $\sigma_H + \Delta\sigma_X + \Delta\sigma_{2T} + \Delta\sigma_{2p}$

$\sigma_Y$  = stress in the Y direction =  $\sigma_h + \Delta\sigma_Y + \Delta\sigma_{1T} + \Delta\sigma_{1p}$

$\tau_{XY}$  = shear stress in the X-Y plane =  $\Delta\tau_{XY}$

205

Principal planes are defined as the planes on which the principal stresses act and the shear stress is zero. Stress rotation angle is determined by using Equation 32.

$$2\theta_p = \tan^{-1} \frac{2\tau_{XY}}{\sigma_X - \sigma_Y} \quad (32)$$

210 Where  $\theta_p$  = stress rotation angle around the vertical axis.

## 2.6 Evaluation of Shear Failure Potential on Natural Fractures

The shear failure potential of natural fractures around an induced hydraulic fracture was analyzed in this work, because slip on natural fractures can induce microseismic events which can be detected and located if appropriate monitoring technologies are used. Several failure criteria for shear failure for rock joints have been developed by various scholars including the Barton-Bandis failure criterion (Barton & Choubey, 1977; Barton and Bandis, 1980, Barton, 1976). Various investigators have offered criteria for shear failure of rock mass (Sheorey, 1997) such as the Bieniawski-Yudhbir criterion, the Ramamurthy criterion, and the Hoek-Brown criterion (Hoek & Brown, 1980). In petroleum geomechanics, the Mohr-Coulomb failure criterion is widely used due to its simplicity. The Mohr Coulomb failure criterion for natural fracture is given as follows:

215

$$|\tau_f| = c + \sigma_n' \tan \varphi \quad (33)$$

220

Where  $c$  = cohesion (generally considered zero as a lower bound for strength in microseismic prediction)

$\sigma_n'$  = effective normal stress

$\tau_f$  = shear strength of fracture

$\phi$  = natural fracture friction angle

225 Failure along the natural fracture can be quantified in terms of a slip criterion which is defined as follows:

$$Slip = |\tau| - |\tau_f| \quad (34)$$

Where  $Slip$  = slip parameter (values  $\geq 0$  denote slip)

$\sigma_n'$  = effective normal stress

$|\tau|$  = magnitude of shear stress, acting on natural fracture face

A negative value of the parameters indicates that shear failure is not predicted for the fracture.

230 For analyzing this slip criterion, shear and normal stress on fracture plane are determined by using the following methodology (Zoback, 2007):

1. Transforming stress from the X-Y-V coordinate to the geographic coordinate (N-E-D) (Figure 7). For this, the stress tensor around the hydraulic fracture in the X-Y-V coordinate system, denoted by  $S$  (Equation 35) is transformed to  $S_g$ , which denotes stress in the geographic coordinate system (equations 36 and 37)

$$S = \begin{bmatrix} \sigma_V & 0 & 0 \\ 0 & \sigma_X & \tau_{XY} \\ 0 & \tau_{XY} & \sigma_Y \end{bmatrix} \quad (35)$$

$$S_g = R_1' S R_1 \quad (36)$$

235 Where

$$R_1 = \begin{bmatrix} \cos a \cos b & \sin a \cos b & -\sin b \\ \cos a \sin b \sin c - \sin a \cos c & \sin a \sin b \sin c + \cos a \cos c & \cos b \sin c \\ \cos a \sin b \cos c + \sin a \sin c & \sin a \sin b \cos c - \cos a \sin c & \cos b \cos c \end{bmatrix} \quad (37)$$

Because  $\sigma_V$  is vertical:

$a$  = azimuth of maximum horizontal stress ( $AZ-\sigma_H$ )  $-\frac{\pi}{2}$  (radians)

$b = \frac{\pi}{2}$  (radians)

$c = 0$

- 240
2. Transforming stress from the geographic coordinate (denoted by  $S_g$ ) to an arbitrary coordinate system (denoted by  $S_f$ ), which is defined by the orientation of a natural fracture (Equation 38).

$$S_f = R_2 S_g R_2' \quad (38)$$

Where

$$R_2 = \begin{bmatrix} \cos(str) & \sin(str) & 0 \\ \sin(str) \cos(dip) & -\cos(str) \cos(dip) & -\sin(dip) \\ -\sin(str) \sin(dip) & \cos(str) \sin(dip) & -\cos(dip) \end{bmatrix} \quad (39)$$

245

$Str$  = strike (measure clockwise from north; see Figure 8 for definition of strike using the right-hand rule)

$dip$  = dip angle (measured downwards from the horizontal plane)

Figure 8 shows the natural fracture in three dimensions. If shear failure occurs in the fracture plane the slip direction is denoted by the rake angle (i.e., the angle between the slip direction and a horizontal line contained within the fracture plane).

250 Finding the shear and normal stresses acting on the fracture plane as follows:

$$\tau = S_r(3,1) \quad (40)$$

$$\sigma_n = S_f(3,3) \quad (41)$$

$$S_r = R_3 S_f R_3' \quad (42)$$

$$R_3 = \begin{bmatrix} \cos(rake) & \sin(rake) & 0 \\ -\sin(rake) & \cos(rake) & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (43)$$

$\tau$  (hence potential slip direction) acts in the direction of the rake angle (see Figure 8 for definition), which is determined as follows:

If  $S_f(3,2) > 0$  and  $S_f(3,1) > 0$  or  $S_f(3,2) > 0$  and  $S_f(3,1) < 0$ ; then

$$rake = \arctan\left(\frac{S_f(3,2)}{S_f(3,1)}\right) \quad (44a)$$

255

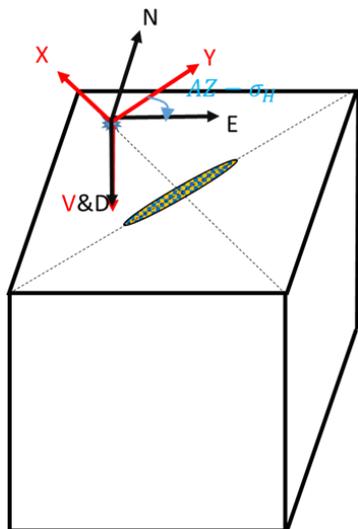

If  $S_f(3,2) < 0$  and  $S_f(3,1) > 0$ ; then

$$rake = \pi - \arctan\left(\frac{S_f(3,2)}{-S_f(3,1)}\right) \quad (44b)$$

If  $S_f(3,2) < 0$  and  $S_f(3,1) < 0$ ; then

$$rake = \arctan\left(\frac{-S_f(3,2)}{-S_f(3,1)}\right) - \pi \quad (44c)$$

In this work, the values of  $\sigma_V$ ,  $\sigma_X$ ,  $\sigma_Y$  and  $\tau_{xy}$  used as input for slip analysis were calculated based on in-situ stresses plus stress shadow components (as defined following Equation 29). As such, the effects of induced stresses on natural fractures were considered.

### 3 Case Study Incorporating Stress Shadow Analysis

#### 3.1 Geological Setting

The case study presented in this work is focused on the Bakken Formation in the province of Saskatchewan, in Western Canada. The Devonian to Carboniferous-age Bakken Formation lies in the subsurface of northeast Montana (U.S.A.), northwest North Dakota (U.S.A.), southeast Saskatchewan (Canada) and southwest Manitoba (Canada) (see Figure 9). This formation hosts one of the most active oil plays in North America in recent decades. The Bakken Formation is subdivided into the lower, middle and upper members (Angulo & Buatois, 2012; Gorjian, 2019) (Figure 10). The lower and upper members are organic-rich shales, which were deposited under oxygen-depleted conditions in a shelf environment. The calcareous to dolomitic sandy to silty middle member was deposited in a shallow marine environment (Halabura et al., 2007; Gorjian, 2019) and has been subdivided informally by many authors (Lefever et al., 1991; Gorjian, 2019). The middle member serves as the oil reservoir; multi-stage hydraulic fracturing is generally required to achieve economic production rates from this member.

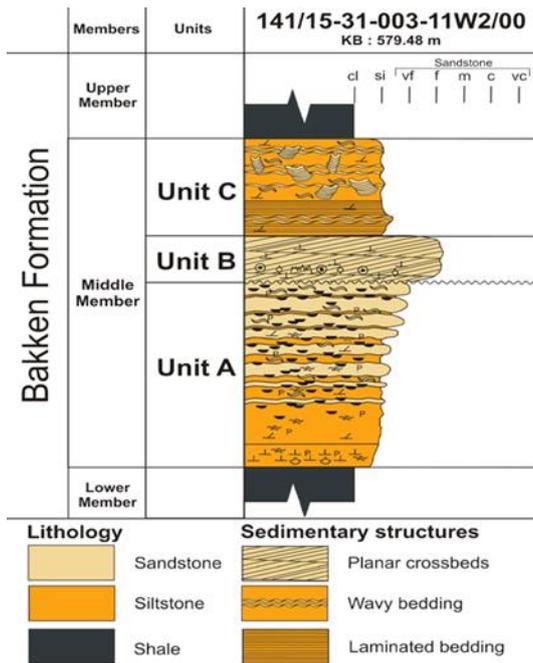

**Figure 9: Figure 9: Map showing the extents of the Bakken Formation within the Williston Basin, northwestern North America. (After EERC, 2014)**

The authors previously completed an extensive study of the Bakken Formation in the Viewfield region of southeast Saskatchewan, including geomechanical site characterization using data from 13 wells, numerical simulation of hydraulic fracture simulation using GOHFER, and comparison of the simulation results to field data. Interested readers are referred to Gorjian (2019) for details. In this paper, we focus on stress shadow analyses conducted on one well from the original study, referred to here as well S for simplicity (the actual well name is 191/14-15-007-07w2). Well S was chosen because of the

285 availability of instantaneous shut-in pressures (ISIP's) from each stage of a multi-stage hydraulic fracture treatment, and its proximity to another well (11/16-28-008-07w2) which had been used for rock mechanical properties analysis.

