**Abstract.** Geological carbon sequestration provides permanent CO<sub>2</sub> storage to mitigate the current high concentration of CO<sub>2</sub> in the atmosphere. CO<sub>2</sub> mineralization in basalts has been proven to be one of the most secure storage options. For successful implementation and future improvements of this technology, the time-dependent deformation behavior of reservoir rocks in presence of reactive fluids needs to be studied in detail. We conducted load stepping creep experiments on basalts from the CarbFix site (Iceland) under several pore fluid conditions (dry, H<sub>2</sub>O-saturated and H<sub>2</sub>O+CO<sub>2</sub>-saturated) at temperature, T≈80°C and effective pressure, P<sub>eff</sub> = 50 MPa, during which we collected mechanical, acoustic and pore fluid chemistry data. We observed transient creep at stresses as low as 11% of the failure strength. Acoustic emissions (AEs) correlated strongly with strain accumulation, indicating that the creep deformation was a brittle process in agreement with microstructural observations. The rate and magnitude of AEs were higher in fluid-saturated experiments than in dry conditions. We infer that the predominant mechanism governing creep deformation is time- and stress-dependent sub-critical dilatant cracking. Our results suggest that the presence of aqueous fluids exerts first order control on creep deformation of basaltic rocks, while the composition of the fluids plays only a secondary role under the studied conditions.

## 1 Introduction

The concentration of atmospheric CO<sub>2</sub> has seen a significant increase over the last century, raising concerns about the more frequent occurrence of extreme weather, sea-level rise and the projected increase of average global temperature (Broecker, 1975). It is estimated that about 800 Gt CO<sub>2</sub> will need to be stored by the end of the century to keep the global temperature increase below 1.5 °C compared to pre-industrial levels (National Academies of Sciences, Engineering, 2019). Such large volumes can practically be stored in the sub-surface. Geological carbon sequestration (GCS) by in-situ carbon mineralization is recognized as one of the most secure, long-term storage solutions (Gislason and Oelkers, 2014; Kelemen and Matter, 2008; Lackner et al., 1995; Mani et al., 2008; Seifritz, 1990; Snæbjörnsdóttir et al., 2020; Tutolo et al., 2021). To date, several pilot projects have been launched to study GCS in basalt reservoirs, including the CarbFix program in Iceland (Callow et al., 2018; Gislason et al., 2010; Oelkers et al., 2008; Snæbjörnsdóttir et al., 2018) and the Wallula basalt (part of Columbia River Basalt Group) sequestration project in Washington, US (McGrail et al., 2006, 2011, 2017; Zakharova et al., 2012).

GCS involves the injection of fluids, either supercritical CO<sub>2</sub> or CO<sub>2</sub> in an aqueous solution, into the formations. Basalts are composed of mafic minerals such as pyroxene ((Mg,Fe)<sub>2</sub>Si<sub>2</sub>O<sub>6</sub>), plagioclase ((Ca,Na)Al<sub>1.70</sub>Si<sub>2.30</sub>O<sub>8</sub>), and olivine ((Mg,Fe)<sub>2</sub>SiO<sub>4</sub>) as well as mafic glass, which react with CO<sub>2</sub> to form carbonate minerals (e.g MgCO<sub>3</sub>, CaCO<sub>3</sub>, FeCO<sub>3</sub> etc.), thus binding the injected CO<sub>2</sub> in mineral structure (Gislason and Hans, 1987; Hangx and Spiers, 2009;

34 Matter et al., 2007; Oelkers et al., 2008). Carbonation reactions appear to be rapid in natural conditions; more than  
 35 95% of the CO<sub>2</sub> injected into the CarbFix site in Iceland was converted to carbonate minerals in less than 2 years  
 36 (Matter et al., 2016). Relevant fluid and mineral reactions can be formulated as follows (Hangx and Spiers, 2009;  
 37 Hansen et al., 2005; Kelemen and Matter, 2008; Oelkers et al., 2008):

38 Dissociation:

41 Dissolution:

45 Precipitation:

47 CO<sub>2</sub> is dissolved in water to form an acidic solution (Eq. 1-2). The rocks dissolve to liberate divalent cations (Eq. 3-  
 48 5), which upon saturation in the fluid, precipitate as carbonate minerals (Eq. 6) further downstream from the injection  
 49 site.

50 The mechanical and transport behavior of rocks can be significantly affected during GCS by the interaction between  
 51 rock and fluid, both from a mechanical as well as chemical perspective ( Baud et al., 2000; Dunning & Miller, 1985;  
 52 Heard, 1960; Helmons et al., 2016; Rutter & Hackston, 2017). The mechanical effect of pore fluid is readily accounted  
 53 for by using the effective pressure law (Terzaghi, 1943). The pore fluid acts against the normal stresses acting on crack  
 54 surfaces hence reducing the shear stress necessary to overcome internal friction of the rocks. Increase in pore pressure  
 55 during injection can trigger seismicity and therefore pore pressure has to be carefully monitored (Atkinson et al., 2020;  
 56 Guglielmi et al., 2015). In addition to this mechanical effect, a number of chemical processes can occur in the presence  
 57 of reactive fluids, leading to complex coupling between processes. For example, the replacement of mafic minerals  
 58 with carbonates can result in an up to ~44% increase in solid molar volume (Goff and Lackner, 1998; Hansen et al.,  
 59 2005; Kelemen and Matter, 2008) potentially clogging pore space, reducing permeability and increasing pore pressure.  
 60 Alternatively, this volume expansion can generate stresses causing reaction-induced fracturing, which provides  
 61 additional fluid pathways and maintains porosity and permeability for the reaction to proceed (Iyer et al., 2008;  
 62 Jamtveit et al., 2009; Kelemen & Matter, 2008; Lambart et al., 2018; Macdonald & Fyfe, 1985; Renard et al., 2020;  
 63 Rudge et al., 2010; Skarbek et al., 2018; Xing et al., 2018; Zhu et al., 2016). The fracturing behavior itself is affected  
 64 by the fluid chemistry via kinetic reduction of fracture energy due to fluid absorption on mineral surfaces and crack  
 65 tip blunting (Baud et al., 2000; Orowan, 1944; Rutter, 1972; Scholz, 1968), and activation of fluid-promoted stress  
 66 corrosion processes such as subcritical crack growth resulting in time-dependent deformation, which is the focus of

67 this paper (Anderson & Grew, 1977; Atkinson, 1984; Atkinson & Meredith, 1987; Brantut et al., 2013; Nara et al.,  
68 2013; Rice, 1978).

69 This time-dependent deformation, often called “brittle creep” or “static fatigue”, has been observed in all types of  
70 rocks tested to date (Atkinson & Meredith, 1987; Brantut et al., 2012; Heap et al., 2011; Kranz et al., 1982; Robertson,  
71 1960; Scholz, 1968; Zhang et al., 2012). During brittle creep, flaws such as micro-cracks contained in natural rocks  
72 are sub-critically stressed and propagate slowly due to stress corrosion (a chemical weakening process) at crack tips  
73 in the presence of fluids. Sample-scale fracture then occurs after some time delay when the cracks coalesce and reach  
74 a critical length. As a result, the rocks lose their load bearing capabilities and fail along a macroscopic fault plane at  
75 stresses well below their short term strength (Scholz, 1972). For the sake of simplicity, we will use creep in the  
76 following text to refer to this brittle creep deformation.

77 It has been shown by experiments, observations and modelling that stress corrosion is the dominant mechanism of  
78 subcritical crack growth in rocks under upper crustal conditions (Brantut et al., 2012; Michalske and Freiman, 1983;  
79 Reber and Pec, 2018). Brittle creep deformation can be accelerated due to changes in the rate of stress corrosion  
80 induced by the chemistry of the injected fluids (Renard et al., 2005, 2020) or decelerated by crack tip blunting due to  
81 fluid interaction (Scholz, 1968). Overall, it is hypothesized that changes in stress corrosion crack growth rate due to a  
82 change in fluid chemistry will be reflected in similar changes of the macroscopic creep strain rate, either accelerating  
83 or decelerating based on the details of the ongoing dissolution – precipitation reactions (Brantut et al., 2013). Hence,  
84 the effect of CO<sub>2</sub>-rich fluids needs to be quantified for GCS applications.

85 To summarize, the influence of rock-fluid interaction on deformation is complicated and includes the coupled effects  
86 of mineral dissolution and precipitation, kinetics of fluid assisted deformation and injection pressure built-up, finally  
87 resulting in time-dependent rock deformation. Carbonation changes the bulk composition of the basalts, alters their  
88 strength and pore structure, and affects the permeability of the rocks (Dunkel et al., 2017; Kanakiya et al., 2017;  
89 Kelemen et al., 2013; Kelemen & Hirth, 2012; Lisabeth et al., 2017; Xing et al., 2018; Zhu et al., 2016). Understanding  
90 of the effects of rock-fluid interaction on deformation requires dedicated laboratory studies with diverse fluid  
91 compositions at in-situ pressure conditions and at elevated temperatures acting over extended timescales. The present  
92 study aims at elucidating the effect of rock-fluid interaction on the time-dependent rock deformation by investigating  
93 long-term creep of Iceland Basalt saturated with various fluid compositions.

## 94 **2 Materials and Methods**

### 95 **2.1 Starting Material and Sample Configuration**

96 We used Iceland Basalt drill cores from the CarbFix site, collected at ~350 m depth. The composition of Iceland Basalt  
97 has been identified as tholeiite and contains ~ 25 wt% of calcium, magnesium and iron oxides (7-10 wt% Ca; 5-6 wt%  
98 Mg; 7-13 wt% Fe) with an average porosity of ~ 8% based on hydrological and tracer recovery modeling (Alfredsson  
99 et al., 2008, 2013; Aradóttir et al., 2012; Matter and Kelemen, 2009; Snæbjörnsdóttir and Gislason, 2016). The rock  
100 is formed by an aphanitic matrix that consists of crystals of feldspars, clinopyroxene, olivine, glass and secondary  
101 alteration minerals as shown in Figure 1 and A1. Our observations are consistent with previously reported petrographic

102 analysis which shows that the primary minerals of the Iceland Basalt are predominantly plagioclase (An90-30), olivine  
103 (Fo90-80), clinopyroxene (augite), magnetite-ilmenite, and interstitial glass, alteration of the basaltic lava flows  
104 commonly leads to smectite and zeolite precipitation (Alfredsson et al., 2013; Larsson et al., 2002). The fraction of  
105 crystal-to-glass ratio as well as crystal habitat is variable as documented in Figure 1. Round pores with a mean diameter  
106 of  $\sim 0.5$  mm are randomly distributed throughout the matrix, some are filled with feldspar (primarily potassium  
107 feldspar) and some are voids with no filling (Figure 1). Pore-, as well as pre-existing crack-walls are coated by a thin  
108 layer of a phyllosilicate as documented in Figure 1d and 1e. The matrix is locally altered by dissolution of larger  
109 subhedral feldspar crystals and local replacement by phyllosilicate (see Figure 1b and 1e). Cylindrical samples were  
110 ground to  $\sim 40$  mm in diameter and  $\sim 80$  mm in length (see Table 1). The samples were jacketed using copper foil of  
111  $\sim 0.05$  mm thickness, joined to titanium end-caps by Viton tubes and coated with Duralco 4538 epoxy. The end-caps  
112 had a concentric hole which allows fluid access to the sample. Figure 2 shows the schematics of the sample  
113 configuration in this study. An internal force gauge was mounted below the sample inside the vessel, allowing direct  
114 measurement of the differential stress ( $\Delta\sigma = \sigma_1 - \sigma_3$ ). Displacement of the axial piston was measured externally using  
115 a linear variable differential transformer (LVDT). Variations of the sample length were measured using two internal  
116 LVDTs. Local axial ( $\epsilon_a$ ) and radial strains ( $\epsilon_r$ ) of the rock were measured using strain gauges affixed to the copper  
117 jacket around the sample. Piezoelectric sensors were installed around the sample for passive monitoring of acoustic  
118 emissions (AE).

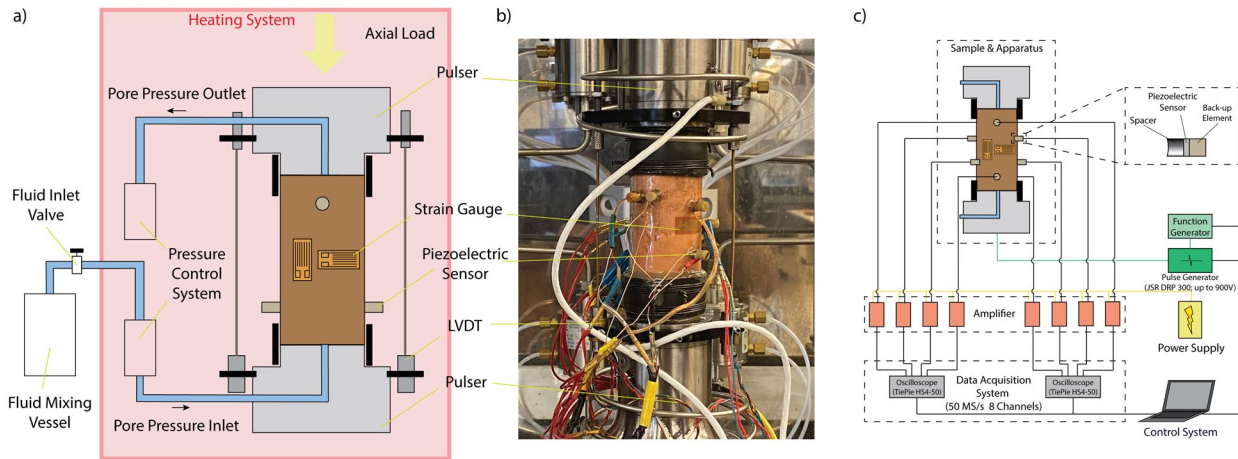

119

120 **Figure 1.** Backscattered electron (BSE) images of the starting material. Location of higher-magnification images is  
 121 shown by yellow rectangles a) Representative sample microstructure; Glassy matrix shows a range of crystal content  
 122 and habitat and is locally altered; Area where Energy Dispersive Spectroscopy (EDS) analysis is conducted (see details  
 123 in Appendix Figure A1) is marked by the dashed rectangle; b) Another common glassy matrix microstructure with  
 124 finer, more homogenous crystals; c) Detail of altered matrix and pore wall. Note black voids in the shape of subhedral  
 125 feldspar laths in the matrix; d) Detail of patchy phyllosilicate alteration and dendritic crystals in altered matrix; e)  
 126 high-magnification image of dendritic crystals forming the matrix and phyllosilicate coating of the pore wall; f) high  
 127 magnification image of glassy matrix with homogenous small crystals g) high-magnification image of dendritic  
 128 crystals forming the unaltered matrix and high magnification image of the phyllosilicate alteration.

129 Because of the variation in structure and composition of the natural material and limited drill core material available,  
 130 we adopted the 'stress-stepping' experimental procedures to study creep deformation (Heap et al., 2009; Lockner,  
 131 1993). This method allows several creep experiments to be conducted on a single sample at different stress levels and

132 minimizes the issue of inter-sample variability (see details in Section 2.2). Piezoelectric sensors allowing independent  
 133 recording of compressional and shear waves were fabricated with PZT-5A ceramics with thickness of 3 to 5 mm and  
 134 resonance frequency of  $\sim 450$  kHz to 1 MHz. The PZT-5A crystals were mounted on titanium spacers with one side  
 135 concavely curved to match the sample surface, thus providing protection of the sensing crystals and optimal contact  
 136 area. A back-up element was epoxied to the back of the sensor to minimize ringing. We also used analog low pass  
 137 filters ( $\sim 500$  kHz) compatible with the frequency range of the employed PZT ceramics to reduce the electromagnetic  
 138 interference (EMI) effect. Data was collected using two combined 4-channel universal serial bus (USB) oscilloscopes,  
 139 recording at 50 MS/s with a 12-bit resolution (TiePie HS4-50). Using low noise amplifiers (ITASCA-60dB), we  
 140 carefully selected the most sensitive sensor positions, preferably far from each other, as master channels. The data  
 141 collection system was set such that, if the master channels detected a signal satisfying a sufficiently large signal/noise  
 142 ratio in a moving time window, the event would be recorded in all channels. We amplified the two master channels  
 143 with a flat gain of 60 dB in a frequency range of 50 kHz to 1.5 MHz. Frequencies from 1.5 MHz to 15 MHz were  
 144 amplified nonlinearly, the gain decreasing exponentially from 52 dB to 37 dB with increasing frequency (Ghaffari et  
 145 al., 2021; Ghaffari and Pec, 2020). Considering the above limitations, the main frequency range of the recording  
 146 system was between  $\sim 50$  and 500kHz, although other frequencies could be recorded owing to the exponential nature  
 147 of the amplification filters.

148  
 149 **Figure 2.** a) Schematics of sample configuration. The whole sample assembly and pore fluid actuators are enclosed  
 150 in a servo-controlled heating system to ensure a uniform temperature condition; b) Photo of the sample assembly; c)  
 151 Illustration of the acoustic emission recording system.

152  
 153 All experiments were conducted at 50 MPa effective pressure,  $P_{\text{eff}}$ , with pore fluid pressures,  $P_f$ , of either 0 or 5 MPa  
 154 for dry and fluid-saturated experiments, respectively. The fluids used in this study were  $\text{H}_2\text{O}$  and  $\text{H}_2\text{O}+\text{CO}_2$ . The  
 155  $\text{H}_2\text{O}+\text{CO}_2$  fluid is prepared in the fluid mixing vessel (Figure 2a) where deionized water is saturated with  $\text{CO}_2$  in the  
 156 vessel under a gas pressure of 5 MPa. The fluid-saturated samples were first immersed in deionized water under  
 157 vacuum for more than 30 days prior to the experiment. Details of the experimental conditions are listed in Table 1.  
 158 The samples were inserted in the NER Autolab 3000 testing rig installed at MIT and deformed under tri-axial stress  
 159 conditions, with the maximum principal stress ( $\sigma_1$ ) acting in the axial direction. The radial principal stresses ( $\sigma_2$  and  
 160  $\sigma_3$ ) were generated by the confining pressure, i.e.,  $\sigma_2 = \sigma_3 = P_c$ . The effective pressure is calculated as  $P_{\text{eff}} = P_c - P_f$ .  
 161 During deformation, a constant pressure difference of 0.5 MPa was maintained between the inlet and outlet of the pore

162 pressure system, while the mean pore pressure was kept at 5 MPa. We thus maintained fluid flow across the sample  
 163 and measured the permeability evolution during deformation. In one H<sub>2</sub>O+CO<sub>2</sub> experiment (OR2\_M), we closed the  
 164 fluid mixing vessel after the initial filling of the sample and thus formed a close pore fluid loop (OR2\_M was referred  
 165 to as H<sub>2</sub>O+CO<sub>2</sub> close experiment in the following discussion). In the other H<sub>2</sub>O+CO<sub>2</sub> experiment (OR3\_B), the pore  
 166 fluid system was connected to the fluid mixing vessel during the entire experiment and therefore acted as a semi-open  
 167 system since it was in constant communication with a large CO<sub>2</sub> source (OR3\_B was referred to as H<sub>2</sub>O+CO<sub>2</sub> open  
 168 experiment in the following discussion).

Experiment Number	Sample Length (mm)	Sample Diameter (mm)	Confining Pressure (MPa)	Pore Pressure (MPa)	Effective Pressure (MPa)	Pore Fluid Composition	Temperature (°C)	Young's Modulus (GPa)	Failure Strength (MPa)	Strain at Failure (%)	Initial Porosity (%)
OR5	77.37	39.32	50	0	50	-	78	17.6	>105	1.89	15
OR2_T	81.5	38.01	55	5		H <sub>2</sub> O		12.1	72	1.71	11
OR2_M	81.48	39.22	55	5		H <sub>2</sub> O + CO <sub>2</sub>		16.2	55	0.84	5
OR3_B	77.94	39.81	55	5		H <sub>2</sub> O + CO <sub>2</sub>		28.0	130	2.00	-

169 **Table 1.** Details of the sample parameters and experimental conditions. Sample OR5 was not loaded to its failure  
 170 strength due to early failure of the strain gauges and LVDTs. Porosity is estimated from the X-ray tomographic image  
 171 of the sample. Initial porosity of the sample OR3\_B is not available due to limited access to the X-ray tomography  
 172 facility during COVID-19 pandemic.