290 **Figure 10: Figure YY. Stratigraphic chart showing a typical geological section of the Bakken Formation in Saskatchewan (National Energy Board, 2015)**

Well S was completed by 30<sup>1</sup>-stages of hydraulic fracturing. Each stage used 4 tonnes of proppant mixed with 32.9 m<sup>3</sup> of ELE-Stim for proppant stages and ELE-Stim 18cp for non-proppant stages fracture fluid injected over a time interval of 47 minutes. For initial conditions (i.e., no stress shadow effects; key input parameters as summarized in Table 1), the numerical simulator predicted a maximum fracture height of 19.8 m, half-length of 81 m, and average propped width of 5.7 mm.

295 **Table 1: Average properties assigned for Middle-Bakken reservoir interval as initial condition**

Parameter	Minimum Horizontal Stress Magnitude (Mpa)	Maximum Horizontal Stress Magnitude (Mpa)	Vertical Stress Magnitude (Mpa)	Reservoir Pressure (Mpa)	Young's Modulus (Gpa)	Poisson's Ratio	Porosity (%)	Permeability (md)	Biot's Coefficient
Average Value	20.8	26.1	35	13.7	25	0.25	11	0.11	0.8

<sup>1</sup> The first stage of this fracture treatment failed, so the first successful stage is titled stage 2.

### 3.2 Stress Shadow Modeling for a Single Stage Fracturing

#### 3.2.1 Mechanical Stress Shadow

300 Figures 12 and 13 were generated by the author using Matlab code written to solve the equations presented in sections 2.1 and 2.4. Figure 11 shows the normal stresses perpendicular and parallel to the fracture at the end of treatment (immediately after shut-in), whereas Figure 12 shows the shear stress in the horizontal plane and the rotation angle of the principal stresses. According to these results, if hydraulic fracturing of stage 3 began immediately after shut-in of stage 2, the minimum horizontal stress would be greater than the original in-situ value (22.7 MPa compared to 20.8 MPa), the maximum horizontal stress would be less than the original value (25.9 MPa compared to 26.1 MPa), and the tips of the hydraulic fracture would be rotated 11° towards stage 2 (rather than parallel to the stage 1 fracture).

305 In general, it is most important to note that the stress shadow results in an increase in minimum horizontal stress, hence an increase in the pressure required to initiate and propagate a fracture, and in the tendency for the induced fracture to deviate towards the previous fracture stage. Furthermore, sensitivity analyses showed that these effects become more pronounced as fracture stage spacing is decreased, and the fracture rotation tendency can become particularly pronounced if the anisotropy in horizontal stresses is small. One final note pertaining to the results shown here is that these results represent an upper bound because they were generated for a scenario with no lag time between stages 2 and 3. In reality, pressure dissipation will occur with time following stage 2, which would diminish the magnitude of the stress shadow. Eventually, the fracture width would become constant with time, once both faces are in firm contact with proppant.

#### 3.2.2 Thermo and Poro-elastic Stress Shadows

310 Thermo and poro-elastic stress shadows were analyzed by writing code in Matlab to solve the equations presented in sections 2.2 and 2.3. It should be noted that all the key input parameters in this analysis is given in Table A.1. To the best of authors' knowledge, it is the first time that the thermal properties (Thermal conductivity, linear coefficient of thermal expansion, specific heat of mineral grains per unit volume) for Bakken Formation are measured in laboratory and reported. These shadows were found to be insignificant for the Bakken Formation, largely due to its low permeability (hence the limited extent of pressure increase and cooling around fractures). To illustrate the use of these solutions, extreme cases were analyzed; the results are given in Appendix A (thermo-elastic) and Appendix B (poro-elastic). It is worth noting that it is not necessary to analyze the distribution of poro- and thermo-elastic stress shadows throughout the entire model domain, if seeking to minimize analytical effort while assessing the relative significance of the different stress shadow mechanisms. Rather, it would be sufficient to calculate the change in minimum horizontal stress at a point corresponding to  $\theta = 90^\circ$  and  $R =$  fracture stage spacing for each stress shadow mechanism (see Figure 4). Any stress change deemed negligible at this point should have a negligible influence on a fracture being initiated at this point. For example, in the case analyzed here, the horizontal stress change predicted at this point is 1.9 MPa for the mechanical stress shadow mechanism, 0 MPa for the thermo-elastic and 0 for the poro-elastic.

### 3.2.3. Stress Shadow Modeling for Multistage Hydraulic Fracturing

The lateral spacing and time lag between successive stages for well S are shown in figures 13 and 14, respectively.

#### 3.2.3.1 Stress Shadow of Stage 2 on Stage 3

In Section 3.2.1, the stress shadow effect for stage 3 was analyzed for conditions existing immediately after shut-in for stage 2. However, in practice there is generally a time lag between performing the successive fracture stages, which should be considered because during that time fluid can leak off from the fracture to the formation, thus decreasing pressure and the magnitude of the stress shadow effect. Based on a 73 minute time lag between stages 2 and 3 (see Figure 14), the calculated distributions of normal stresses are shown in Figure 15 and shear stresses and principal stress rotation in XY plane are shown in Figure 16.

335

340

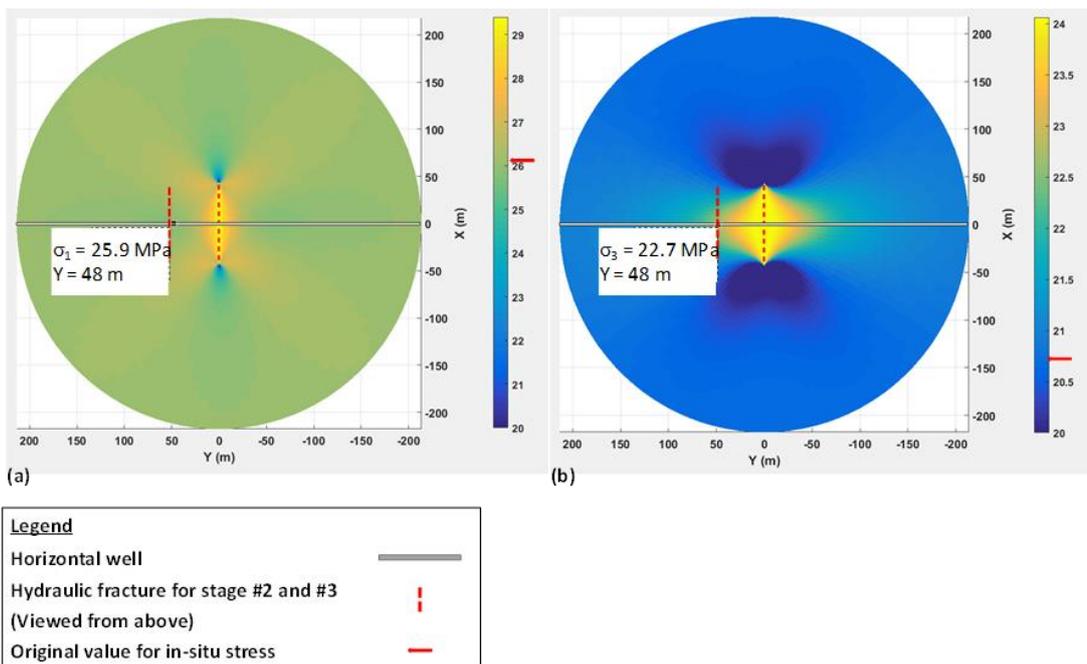

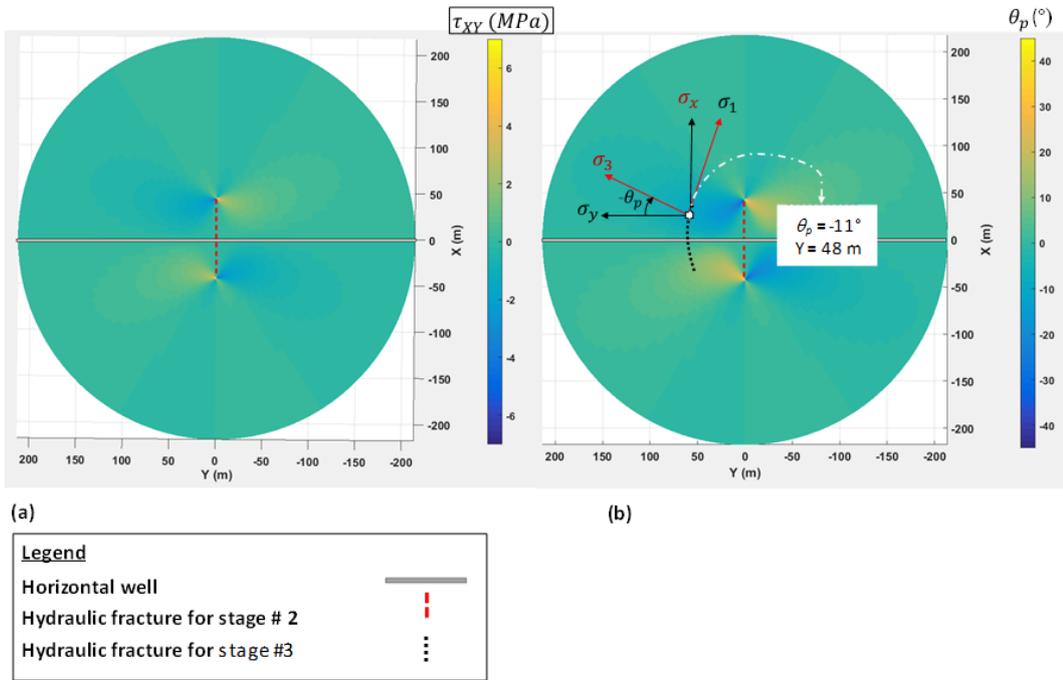

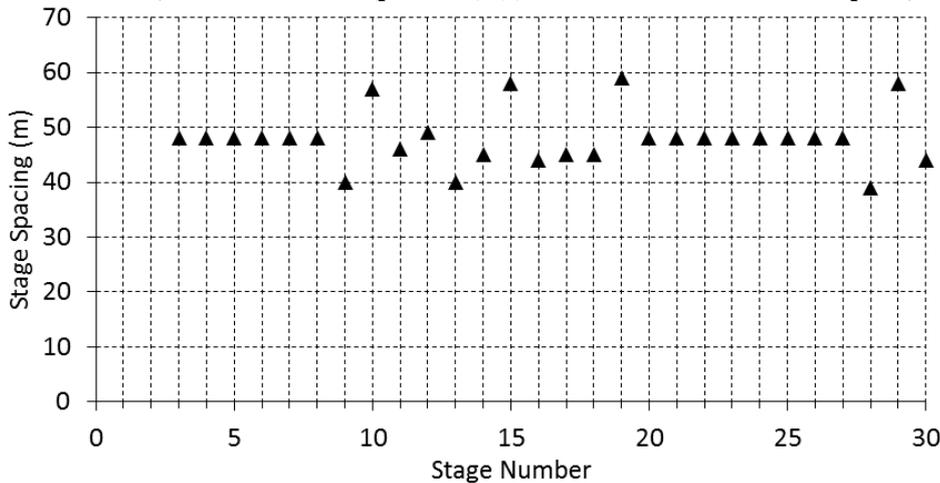

Figure 11: Predicted stress distribution resulting from mechanical stress shadow effects (immediately after shut-in) around a single hydraulic fracture, viewed from above (plan view). (a) Normal stress in the direction of X-axis; (b) normal stress in the direction of Y-axis. The Y-axis is aligned parallel to the in-situ minimum horizontal stress. The vertical dashed line at the centre shows the location of the newly created fracture (stage 2); the vertical dashed line offset 48 m to the left represents the location planned for the next fracture (stage 3).

345

350 **Figure 12: Predicted stress distribution resulting from mechanical stress shadow effects (immediately after shut-in) around a single hydraulic fracture, viewed from above (plan view). (a) Induced shear stress in the XY plane; and (b) principal stress rotation angle.**

355 **Figure 13: Stage spacing in well S. The spacing plotted represents the distance between the stage represented on the X-axis and the preceding stage. For example, the value of 48 m plotted for stage 3 indicated a 48 m spacing between stage 2 and stage 3. (Note: Stage 1 in this treatment program failed).**

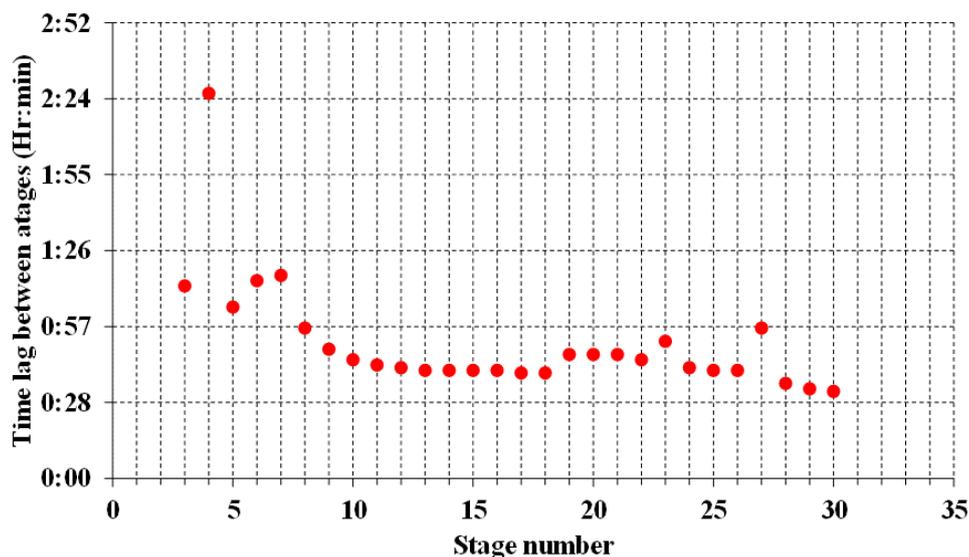

Figure 14: Inter-stage time lags recorded for well S. The time lag plotted represents the time elapsed between start of injection for the stage represented on the X-axis and shut-in of the preceding stage. (Note: Stage 1 in this treatment program failed.)

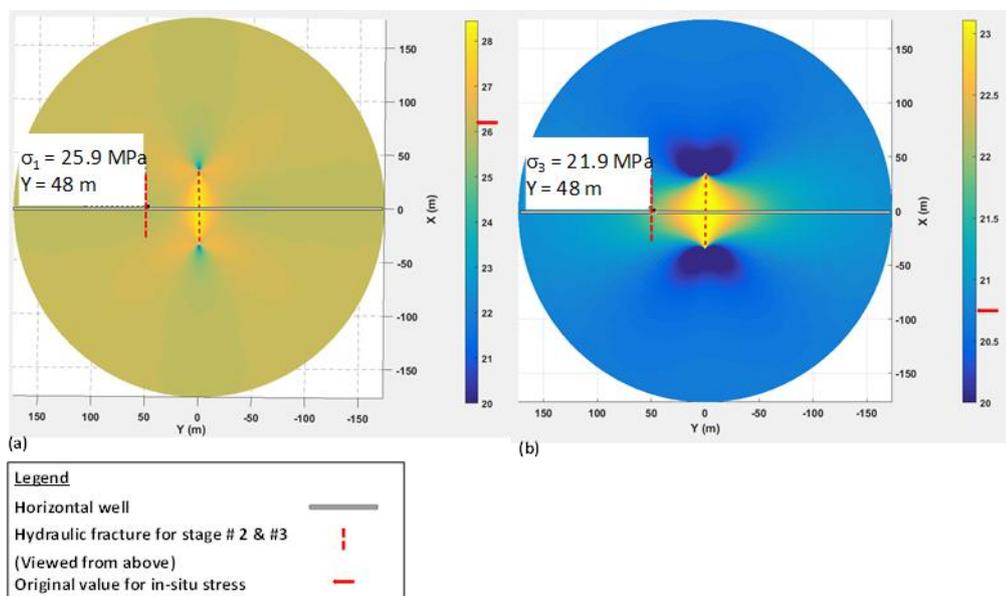

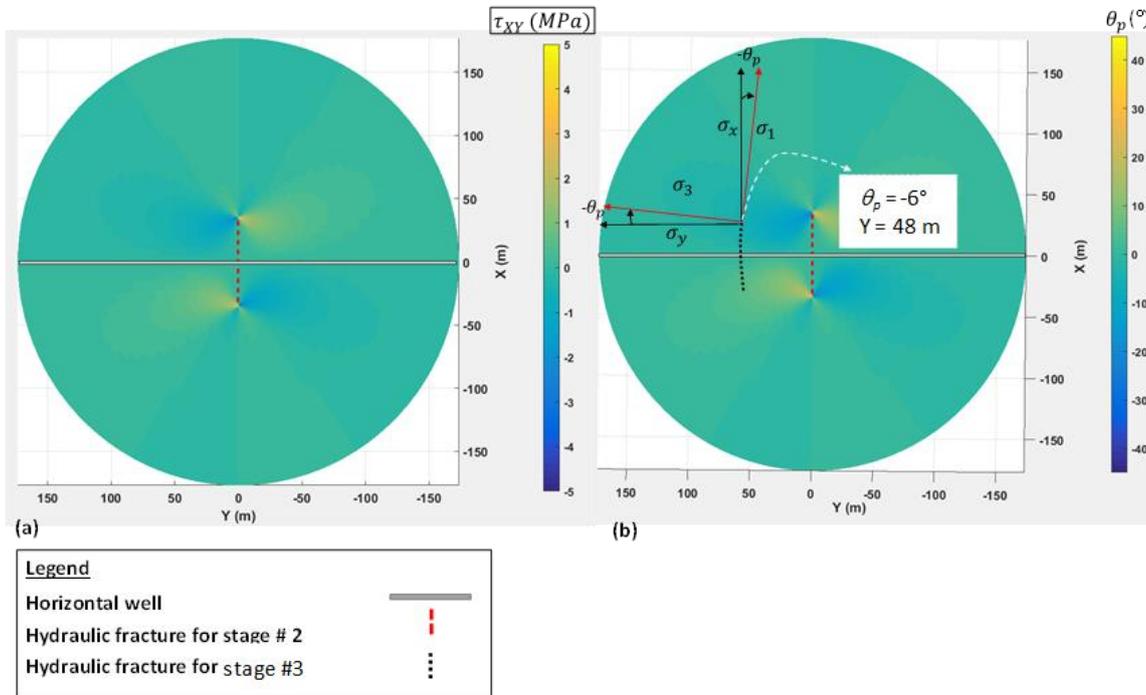

Figure 15: Predicted stress distribution resulting from mechanical stress shadow effects (73 minutes after shut-in) around a single hydraulic fracture, viewed from above (plan view). (a) Normal stress in the direction of the X-axis; (b) normal stress in the direction of the Y-axis. The Y-axis is aligned parallel to the in-situ minimum horizontal stress. The vertical dashed line at the centre shows the location of the newly created fracture (stage 2); the vertical dashed line offset 48 m to the left represents the location planned for the next fracture (stage 3).