173 We started the experiments by bringing the sample to an effective pressure of 50 MPa and subsequently to a  
 174 temperature of ~80°C while holding the pressure constant. Heating the sample took ~12 hours, long enough to allow  
 175 thermal equilibrium to be reached. After reaching the desired P - T conditions, the samples were deformed using a  
 176 step loading procedure. During a step, the differential stress was increased at a rate of ~2 MPa/min, which corresponds  
 177 to an axial strain rate of  $\sim 1.1 \times 10^{-6} \text{ s}^{-1}$ . Once the desired stress level was reached, we kept the load constant for ~24  
 178 hours, while monitoring the sample deformation. This step sequence was repeated until failure of the sample occurred  
 179 – typically during the increase of differential stress. We recorded the stress level at which the failure occurred as  
 180 ‘failure strength’ and use this parameter to quantify the strength of the tested material. We point out that the definition  
 181 of ‘failure strength’ used here presents a lower bound for the commonly presented ‘ultimate strength’ which is  
 182 measured in short-term, constant displacement rate deformation experiments. The dry experiment is halted earlier due  
 183 to failure of the strain gauges and LVDTs and therefore the strength estimate is only a lower bound of the failure  
 184 strength. The total duration of the experiments ranged between 5 to 12 days. Details of the load steps are summarized  
 185 in Appendix (Figure A2).

186 In this study, we focus on the transient creep evolution and only creep steps where final failure is not observed are  
 187 analyzed. We use the term phase I to refer to the creep immediately following a stress change, during which the creep  
 188 strain evolves rapidly (i.e., relatively higher strain rate). We call phase II the portion of the creep curve with an  
 189 approximately constant or very slowly varying strain rate over a ~24h window (i.e.  $d\varepsilon/dt = cte.$ ; see Appendix  
 190 Figure A3). For comparison with previous work on brittle creep, we calculate a characteristic creep strain rate using a  
 191 least-squares fit to the slope of the creep strain vs. time curve during the identified phase II transient creep (Appendix  
 192 Figure A5; we will simply refer to it as creep rate in the following discussion).

193 To investigate the micro-structural changes occurring during deformation, the rock samples were scanned before and  
194 after deformation using X-ray computed tomography with scan parameters set at ~150 kV and ~250  $\mu$ A. The obtained  
195 X-ray images have a pixel size of ~90 $\times$ 90  $\mu$ m. Thin sections were prepared from selected samples and imaged using  
196 a field emission scanning electron microscope (SEM).

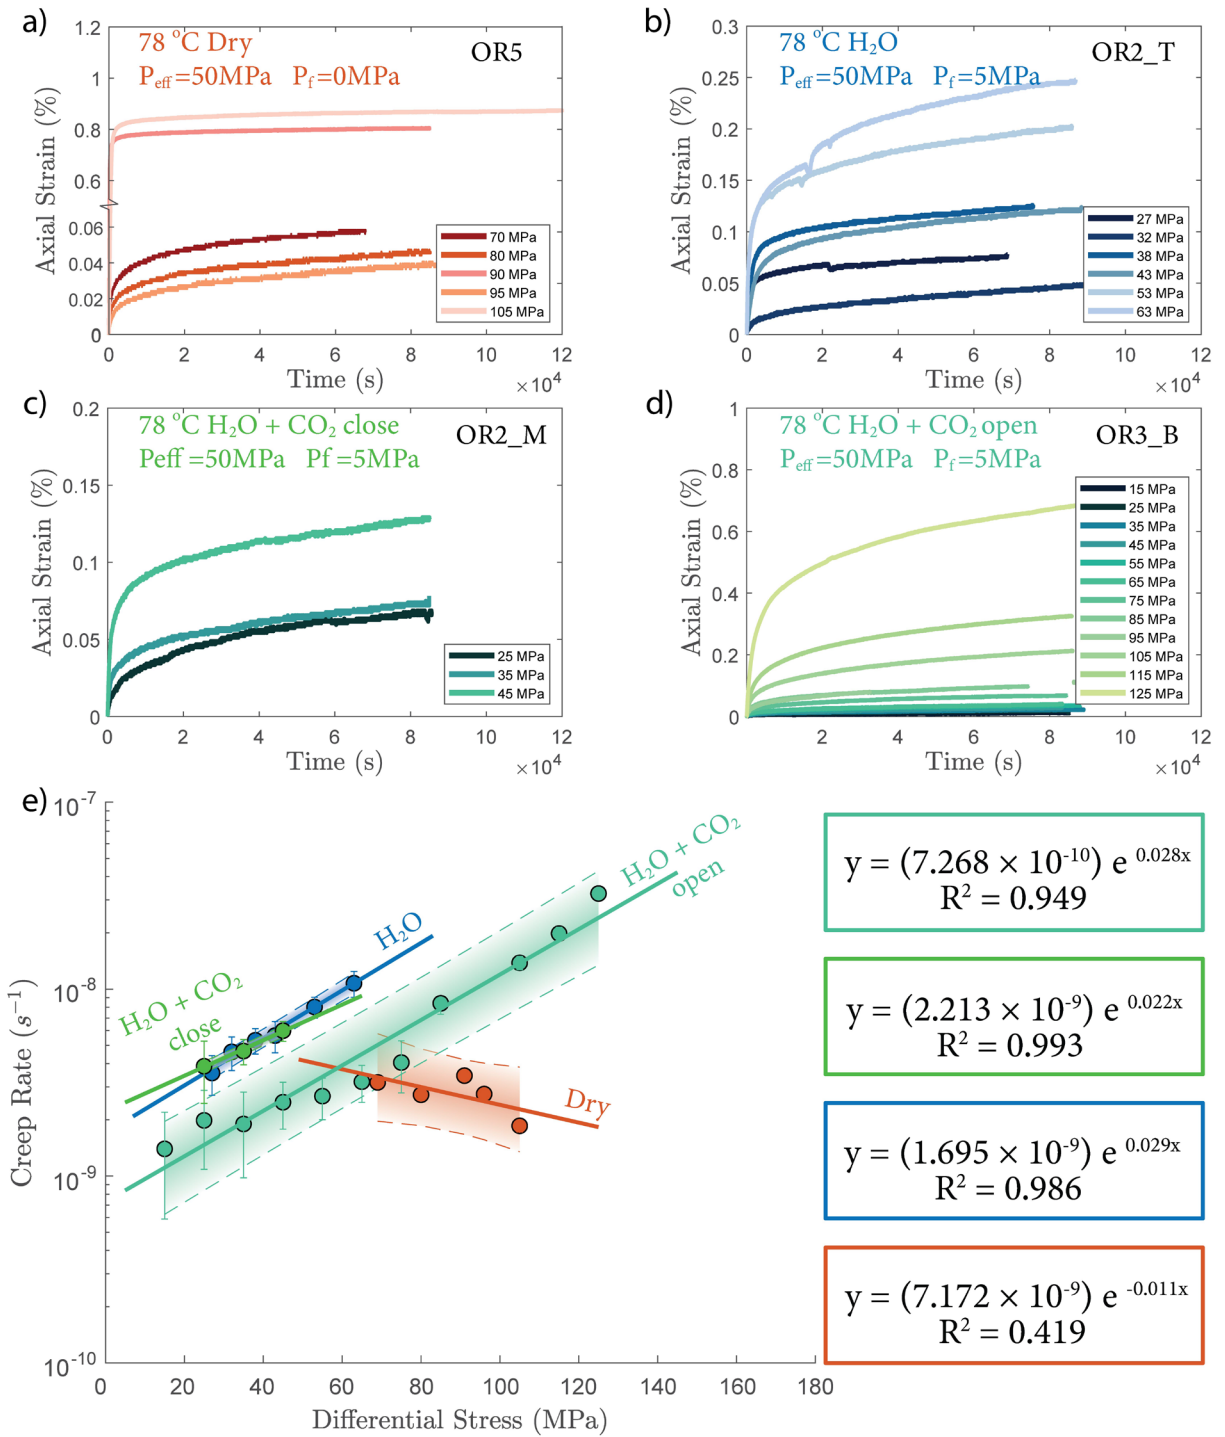

197 The evolution of fluid composition was evaluated by collecting fluid samples from the end of the pore fluid outlet  
198 (Figure 2a) after each creep step. The concentration of  $Mg^{2+}$ ,  $Ca^{2+}$  in the fluid sample were analyzed using the  
199 Inductively Coupled Plasma Mass Spectrometry (ICP-MS).

## 200 **3 Results**

### 201 **3.1 Creep Deformation and Creep Strain Rate**

202 The creep deformation during each load step exhibited typical transient creep evolution (Brantut et al., 2013;  
203 Robertson, 1964; Scholz, 1968) with a transition from phase I where rapid straining occurs to a slowly varying phase  
204 II which exhibits an approximately constant strain rate over our observation time (Figure 3). This transition generally  
205 took place within the first  $10^4$  s (~2.7 hrs) of the loading step. In the dry experiment, large variations in phase I creep  
206 strains were observed (Figure 3a & 4c) and the creep rates measured during the slowly evolving phase II stages showed  
207 a neutral sensitivity to stress (Figure 3e). In experiments where pore fluids were present ( $H_2O$  and  $H_2O+CO_2$ ), the  
208 strain accumulated during the phase I creep systematically increased with increasing stress and the creep strain rate  
209 during the phase II creep displayed a clear exponential dependence on stress (Figure 3e). This stress sensitivity of  
210 creep strain rate showed strong similarity in the different experiments irrespective of the pore fluid composition and  
211 can be adequately described by power law (e.g. Atkinson, 1984; Meredith and Atkinson, 1983) as well as exponential  
212 functionals (Charles and Hillig, 1962; Hillig, 2006), but the exponential model seems to work slightly better with our  
213 data according to the  $R^2$  value (see Appendix Figure A6).