**Figure 16: Predicted stress distribution resulting from mechanical stress shadow effects (73 minutes after shut-in) around a single hydraulic fracture, viewed from above (plan view). (a) Induced shear stress in the XY plane; and (b) principal stress rotation angle**

Figure 17 shows the minimum horizontal stress ( $\sigma_y$  at  $X=0$ ), maximum horizontal stress ( $\sigma_x$  at  $X=0$ ) and vertical stress versus  $Y$  at  $X=0$  (center of fracture) around the hydraulic fracture at stage 2 both immediately after shut-in and 73 minutes after shut-in. General observations based on Figure 17 are as follows:

- Based on defining the stress shadow zone as the zone in which a stress change of 0.5 MPa has occurred, the vertical lines #h0 ( $Y = 122\text{m}$ ) and #ht ( $Y = 82\text{m}$ ) show the boundaries of the stress shadow zone for scenarios of 0 and 73 minutes of time lag, respectively. This suggests that the stage spacing required to avoid stress shadow effects for hydraulic fracturing of stage 3 would be 122 m and 82 m, for a time lag scenarios of 0 and 73 minutes, respectively.
- The maximum horizontal stress decreases more acutely than minimum horizontal stress. This is shown with the stress shadow zone (as shown by dashed line #H0) at  $Y = 38$  m for immediately after stage 2 and at  $Y = 25$  m (as shown by dashed line #Ht) for a time lag of 73 minutes.
- The vertical stress has the same trend as maximum horizontal stress and can be assumed unchanged for any distance further than 38 m.

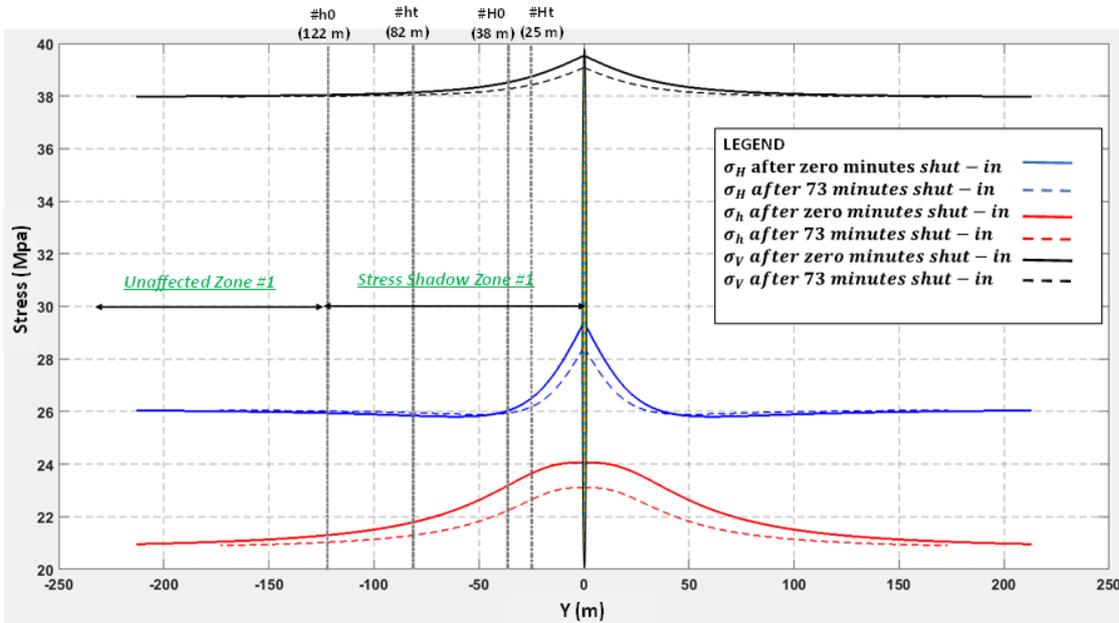

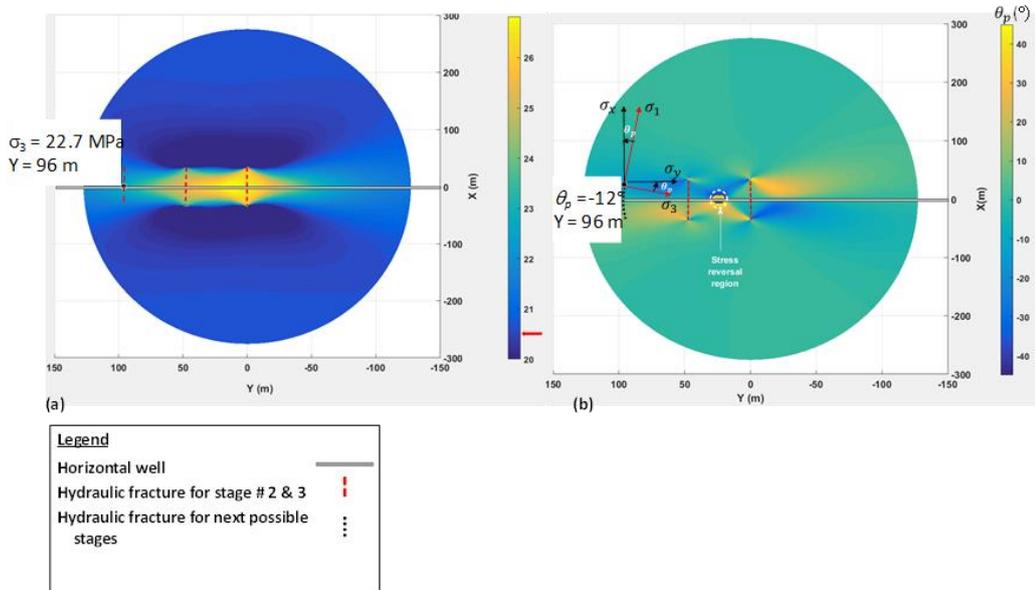

Figure 17: Horizontal stresses in the X direction (parallel to the fracture), Y direction (perpendicular to the fracture) and vertical direction versus Y at X = 0 around a hydraulic fracture at stage 2 after shut-in times of zero and 73 minutes. The dashed lines #h0, #ht denote the limits of the stress shadow zones for the minimum horizontal stress after 0 and 73 minutes of shut-in, and the dashed lines #H0, #Ht denote the limits of the stress shadow zones for the maximum horizontal stress and vertical stress after 0 and 73 minutes of shut-in. The limits of the vertical stress shadow zone are not shown, but they are effectively the same as the maximum horizontal stress shadow zone. [Note: The criterion used to delimit stress shadow zones in this work is a change of 0.5 MPa]

### 3.2.3.2 Cumulative Stress Shadow of Effects of Stage 2 and 3 on Stage 4

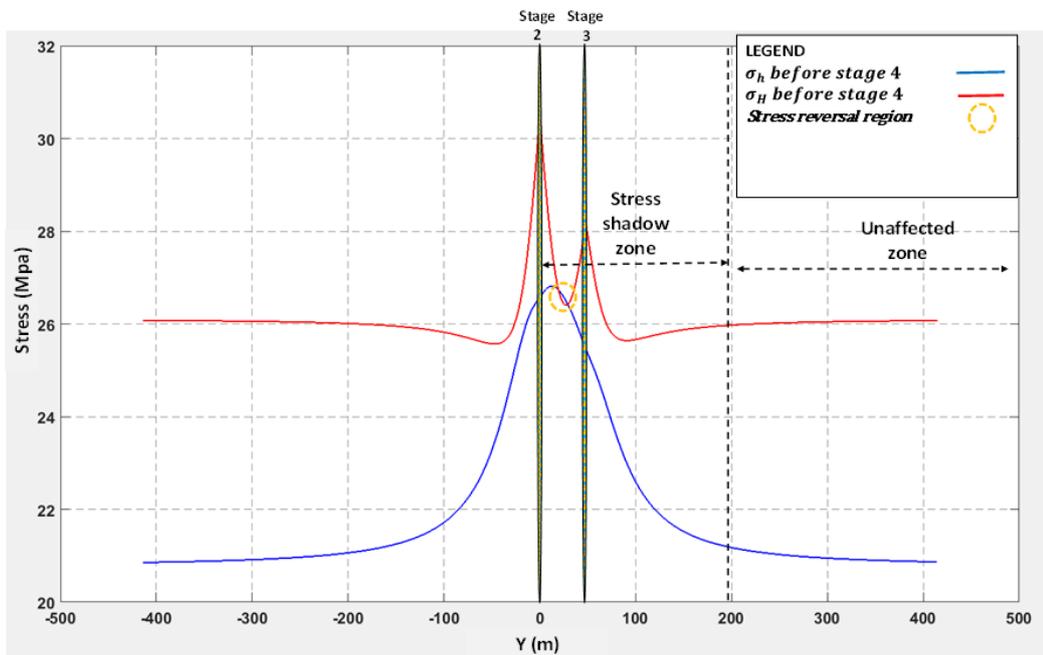

By considering 219 minutes and 146 minutes lag times after stages 2 and 3 respectively, the predicted distribution of minimum horizontal stress and principal stress rotation angle at Y = 96 m (i.e., the location of stage 4) are shown in Figure 18. Figure 19 shows the minimum horizontal stress and maximum horizontal stress versus Y at X=0 (center of fracture). Notable observations based on Figures 18 and 19 are as follows:

- Predicted minimum horizontal stress at Y = 96 m (stage 4) is 22.7 MPa, compared to 20.8 MPa initially. [Note: Model validation by comparison of model predictions against field data is shown in discussion section.]
- There is a predicted region of stress reversal at approximately Y = 25 m.
- To avoid stress shadow effects, stage 4 would have to be spaced 152 m from stage 3 (i.e., nearly 200 m from stage 2) based on a shadow threshold criterion of 0.5 MPa.
- The predicted principal stress rotation angle doubles from 6° to 12° when accounting for a cumulative stress shadow on stage 4 caused by stages 2 and 3.

400

Figure 18: Predicted stress distribution resulting from cumulative mechanical stress shadow effects resulting from stage 2 and 3, at the time when pumping begins for stage 4. (a) Induced shear stress in the XY plane; and (b) principal stress rotation angle.

405

Figure 19: Minimum horizontal stress and maximum horizontal stress vs. Y at X=0 due to hydraulic fracturing of stages 2 and 3 at the beginning of pumping for stage 4.

### 3.2.3.3 Stress Shadow for the Final Fracture Stage (“Stage 30”)

Calculations for stage 30 were undertaken in a manner consistent with those described for stage 4, except in this case the time lag and distance between stage 2 and 30 were used to calculate stage 2’s stress shadow for stage 30. Then the time lag and distance between stages 3 and 30 were used to calculate stage 3’s stress shadow for stage 30, and so on (up to stage 29). Upon summing the stress changes resulting from stage 2 through 29, the stress conditions during stage 30 were obtained.

Figure 20 shows the predicted minimum horizontal stress magnitude during stage 30. At  $X = 0$  m and  $Y = 1341$  m (center of stage 30 fracture), the minimum horizontal stress was calculated as 25.4 MPa (compared to 20.8 MPa originally). The principal stress rotation angle is shown in Figure 21. This figure shows a rotation angle of  $35^\circ$  at the tip of the fracture, which is greater than the  $6^\circ$  predicted for the effect of stage 2 on stage 3 (Figure 16). Figure 22 shows horizontal stress magnitudes in the X and the Y directions versus Y at  $X = 0$  (center of fracture) immediately before stage 30. This figure also reveals that the vertical line at  $Y = 1294$  m is the boundary of a stress reversal zone. Beyond this boundary (i.e., for  $Y > 1294$  m), the horizontal stress state become nearly isotropic up to  $Y = 1341$  m, beyond which normal stress in the X direction becomes greater than normal stress in the Y direction. This result is important because it suggests that fracture orientation could rotate by up to  $90^\circ$ , or there might not be a strongly preferred growth direction at all.

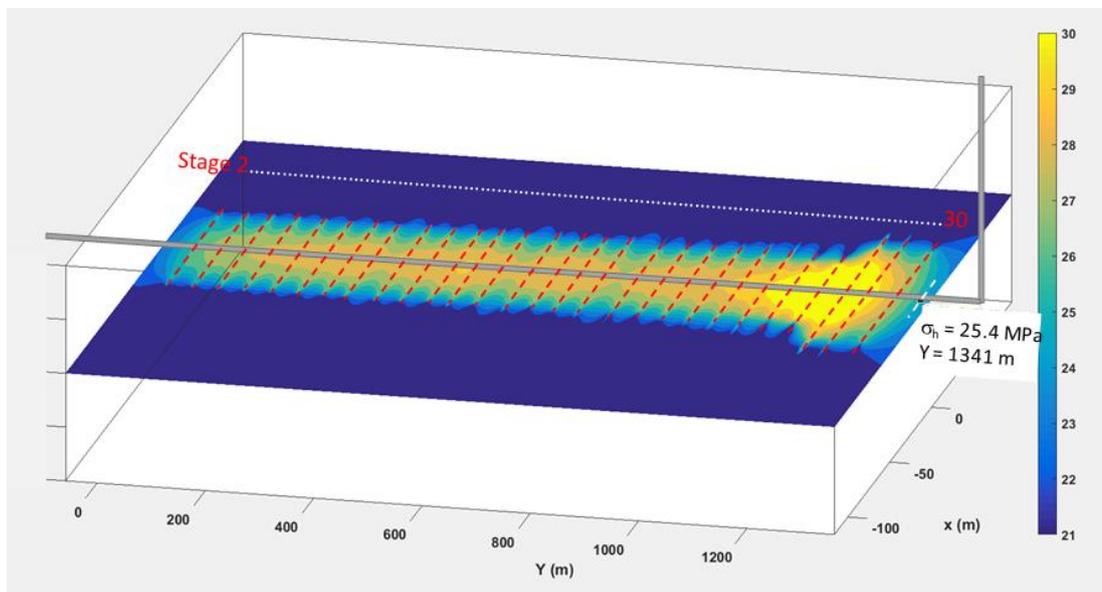

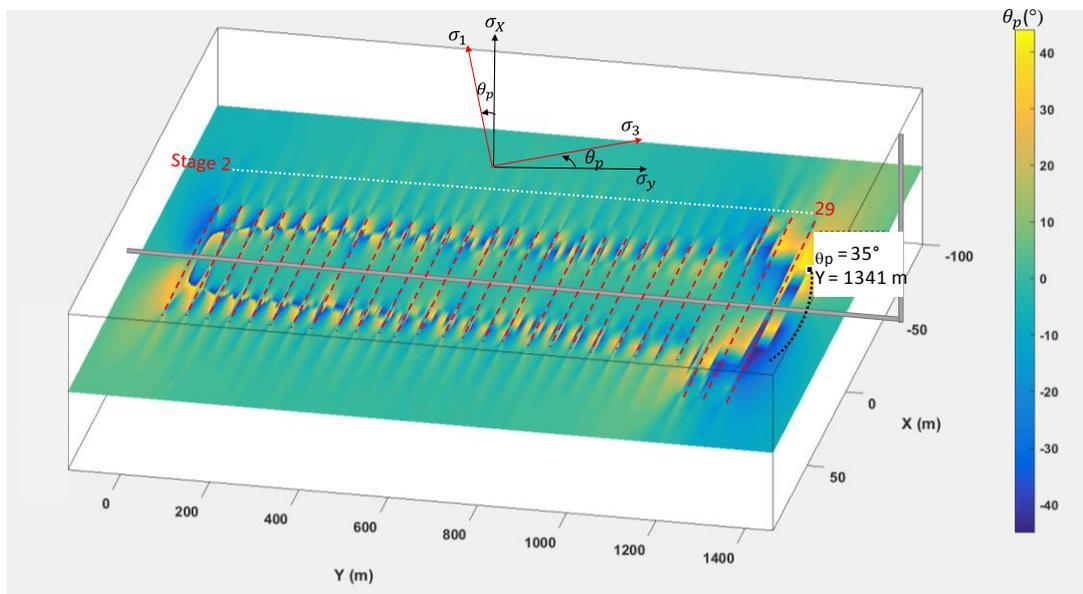

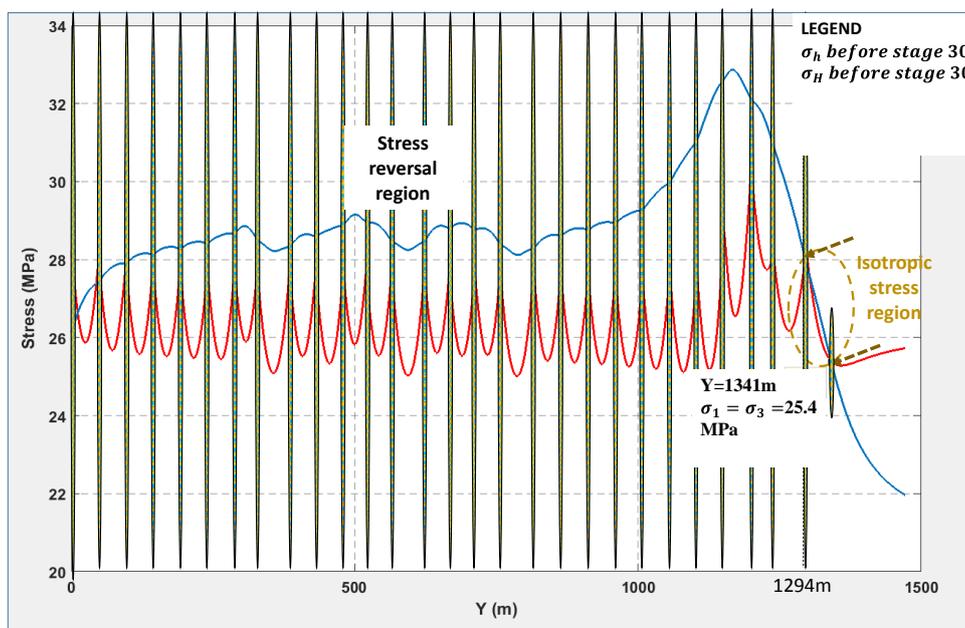

Figure 20: Predicted minimum horizontal stress (MPa) at the time of stage 30 (at  $Y = 1341$  m, which is shown by the white dashed line)

425 **Figure 21:** Rotation angle of principal stress due to the combined effects of all stages before stage 30 (at Y=1341 m), showed by black dashed line.