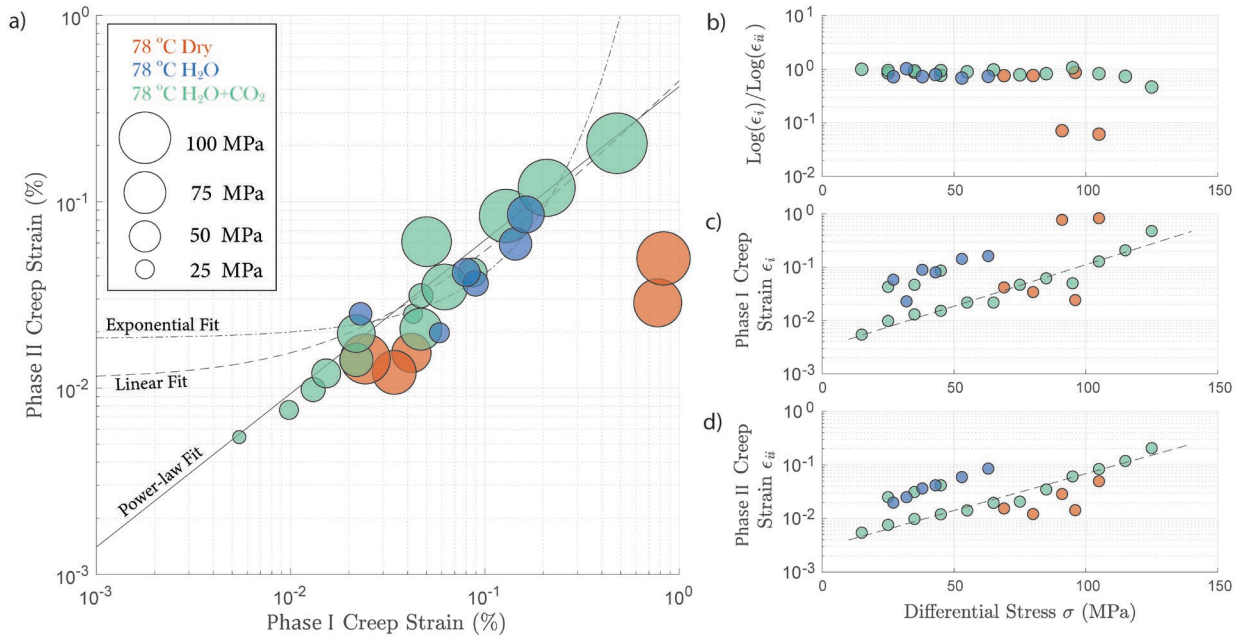

214

215 **Figure 3.** a) - d) Axial strain evolution of each individual stress step for all experiments; e) Stress dependence of creep  
 216 rate. The error bar marks the 95% confidence interval of each calculated creep rates. The stress-creep rate relationship  
 217 can be best modeled using an exponential law. The dash line and shaded area marks the 95% confidence interval of  
 218 the fitted exponential relationship. The stress dependence of creep rate in the dry experiment is considered neutral as  
 219 the  $R^2$  becomes low for the fitting with negative slope. Color code of the plot follows the same as a) - d).

220 In Figure 4 we compare the strain accumulation during phase I and II of the transient creep as illustrated in Figure  
 221 A4a. We observe a universal power-law relationship of the accumulated creep strain during phase I ( $\epsilon_i$ ) to creep strain  
 222 accumulated during phase II ( $\epsilon_{ii}$ ) in all experiments irrespective of fluid presence or the composition of the fluid  
 223 (Figure 4a), i.e. the ratio between  $\log \epsilon_i$  and  $\log \epsilon_{ii}$  remains constant. The accumulated creep strains during both phase  
 224 I and phase II were exponentially dependent on creep stress (Figure 4c and 4d). In Figure 4b we show that regardless  
 225 of the creep stress level, the ratio between the logarithmic accumulated phase I and logarithmic phase II creep strain  
 226 after  $\sim 24$  hrs was approximately constant, except for two outliers associated with two stress steps in the dry  
 227 experiment, during which anomalously large phase I creep strains occurred (Figure 4a and 4c).

228 Overall, the fluid saturated samples crept faster than the dry sample during phase II stages in similar stress conditions.  
 229 In spite of variations in failure strength, the fluid saturated samples consistently showed stronger stress dependence of  
 230 the creep rate than the dry sample. Comparing the fluid saturated experiments, we observe that the sample saturated  
 231 with  $H_2O$  had the same creep rate as the  $H_2O + CO_2$  close experiment and a higher creep rate than the  $H_2O + CO_2$  open  
 232 experiment under similar stress level. (Figure 3e). Analysis of the fluid chemistry demonstrates that the  $H_2O + CO_2$   
 233 close and  $H_2O$  experiment show same fluid composition which we will describe in more detail in Section 3.6.

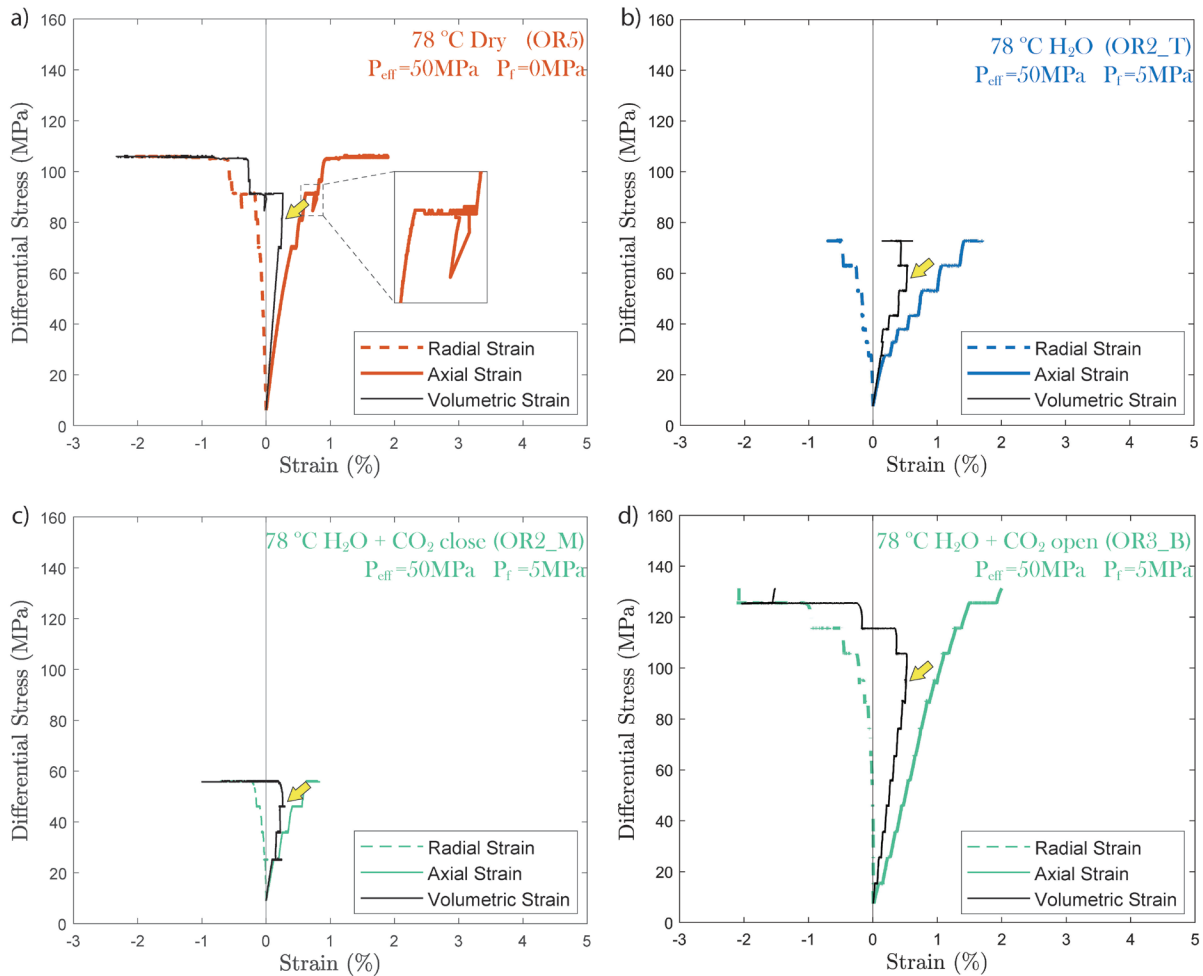

234  
 235 **Figure 4.** a) Relationship between total phase I creep strain and phase II creep strain  $\sim 24$  hrs after the stress step  
 236 loading. The creep stress level is reflected by the size of the circles; b) ratio between the logarithmic total phase I and  
 237 logarithmic phase II creep strain remains constant and is independent of stress; the cumulated c) phase I and d) phase  
 238 II creep strain is exponentially dependent on the creep stress; The fitted lines are calculated based on the data obtained  
 239 from  $H_2O + CO_2$  open experiment (OR3\_M).

### 240 3.2 Volumetric Strain

241 In all experiments, creep deformation was initially compactive as indicated by a positive change in the volumetric  
 242 strain,  $\epsilon_v$ , calculated from the strain gauge measurements ( $\epsilon_v = \epsilon_a + 2\epsilon_r$ ). Shear-enhanced dilation (Brace et al., 1966)  
 243 started 10 - 20 MPa before the failure strength of the sample was reached (highlighted by yellow arrowheads in Figure

244 5). The onset of dilation generally occurred at lower stress level in the fluid saturated experiments than in dry  
 245 conditions. The largest dilation was observed in H<sub>2</sub>O+CO<sub>2</sub> open experiments as shown in Figure 5d. In the dry  
 246 experiment, large amount of dilation ( $\Delta\epsilon_v > 0.5\%$ ) was also observed at creep stress of  $\sim 90$  MPa and  $\sim 105$  MPa which  
 247 is significantly higher than in other steps ( $\Delta\epsilon_v < 0.1\%$ ). Furthermore, the dilation at  $\sim 90$  MPa is also accompanied by  
 248 a drop in stress (see Figure 5). The strength of the tested samples seems to be correlated with the elastic modulus  
 249 measurements, the stiffer the rock the higher the strength (see Table 1).

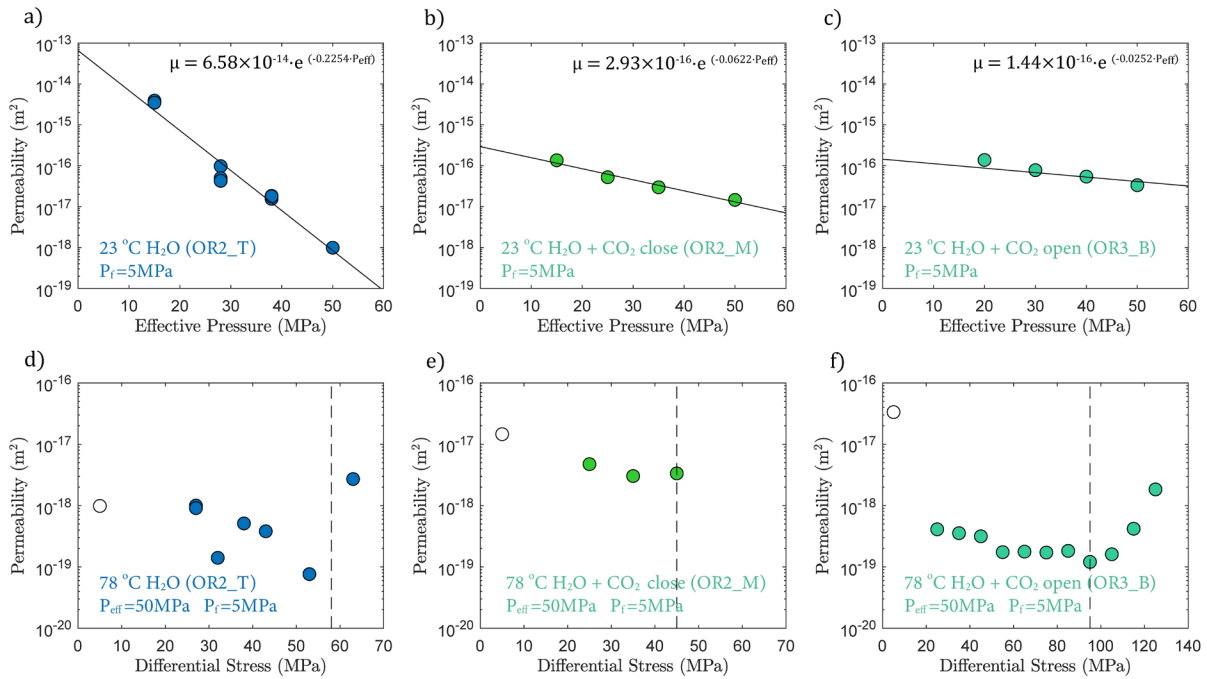

250  
 251 **Figure 5.** Plots of volumetric strain for a) dry, b) H<sub>2</sub>O, c) H<sub>2</sub>O+CO<sub>2</sub> close and d) H<sub>2</sub>O+CO<sub>2</sub> open experiments. The  
 252 onset of transition from compaction to dilatancy (C\*) is marked by the yellow arrowhead. In the dry experiment, the  
 253 differential stress exhibits temporary fluctuation at  $\sim 90$  MPa (highlighted by the dashed rectangle).

### 254 3.3 Permeability

255 In fluid-saturated experiments, permeability decreased with increasing effective pressure during hydrostatic loading  
 256 (Figure 6a, b and c). The largest decrease in permeability was observed in the water-saturated experiment, where  
 257 permeability dropped by 3 orders of magnitude as effective pressure was raised from 15 to 50 MPa (Figure 6a).  
 258 Permeability reduction was much lower in both H<sub>2</sub>O+CO<sub>2</sub> experiments, only  $\sim 1$  order of magnitude, over the same  
 259 effective pressure range (Figure 6bc). Permeability variations after heating are shown in Figure 6d 6e and 6f, where

260 the minimum permeability reached during hydrostatic loading is indicated for comparison (empty circles in Figure 6d,  
 261 e and f). The permeability change during heating was rather small in the H<sub>2</sub>O and H<sub>2</sub>O+CO<sub>2</sub> close experiment, while  
 262 the H<sub>2</sub>O+CO<sub>2</sub> open experiment exhibited more than an order of magnitude permeability reduction after heating.  
 263 During creep, permeability did not evolve much with time but did show a clear dependence with the stress level of the  
 264 individual creep stages, first slightly decreasing with increasing differential stress and then substantially increasing  
 265 when the onset of transition from compaction to dilatancy (C\*) was passed, shortly before failure (Figure 6d and 6f).

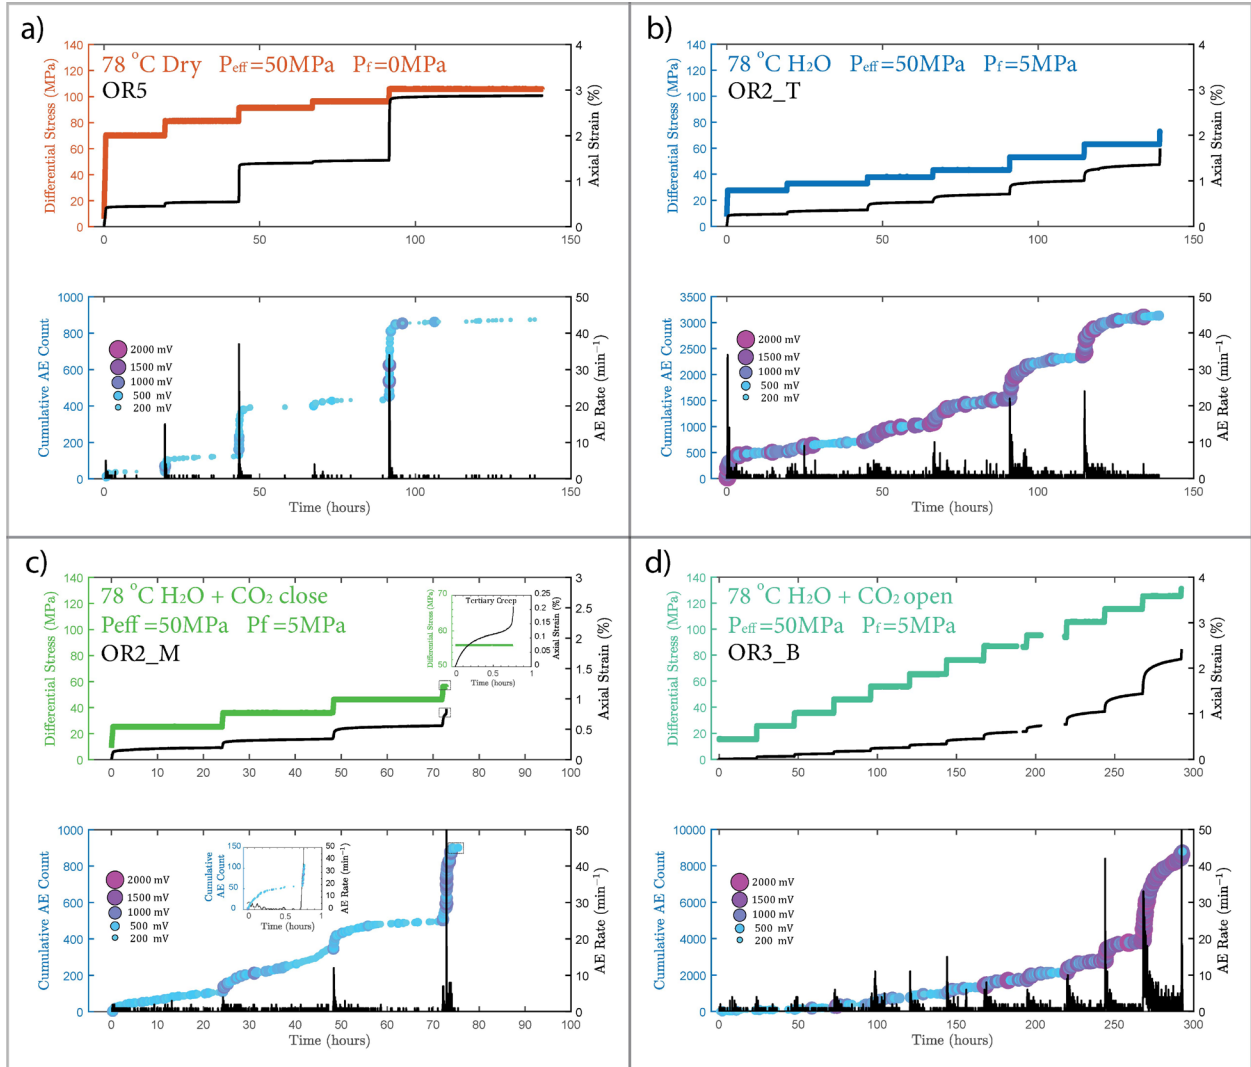

266  
 267 **Figure 6.** Permeability evolution due to changes in a) b) c) effective pressure and d) e) f) differential stress. The dash-  
 268 line marks the onset of transition from compaction to dilatancy (C\*) as previously shown in Figure 4. The empty  
 269 circle indicates the permeability measurement before heating.