430 **Figure 22:** Horizontal stresses in the X and Y directions at the time of stage 30, showing the cumulative stress shadow resulting from stages 2 to 29.

### 3.2.3.4 Model Simplification

Given that the stress changes occurring along the well trajectory (at each fracture port) are the only components of stress change that can be used as input to Gohfer, calculation of the full stress field is not useful for fracture simulations. For such conditions, the following simplified equations can be used for stress shadow modeling. For  $X = 0$  (for any point along the well trajectory), the stress shadow in the Y and X directions for stage  $n$  can be calculated by simplifying equations 1 and 2 as follows:

$$\Delta\sigma_{Y,X=0} = \sum_{i=i_i}^{n-1} -\frac{2E\varpi_i}{(1-\nu^2)\pi h_{fi}} \left[ \frac{Y_i}{\left(Y_i^2 + \frac{L_i^2}{4}\right)^{\frac{1}{2}}} - 1 + \frac{Y_i L_i^2}{4 * \left(Y_i^2 + \frac{L_i^2}{4}\right)^{\frac{3}{2}}} \right] \quad (45)$$

$$\Delta\sigma_{X,X=0} = \sum_{i=i_i}^{n-1} -\frac{2E\varpi_i}{(1-\nu^2)\pi h_{fi}} \left[ \frac{Y_i}{\left(Y_i^2 + \frac{L_i^2}{4}\right)^{\frac{1}{2}}} - 1 - \frac{Y_i L_i^2}{4 * \left(Y_i^2 + \frac{L_i^2}{4}\right)^{\frac{3}{2}}} \right] \quad (46)$$

Where:  $i_i$  = the first fracture stage

$E$  and  $\nu$  = Young's modulus and Poisson's ratio (statics values)

$h_{fi}$ ,  $L$  and  $\varpi_i$  = fracture height, length and average propped width

$Y_i$  = the spacing between stage  $i$  and stage  $n$

Given that horizontal stresses may be reversed within the stress reversal region, the minimum horizontal stress must be assessed as follows:

$$\sigma_3 = \min[(\sigma_X + \Delta\sigma_X), (\sigma_Y + \Delta\sigma_Y)] \quad (47)$$

The model may be further simplified by assuming constant values for fracture length ( $L_i$ ), average width ( $\varpi_i$ ) and fracture height ( $h_i$ ) by assuming the propped values for these parameters (i.e., rather than modeling leakoff for each stage, taking the final values for these parameters after pressures have dissipated and the fracture dimensions are controlled solely by the proppant contained within the fractures). Results obtained using this simplified approach seem promising, as illustrated in Figure 23. This figure suggests that the results obtained using the simplified model compare favourably with the more rigorous model, with the discrepancy being less than 0.5 MPa in most cases.

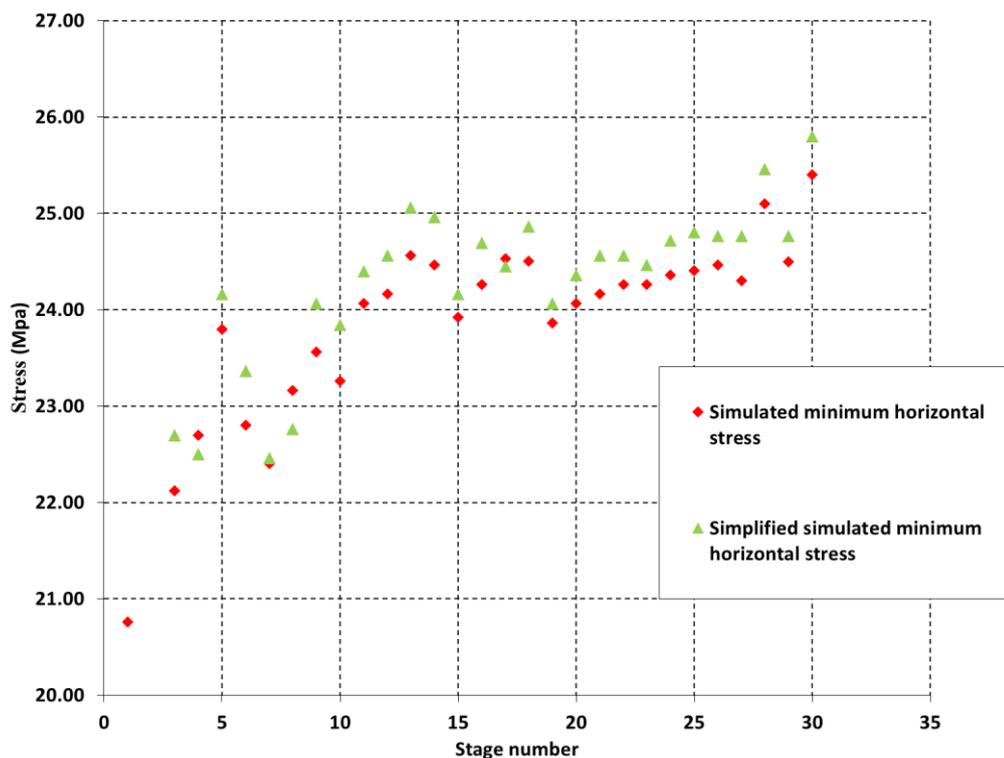

Figure 23: Comparison of simulated minimum horizontal stress (stress shadow effect) calculated with the simplified model (Equation 4.1) and the comprehensive model (see Section 3.4.1).

#### 4 Natural Fracture Shear Failure analysis

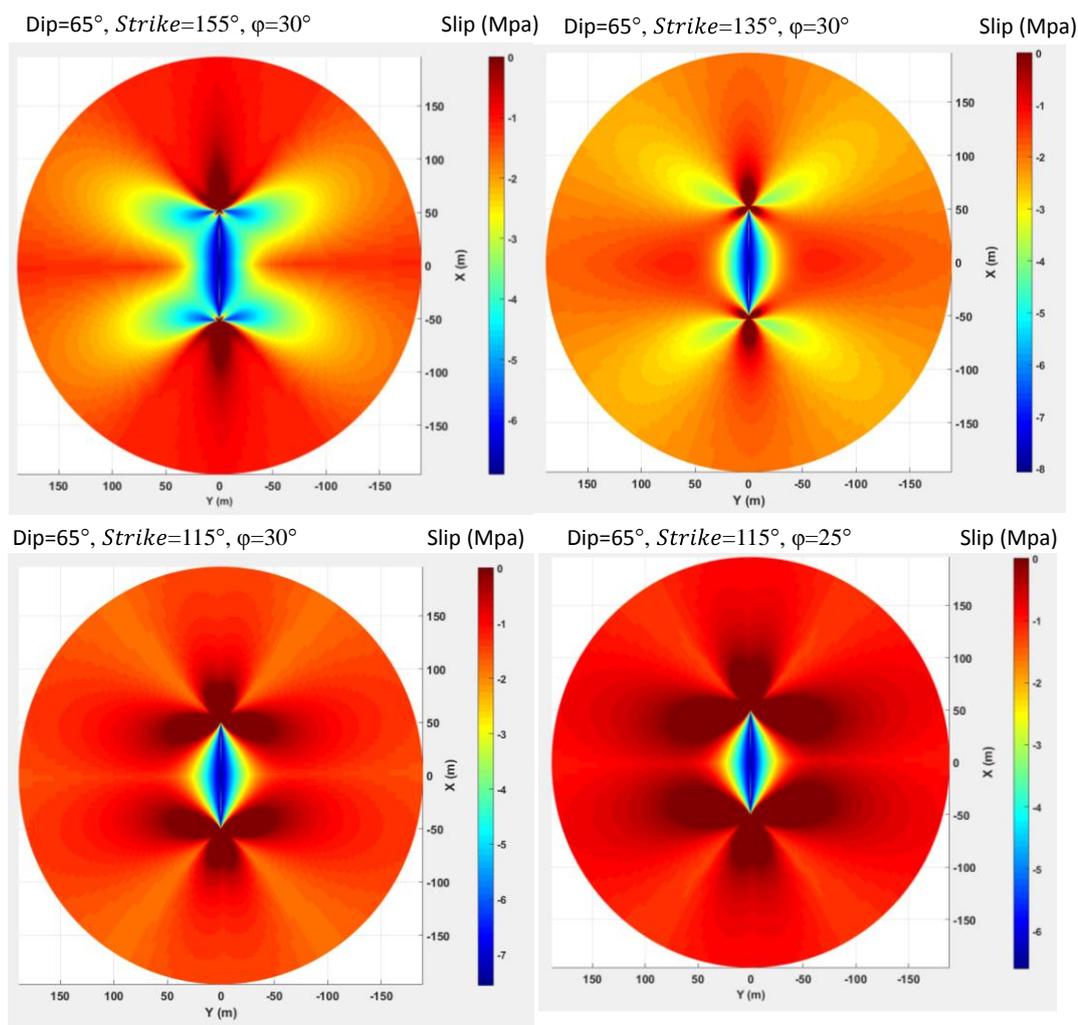

455 Hydraulic fracturing operations can be significantly affected by the presence of natural fractures in the reservoir, depending  
on fracture attributes such as spacing, orientation and shear strength. For example, if natural fractures are present and have  
properties that make them amenable to shear failure (“slip”) during the injection of fracture fluid, dilation of these fractures  
may result in a zone of increased permeability (i.e., a stimulated zone). Furthermore, slip on natural fractures will generally  
result in the release of acoustic energy (microseismic events), which means there is a close association between the  
460 interpretation of microseismic monitoring data and natural fracture attributes (e.g., Zoback, 2007).

In the stress shadow analysis presented in Section 3, the effects of possible natural fractures were not considered. According  
to core logging conducted by the authors, natural fractures were observed in one well in the study area, possessing a strike of  
155° and dip of 65° (Gorjian, 2019).

465 Figure 24 shows the results obtained when shear failure was analyzed for scenarios of 115°, 135°, and 155° strike direction,  
in all cases with a 65° for dip angle. The areas shaded in dark brown on Figure 24 denote areas where natural fracture slip is  
predicted. It is important to note that this figure shows the regions of natural fracture slip that exists once the hydraulic fracture

shown has reached its full length. It is expected that the shear failure zone would have started near the well and grown progressively outwards as the hydraulic fracture propagated, hence resulting in a zone of slip (and associated microseismic events) extending from the well towards an outer bound delineated by the darkly shaded regions in Figure 24.

470

**Figure 24: Shear failure analysis for natural fractures (hence possible microseismic events showed by dark brown coloured area) with dip angle of 65°, strikes of 115°, 135°, 155° and friction angle of 30° around a hydraulic fracture in the Bakken Formation under conditions representative of well S. For a scenario with strike of 115°, a reduced friction angle of 25° was also analyzed.**

475

## 5 Discussion

### 5.1 Assessment of Stress Shadow Effect Based on Field Data

480 To assess the validity of the stress shadow modeling workflow developed in this research (see Section 3.1.2), the instantaneous  
shut-in pressure (ISIP) values measured for stages 2 through 30 during field operations at well S were plotted and compared  
against the model-predicted values of the minimum horizontal in-situ stress (Figure 25). Bottomhole ISIP may be regarded as  
an estimate of minimum in-situ stress measurement, especially in fracture treatments involving relatively small, planar  
fractures. The predicted trend of increasing minimum horizontal stress with increasing stage number (Figure 25) compares  
favourably to the increase in ISIP observed during the treatment program. Both datasets suggest an increase in minimum  
485 horizontal stress of approximately 5 MPa, with minor deviations from the trend which may be explainable in part by the  
deviations in stage spacing and the time lag between stages.

Even the simplified model results (Equation 45) compare favourably to the field ISIP's. This suggests that the approach is  
capable of the predicting minimum horizontal stress (or stress shadow) at each stage (for the Bakken Formation, at least). This  
approach can thus be used for modifying stage spacing and/or inter-stage time lag in the Bakken Formation, if shadow-induced  
490 stress increases are deemed to adversely affect the effectiveness of hydraulic fracturing operations.

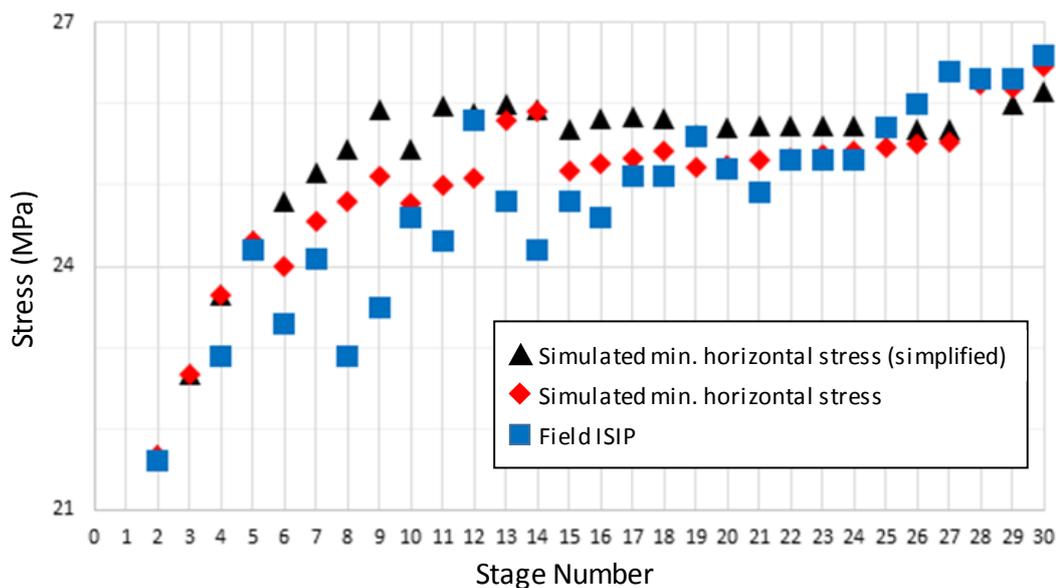

Figure 25: Comparison of simulated minimum horizontal stress and simplified simulated minimum horizontal stress with instantaneous shut-in pressure (ISIP) measurements taken during the stimulation program for well S.

## 5.2 Microseismic Event Evaluation

To evaluate potential hydraulic fracturing-induced microseismic events in the Bakken Formation, shear failure analysis was conducted for an assumed (hypothetical) natural fractures surrounding a hydraulic fracture in the Bakken Formation for conditions existing at well L (191/05-16-009-10w2), which was the only well for which microseismic monitoring data were publically available. Mechanical stress shadow modeling (for a single fracture stage) was repeated for well L, in the same manner as presented for well S in section 3.2.1. Similarly, slip analysis for well L was repeated, in the same manner as presented for well S in section 4. Given the similarity in conditions at wells S and L, and for the sake of brevity, the results are not presented here. Readers may refer to Gorjian (2019) for more details regarding well L.

Table 2 shows a comparison of horizontal extents of shear failure zones with zones of microseismic events logged at well L (see Appendix C). The extents of the predicted zones of shear failure compare favourably with the field data for the scenario with natural fractures striking at 115° with a dip of 65° and friction angles in the range of 25° to 30°. This dip is consistent with observations reported in the lone well that was logged and found to have natural fractures, however the strike is 40° less than the value of 155° that was measured. Given that the strike direction of 155° is based on a limited dataset observed at a different location, it is not unreasonable to expect that fractures striking at 115° might be present near well L. Clearly, more investigation into natural fracture attributes in the Bakken Formation and more public reporting of microseismic monitoring results is required before more confident analyses can be undertaken. When additional data are acquired, the modeling workflow presented here will serve as an effective tool for predicting estimates of the shear failure zone (hence the stimulated reservoir volume).

**Table 2: Comparison of the lateral extents of the zones of microseismic activity monitored at well L (Figure C-1) against the predicted extents of shear failure zones for various scenarios of natural fracture orientation.**

Source / Scenario	Length in direction of $\sigma_h$ (m)	Length in direction of $\sigma_H$ (m)
Field microseismic data (Appendix C)	190	170
Strike 155°; Dip 65° SW; friction angle = 30° (Orientation observed in well G)	40	200
Strike 135°; Dip 65° SW; friction angle = 30°	20	150
Strike 115°; Dip 65° SW; friction angle = 30°	115	170
Strike 115°; Dip 65° SW; friction angle = 25° (Best match to field data)	165	190

520 **6 Conclusion**

The following is a list of conclusions based on this study:

- A new toolbox, based on analytical solutions, was developed for predicting stress shadow effects in multi-stage hydraulic fracture, and was demonstrated to compare favourably against ISIP data collected from a well in the study area. The formulation used in this work only considered mechanical stress shadow effects, as thermo and poro-elastic stress shadows were found to be negligible in the Bakken Formation due to the small injection volumes and times and low permeability. However, if the permeability was 2.5 md instead of 0.1 md, the poro-elastic stress shadow should be considered as well. Thermal stress shadow at the tip of fracture can increase the length of fracture; however, it can also decrease the length of fracture if it creates secondary thermo-elastic fractures perpendicular to the primary hydraulic fracture. Analysis showed that the thermo-elastic stress shadow was still too low to create secondary thermal fractures. The effect of thermo-elastic stress shadow at the fracture tip was not analyzed in this work.
- Shear failure of natural fractures around a hydraulic fracture was analyzed and compared against microseismic monitoring data reported for one well in the study area. The results showed a favourable comparison for a scenario with natural fractures striking at  $115^\circ$  with a dip of  $65^\circ$  and friction angles in the  $25^\circ$  to  $30^\circ$  range. More investigation of natural fracture attributes in the Bakken Formation is required in order to implement this type of analysis in the future, in order to predict stimulated reservoir volumes.