### 270 3.4 Characterization of the Acoustic Emissions

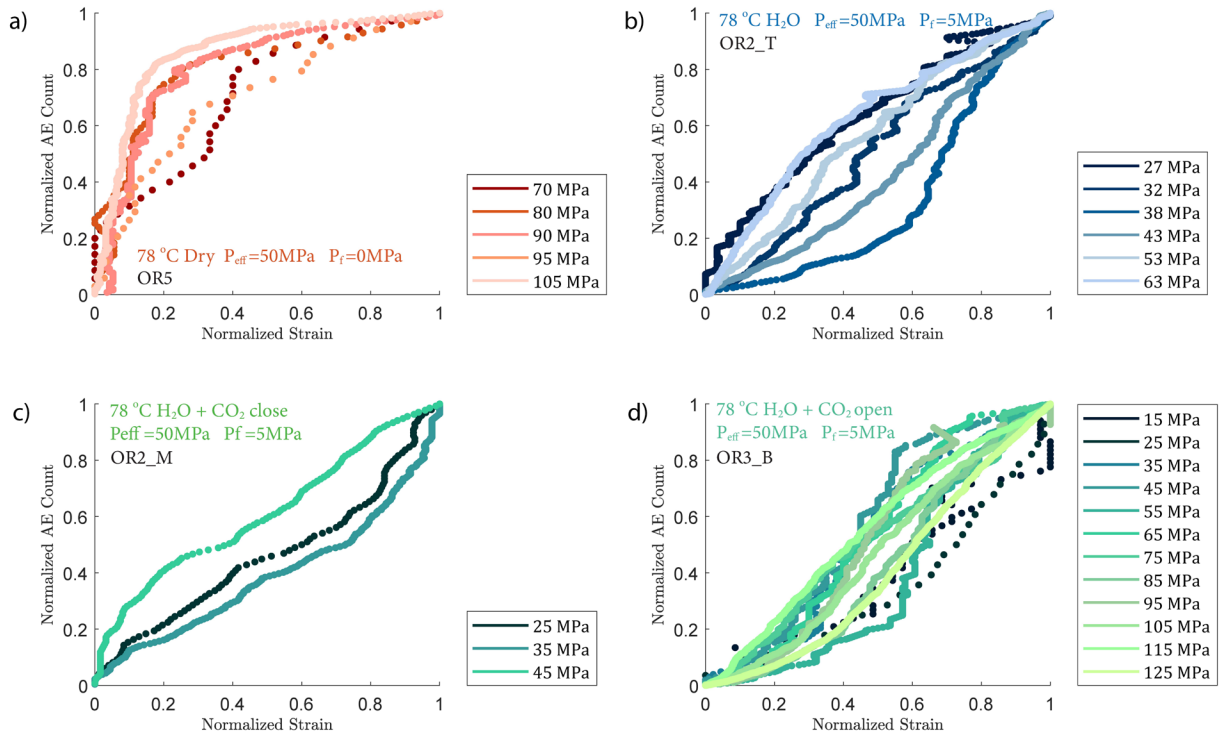

#### 271 3.4.1 Passive Recording & Rate of AEs

272 We observed a strong correlation between acoustic emissions and mechanical data as documented in Figure 7. The  
 273 number and amplitude of AEs was substantially larger in the experiments with pore fluids than in the dry experiment,  
 274 irrespective of fluid composition. The rate of AEs increased during primary creep; the greater the accommodated  
 275 strain was, the higher the AE rate. The AE rate then decayed exponentially as the rock entered the later stage of the  
 276 transient creep. This decay was slower in all fluid saturated experiments where significant amount of AE activity  
 277 continued during the phase II creep stage. The AE rate increased as the stress was approaching the failure strength of  
 278 the sample (Figure 7). In Figure 8, we plot the normalized cumulative AE counts against the normalized creep strain  
 279 measured during each creep step. For all experiments with pore fluids, we see that the data-points tended to cluster  
 280 near the 0-1 diagonal (Figure 8b, c and d), thus supporting a strong correlation between acoustic emissions and creep

281 strain. In the dry experiment, most AEs occurred early in each load step (normalized strain  $\leq 0.2$ ) after which straining  
 282 continued with little AE activity (Figure 8a).

283  
 284 **Figure 7.** Top: Plot of stress loading steps and strain (black) evolution; Bottom: Evolution of cumulative number of  
 285 acoustic emission (AE) and AE rate evolution (black) over time for a) dry, b) H<sub>2</sub>O, c) H<sub>2</sub>O+CO<sub>2</sub> close, note short  
 286 tertiary creep stage accompanied by a burst of AE activities during the last stress step (see insets), d) H<sub>2</sub>O+CO<sub>2</sub> open  
 287 experiments.

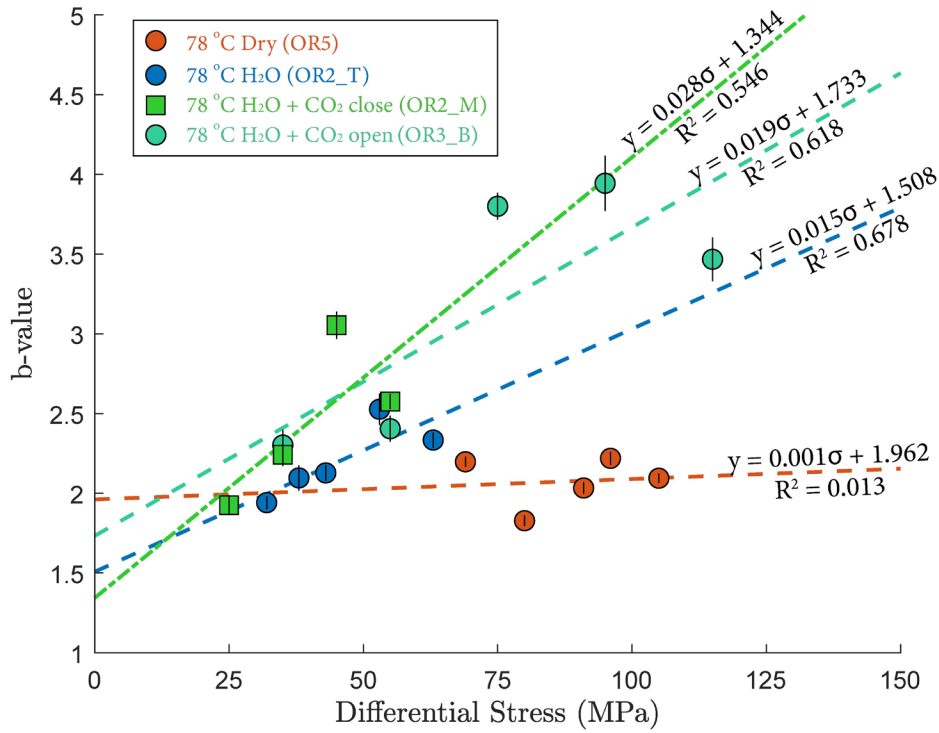

288  
 289 **Figure 8.** Plot of normalized cumulative AE count vs strain a) dry, b) H<sub>2</sub>O, c) H<sub>2</sub>O+CO<sub>2</sub> close and d) H<sub>2</sub>O+CO<sub>2</sub> open  
 290 experiments. the normalized cumulative AE counts and strain during each creep step show an approximately linear  
 291 correlation in most cases except in the dry experiment.

292 **3.4.2 Gutenberg-Richter b-value**

293 The Gutenberg-Richter relationship provides a way to characterize the AE statistics for each creep step. The  
 294 Gutenberg-Richter *b*-value was calculated using the following equation:

295 
$$\log N = a - b \log A \quad (\text{Eq. 7})$$

296 where *A* is the maximal amplitude of individual acoustic events and *N* is the number of events with magnitude larger  
 297 than *A*. Figure 9 shows that the *b*-value increased with increasing stress in the fluid saturated experiments but remained  
 298 constant in the dry experiment. The observed increases of the *b*-values indicate that low amplitude AEs had a  
 299 proportionally larger occurrence frequency with increasing stress.

300

301 **Figure 9.** Differential stress dependence of Gutenberg-Richter  $b$ -values. See detailed  $b$ -value fitting in the Appendix  
 302 Figure A7. The error bar marks the 95% confidence interval of the calculated  $b$ -value.

303 **3.5 Microstructure**

304 Post-mortem examination of the samples reveals that fractures inside the fluid-saturated samples form a complex,  
 305 wide system rather than a clearly defined, distinct shear fault plane (Figure 10 and Appendix Figure A8). The fluid-  
 306 saturated samples exhibit bulging on the surface. In contrast, the dry sample shows a weakly developed fault plane  
 307 and less bulging, however it should be noted that this sample did not, in fact, reach failure strength.

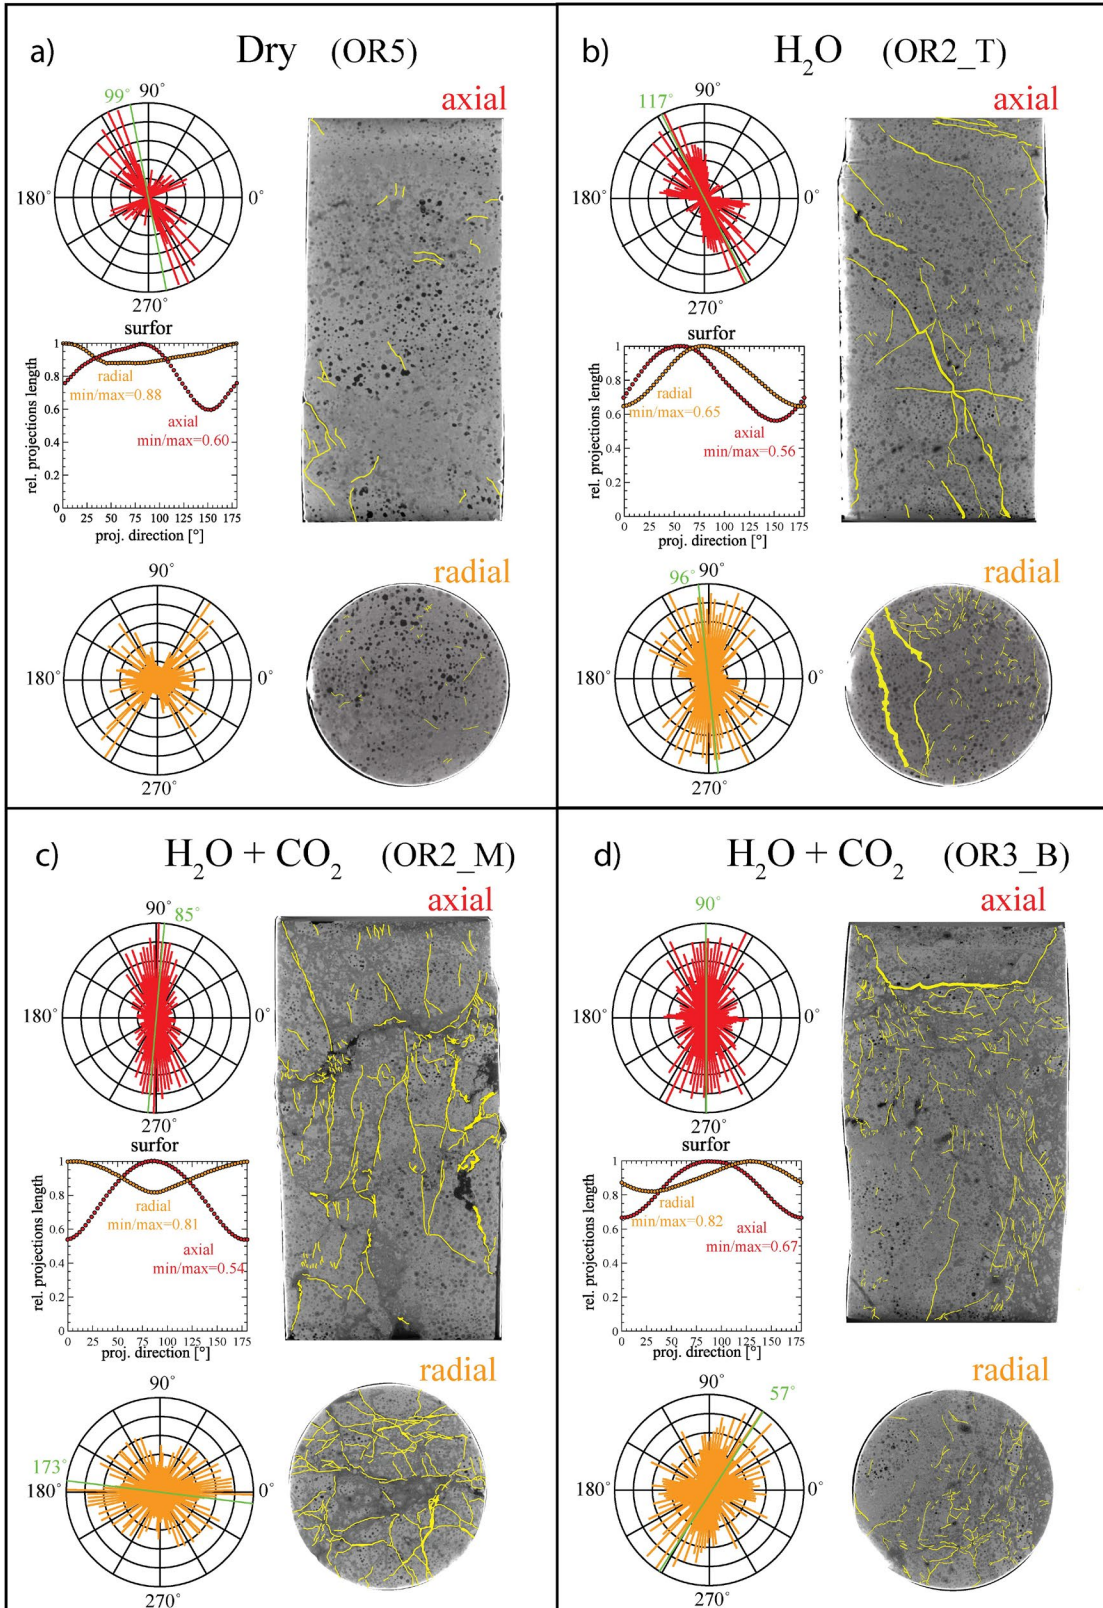

308  
309 **Figure 10.** a) Deformed sample from H<sub>2</sub>O+CO<sub>2</sub> open experiment (OR3\_B). b) Cross-sectional view of the deformed  
310 sample. Top view of the sample c) before and d) after the experiment.

311 X-ray tomographic images (Figure 11) and BSE images (Figure 12) of the deformed samples display abundant  
312 fractures, whereas cracks are much more rare in the pre-deformation CT scans and the BSE images (Figure 1). The  
313 amount of visible cracks in each sample tends to scale with the cumulative AE count; the dry experiment has a lower  
314 fracture density than the experiments with H<sub>2</sub>O and H<sub>2</sub>O + CO<sub>2</sub> despite the fact that the dry sample experienced a  
315 higher stress and developed a larger total strain accumulation. To illustrate these observations, we selected  
316 representative pairs of 2D tomographic slices oriented parallel and perpendicular to the loading direction and traced  
317 the observable microcracks (Figure 11). We quantified both the orientation and anisotropy of the microcracks using  
318 the 'surfor' method that relies on the projection of an outline (Heilbronner and Barrett, 2014; Panozzo, 1984). As  
319 documented in Figure 11, cracks are strongly aligned in the axial sections. The cracks are mainly oriented parallel to  
320 the maximum principal stress in the H<sub>2</sub>O+CO<sub>2</sub> experiment, indicating Mode I cracking, but are aligned 20~30° to the  
321 maximum principal stress in the dry and H<sub>2</sub>O experiments, suggesting mixed Mode I + Mode II cracking. A weaker  
322 alignment is generally observed in radial sections.

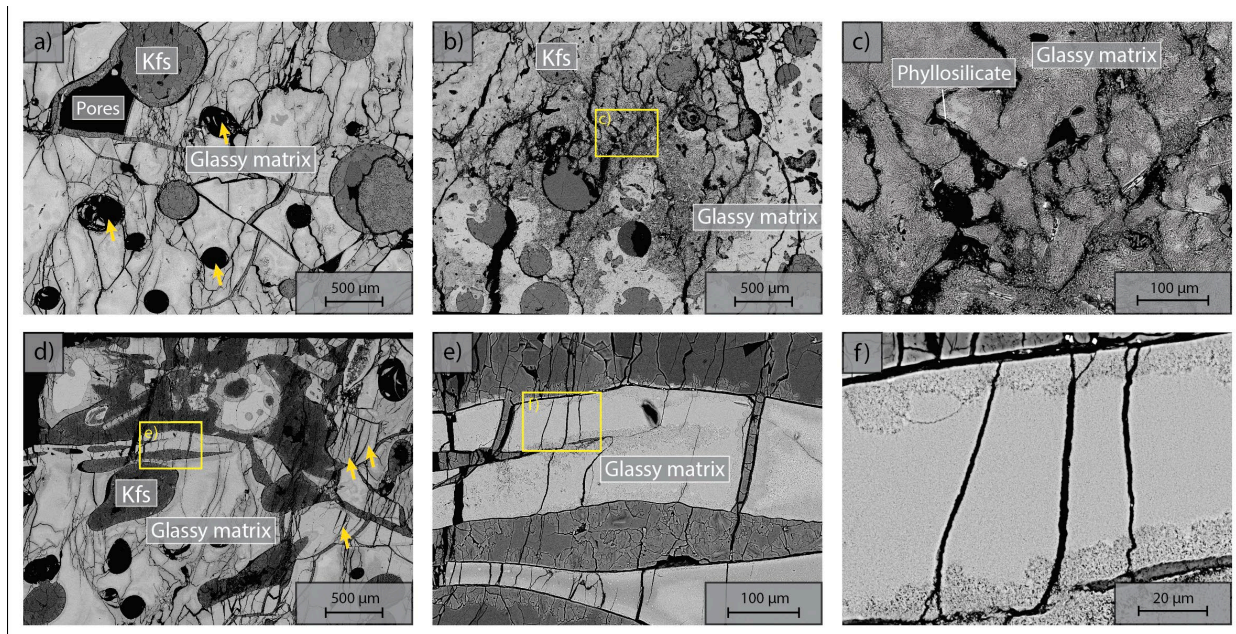

### 323 3.6 Fluid Chemistry

324 Concentration of the Mg<sup>2+</sup> and Ca<sup>2+</sup> cations increased once heating started (Figure 13). This increase in the Mg<sup>2+</sup> and  
325 Ca<sup>2+</sup> concentration reflects the dissolution of Mg and Ca bearing minerals during the reaction. In the H<sub>2</sub>O+CO<sub>2</sub> close  
326 experiment (OR2\_M), the supply of CO<sub>2</sub> was limited and led to a dissolution dominated system that resulted in the  
327 high concentration of Mg<sup>2+</sup> and Ca<sup>2+</sup>, similar to the H<sub>2</sub>O experiment (OR2\_T). In the H<sub>2</sub>O+CO<sub>2</sub> open experiment  
328 (OR3\_B), the cation concentration was significantly lower than in the OR2\_M and OR2\_T experiments. This was  
329 likely caused by the potential precipitation uptake owing to the continuous supply of CO<sub>2</sub> in the semi-open setting of  
330 the pore fluid system. This interpretation is also supported by the ~2 orders of magnitude drop in permeability observed  
331 in the CO<sub>2</sub> open experiment after heating started since precipitation could potentially clog the pore throats and lead to  
332 permeability decrease.

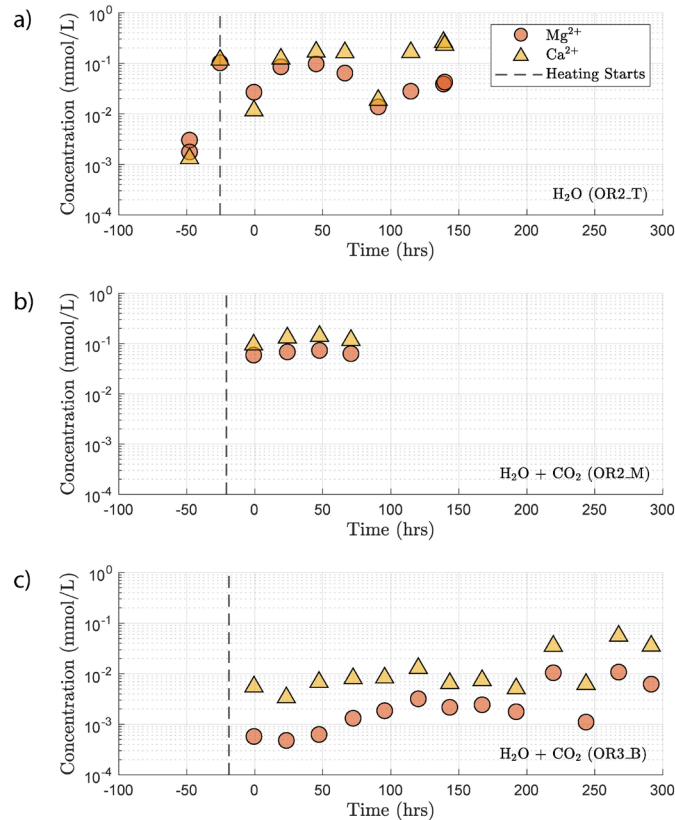

334 **Figure 11.** Orientation analysis of cracks in axial and radial directions from x-ray tomographic images of the deformed  
 335 sample from a) dry, b) H<sub>2</sub>O, c) H<sub>2</sub>O+CO<sub>2</sub> close and d) H<sub>2</sub>O+CO<sub>2</sub> open experiments. The aspect ratio (min/max), which  
 336 is defined by the ratio between the minimum and maximum projection length of the cracks, is 1 when the orientation  
 337 is random (isotropic) (Heilbronner and Barrett, 2014). Strong crack alignment is inferred in the axial sections with  
 338 aspect ratio of 0.5~0.7 compared to the radial sections where the aspect ratio is 0.6~0.9.

339 **Figure 12.** Microstructures of deformed sample from H<sub>2</sub>O+CO<sub>2</sub> open experiment (OR3\_B). Axial view, loading from  
 340 top and bottom. a) Pervasively fractured matrix, note the preferential N-S alignment of cracks indicating most cracks  
 341 are mode I. Note the collapse of void pores with cracks emanating (arrows). b) Crack pattern in altered glass matrix.  
 342 c) close up of b). Note the phyllosilicate coating on the crack wall. d - f) magnification cascade illustrating the crack  
 343 shape and morphology in the deformed sample.  
 344

345  
 346 **Figure 13.** Concentration of  $Mg^{2+}$  and  $Ca^{2+}$  in the sampled fluid from a)  $H_2O$ , b)  $H_2O+CO_2$  close and c)  $H_2O+CO_2$   
 347 open experiments. Time 0 marks the start of the first creep stepping.