610 **Appendix A Thermo-elastic Stress**

For analyzing the thermo-elastic stress shadow effect, the parameters given in Table A.1 were used. For analyzing the influence of a non-uniform temperature distribution around the fracture (rather than the uniform temperature assumed by Perkins and Gonzalez (1985), the heat transfer Equation A.1 was solved numerically by using finite difference method.

$$\rho c_p \frac{\partial T}{\partial t} = \nabla \cdot (\lambda \nabla T) \quad (\text{A.1})$$

Where  $\lambda$  = thermal conductivity

615  $\rho c_p$  = heat capacity per unit volume

The modeled temperature distribution by using the finite difference method and by Perkins and Gonzalez (1985) for a single fracture is shown in Figure A.1. For a maximum injection volume scenario of 11 tonnes of proppant and injection time of 75 minutes per stage  $a_0 = 52$  m and  $b_0 = 0.049$  m for the cool region.

620 The major axis of the elliptical cool region has almost the same length as fracture length with time. Figure D.2 shows the thermo-elastic stress shadow perpendicular and parallel to fracture. According to Figure D.2, the minimum thermo-elastic stress shadow in X-direction is 21.6 MPa. Due to Equation D.2, it was not expected to see secondary thermal fractures during the hydraulic fracture treatment, as the original horizontal stress in X direction ( $\sigma_x$ ) plus the thermo-elastic stress shadow is still more than tensile strength of rock.

$$\sigma_x + \Delta\sigma_{TX} \geq -\sigma_t \quad (\text{A.2})$$

Where  $\sigma_x$  = maximum horizontal stress

625  $\Delta\sigma_{TX}$  = thermo-elastic stress shadow in X direction

$\sigma_t$  = tensile strength, with negative sign, that is mostly assumed zero

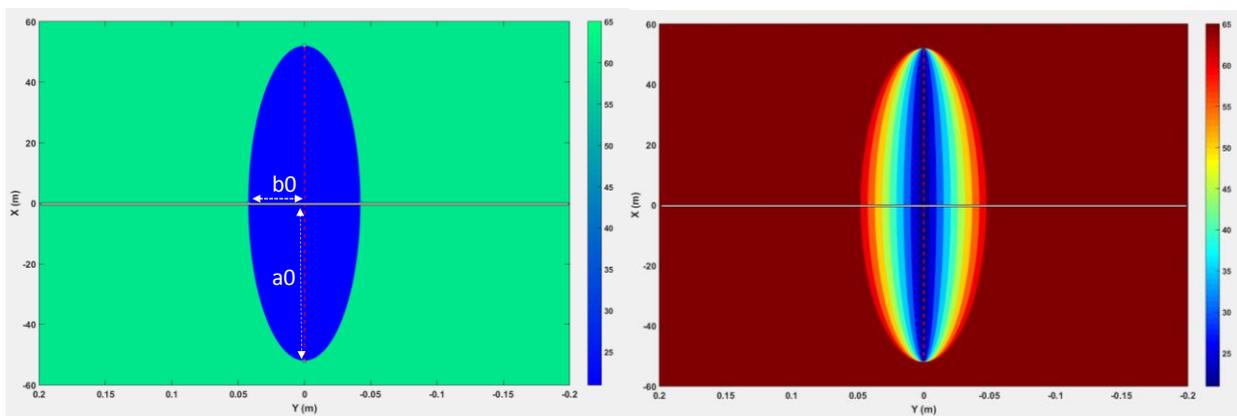

630

635

**Table A.1. Input parameters used for analyzing thermo-elastic stress shadow**

<b>Injection condition</b>	
Depth to the center of the formation (D)	1615 m
Reservoir thickness (h)	7.2 m
Water injection rate (I <sub>w</sub> )	0.65 m <sup>3</sup> /min
Time (t)	47 minutes
Initial Reservoir temperature (TR)	65°C
Bottomhole temp. of the injection water (T <sub>w</sub> )	21.1°C
<b>Reservoir Rock Properties</b>	
Compressibility of grains (C <sub>gr</sub> )	5.43E-05 (MPa) <sup>-1</sup>
Compressibility of formation (C <sub>f</sub> )	6.00E-05 (MPa) <sup>-1</sup>
Young's modulus (E)	25 GPa
Relative perm. To water (K <sub>rw</sub> )	0.29
Residual oil saturation (S <sub>or</sub> )	0.25
Initial water saturation (S <sub>wi</sub> )	0.2
Linear coefficient of thermal expansion (α)	10.5E-06 mm/(mm*K)
Specific heat of mineral grains per unit volume (ρCP)	1.662 MJ/m <sup>3</sup> * K
Thermal conductivity (λ)	2.458 W/(m*K)
Poisson's ratio (ν)	0.25
Reservoir permeability (k)	0.1 md
Porosity (φ)	0.11
<b>Reservoir Fluid Properties</b>	
Viscosity of oil at 65°C (μ <sub>o</sub> )	1.47E-09 Mpa*s
Viscosity of oil at 65°C (μ <sub>whot</sub> )	4.30E-10 Mpa*s
Viscosity of oil at 21°C (μ <sub>wcold</sub> )	9.95E-10 Mpa*s
Compressibility of oil (c <sub>o</sub> )	1.50E-03
Compressibility of water (c <sub>w</sub> )	5.20E-04 (MPa) <sup>-1</sup>
Specific heat of oil (C <sub>o</sub> )	2.1 KJ/(kg*K)
Specific heat of water (C <sub>w</sub> )	4.2 KJ/(kg*K)
Density of oil (ρ <sub>o</sub> )	810 kg/m <sup>3</sup>
Density of water (ρ <sub>w</sub> )	1180 kg/m <sup>3</sup>

## Appendix B: Poro-elastic Stress

655 For analyzing poro-elastic stress shadow, parameters given in Table A.1 were used. By assuming an injection time of 47 minutes and a permeability of 0.1 md, the poro-elastic stress is negligible. However, by assuming an injection time of 75 minutes, and increasing the permeability to 2.5 md, the pore pressure distribution is simulated with results shown in Figure B.1. For this injection time, 2.5 md seems to represent a permeability threshold. Any permeability lower than that gives rise to negligible pore pressure change around the fracture. For a maximum injection volume scenario of 11 tonnes of proppant and injection time of 75 minutes per stage  $a_1 = 52.001$  m and  $b_1 = 0.33$  m for the flood region.

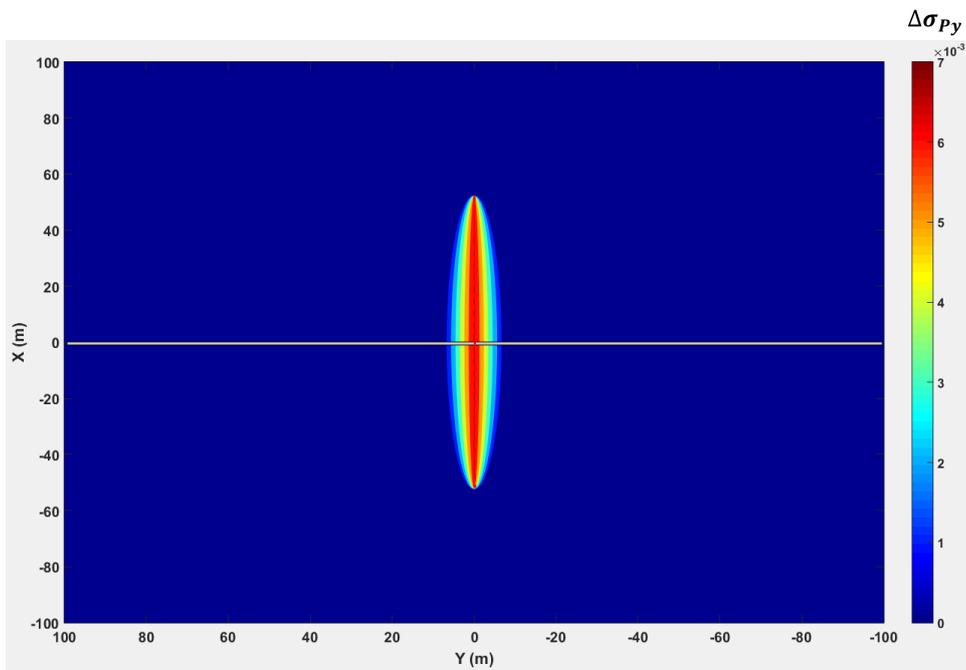

660 The major axis of the elliptical flood region has almost the same length as fracture length with time. Figure B.2 shows the poro-elastic stress shadow perpendicular and parallel to the fracture.

**Figure B.1:** Pore pressure distribution (MPa) around hydraulic fracture after 75 minutes of injection and assuming a reservoir permeability of 2.5 md.