348 **4. Discussion**

349 **4.1 Active Deformation Mechanisms**

350 Acoustic emission, microstructure analysis and mechanical data confirm that the observed deformation is a brittle  
 351 process as is expected at the given P-T conditions. The strong similarity between the time evolution of cumulative AE  
 352 counts and strain (Figure 7 and 8) is consistent with observations from other creep deformation experiments using  
 353 cemented and uncemented porous rocks (e.g. Brzesowsky et al., 2014; Heap et al., 2009). These considerations suggest  
 354 that the creep deformation observed in this study is a result of a time-dependent brittle process such as subcritical  
 355 cracking, that can still generate AE activity (Chester et al., 2007; Chester et al., 2004).

356 Previous studies concluded that observable amount of brittle creep strain is unlikely to occur below 80% of ultimate  
 357 strength defined by the short-term, constant strain rate deformation experiments (Baud & Meredith, 1997; Heap et al.,  
 358 2009). However, all our strain measurements (strain gauges, LVDTs, axial ram displacement) show that, in this study,  
 359 creep did occur at stress levels of only ~11% of failure strength (and therefore even lower percentage of the ultimate  
 360 strength). Similar creep deformation with measurable strain at low stress level has been previously observed in shale  
 361 (e.g. Mighani et al., 2019). We also found that the strain rates measured during all creep steps could be fitted using  
 362 the same exponential law derived from strain rate measurements. Furthermore, the amount of creep strain accumulated

363 during phase I and phase II showed a consistent stress dependence across all stress conditions (Figure 4c and 4d).  
364 Therefore, our experiments demonstrated that there does not seem to exist a threshold below which no creep strain  
365 will be observed. The creep deformation was likely governed by the same mechanism across our tested stress  
366 conditions and the accumulated creep strain at a given time can be formulated as a function of stress.

367 Our AE statistics show that the  $b$ -values were higher for the fluid-saturated experiments than the dry experiment,  
368 indicating a higher proportion of low amplitude AEs (i.e., higher ratio of low-to-high amplitude events). This  
369 abundance of low amplitude events in fluid-saturated rock is a direct evidence that aqueous fluids promoted creep  
370 deformation in basalt. As argued in previous studies, growth of small cracks and low amplitude events are facilitated  
371 when stress corrosion is activated in the presence of aqueous fluids (Hatton et al., 1993). We also observed that the  
372 amplitude of the largest events increased with increasing stress. And this effect becomes more significant in the fluid  
373 saturated experiments ( $H_2O$  and  $H_2O+CO_2$ ). This could be attributed to the increase in micro-crack nucleation,  
374 consequently maximizing the likelihood of an ‘avalanche’ of coalescing cracks, which, in turn, generates large  
375 amplitude events. Overall, as more and more energy is dissipated through micro-cracking and the associated low  
376 amplitude AEs, the macroscopic deformation becomes less dynamic, which is consistent with the increase in the  
377 Gutenberg-Richter  $b$ -value with increasing stress.

378 Post-mortem examination of the fluid-saturated samples demonstrated the presence of a complicated network of  
379 fractures within the sample and absence of a well-defined major shear fracture plane. The samples also exhibited  
380 distributed deformation features such as bulging, likely caused by the bulk formation of dilation cracks in addition to  
381 the cataclastic shear during the final failure. These microstructural observations further support the idea that  
382 deformation during creep is diffuse and distributed rather than localized (Hatton et al., 1993; Heap et al., 2009),  
383 consistent with nucleation-controlled crack growth since the nucleation sites are normally randomly distributed in the  
384 sample.

385 Microstructure analysis of the deformed samples demonstrates that the presence of fluid resulted in more abundant  
386 mode I cracks (Figure 11). Larger amount of cracks oriented parallel to the maximum principal stress were observed  
387 in the  $H_2O+CO_2$  samples, implying dominant Mode I cracking, while the dry experiment showed less cracking, with  
388 the cracks aligned  $20-30^\circ$  to the maximum principal stress, thus pointing to mixed Mode I + Mode II cracking. This  
389 observation is consistent with previous studies on strain localization as they often proposed rock fracture models  
390 predicting that mode II cracking takes place during the localization stage of fracture development (Lockner et al.,  
391 1992; Reches and Lockner, 1994; Wong and Einstein, 2009). Among the present experiments, the samples subjected  
392 to creep deformation under  $H_2O+CO_2$  conditions exhibited the largest amount of mode I cracks. The sample deformed  
393 under dry condition, despite having experienced similar differential stress and total accumulated strain, showed a  
394 lower amount of cracks. As stated in previous studies, mode II cracks often propagate at velocities close to the  
395 Rayleigh velocity, which increases the probability of occurrence of high amplitude events. On the other hand, mode I  
396 cracks have significantly lower rupture velocities and tend to produce low amplitude acoustic events (Broberg, 2006).  
397 Therefore, increased mode I cracking should lead to an increase in the proportion of low amplitude AEs, i.e. an  
398 increase in the Gutenberg-Richter  $b$ -value.

399 We infer that the difference in creep rate of the dry and fluid-saturated experiments is a result of fluid-assisted  
400 subcritical crack growth. The fluid presence promotes stress corrosion, possibly related to hydrolytic weakening  
401 (Atkinson, 1984), accelerates crack growth, activates more crack nucleation sites, and, consequently, leads to a  
402 distributed array of small micro-cracks. In contrast, crack growth under dry conditions is concentrated on fewer and  
403 larger cracks since activation of the nucleation sites is more difficult. Thus, it is easier to create localized deformation  
404 under dry condition.

405 Previous studies also suggested that intergranular pressure solution (IPS) could play a significant role as a deformation  
406 mechanism during creep (Liteanu et al., 2012; Zhang & Spiers, 2005; Zhang et al., 2010). The creep deformation by  
407 IPS involves dissolution and the presence of a fluid phase might be expected to affect creep deformation, generating  
408 additional strain accumulation apart from dilatant cracking. Importantly, because the driving process of IPS is not  
409 producing abrupt stress drops, it is not expected to produce acoustic emissions. Although we did see difference in  
410 creep strain between the dry and fluid-saturated experiments, it was likely caused by dynamic fracturing, as evidenced  
411 by the volumetric strain and AE observations (Figure 5a and A1). We attribute the change in creep strain rate between  
412 dry and fluid-saturated experiments to fluid-assisted subcritical crack growth. We posit that under our experimental  
413 conditions, IPS was not a dominant creep mechanism, however more detailed microstructural observations are needed.

#### 414 **4.2 Time and Stress Dependent Deformation**

415 Our experiments show that the time-dependent creep deformation was also strongly stress dependent. We observed  
416 that the creep strain accumulated during phase I was exponentially dependent on stress (Figure 3c). Two exceptions  
417 are noted in the dry experiment. Both showed high strain accumulation during phase I transient creep and followed a  
418 sharp temporary stress drop during the creep step with a nominal differential stress of ~90 MPa (Figure 5). This  
419 temporary stress drop was accompanied by a swarm of large amplitude AEs (Appendix Figure A2), implying that the  
420 concurrent strong dilation was likely caused by local dynamic fracturing while the bulk of the sample remained mostly  
421 intact and still capable of supporting the applied load.

422 We also observed an exponential relationship between stress and creep rate. Interestingly, the fluid-saturated  
423 experiments yielded approximately equal stress sensitivities of the creep rates,  $\dot{\epsilon} \propto e^{0.02 \sim 0.03 \sigma}$ , despite the variability  
424 in their absolute strengths (Figure 3). The exponential stress dependence of strain rate in fluid-saturated experiments  
425 is consistent with brittle creep being the dominant deformation mechanism. Indeed, the values of the fitting constant  
426 (0.02~0.03) are comparable in order of magnitude to those reported in previous studies on other basaltic rocks (0.05  
427 in Heap et al., 2011, from experiments using Etna Basalt). Since the creep rate was exponentially dependent on stress,  
428 so should be the accumulated phase II creep strain. This inference is supported by our observation in Figure 4d.  
429 Concerning the dry experiment, we attribute the slightly negative dependence of creep strain rate on stress (Figure 3e)  
430 to statistical artefact owing to large data fluctuations as suggested by the low  $R^2$  value of the exponential fitting  
431 (Appendix Figure A6).

432 The fact that both cumulative phase I and phase II creep strains were exponentially dependent on stress (Figure 4c and  
433 4d) implies a power-law relationship between the accumulated phase I and phase II creep strain. This power-law  
434 relationship (i.e. the ratio between the logarithmic total phase I and logarithmic phase II creep strain), based on our

435 experimental observation, is independent of the stress level and even the presence or absence of fluids. This empirical  
436 relationship can be formulated as:

$$437 \quad \frac{\log(\varepsilon_t - \varepsilon_i)}{\log(\varepsilon_i)} = \frac{\log(\varepsilon_{ii})}{\log(\varepsilon_i)} = cte. \quad (\text{Eq. 8})$$

438 where  $\varepsilon_t$  is the total strain accumulated at the end of an individual creep stage (~24 hrs),  $\varepsilon_i$  the creep strain accumulated  
439 during phase I, and  $\varepsilon_{ii}$  the strain accumulated during phase II (see Appendix Figure A5). This phenomenological  
440 power-law relationship is supported by our observation that the ratios in Equation 8 were indeed approximately  
441 constant ~0.8 (Figure 4a and 4b). This power-law relationship expressed in Equation 8 implies that the strain evolution  
442 with time can be predicted; some fundamental link between strain accommodated in phase I creep and strain rate in  
443 phase II creep exists.

#### 444 **4.3 Fluid Chemistry Evolution and Influence of Fluid Composition**

445 The increase in concentration of both  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  occurring after heating in the  $\text{H}_2\text{O}$  and  $\text{H}_2\text{O}+\text{CO}_2$  close experiment  
446 (Figure 13) indicates that the system was dominated by dissolution of Mg and Ca bearing minerals. In the case of the  
447  $\text{H}_2\text{O}+\text{CO}_2$  open experiment, we observed a much smaller increase in cation concentration implying that a significant  
448 amount of the released  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  cations reacted with the continuously supplied  $\text{CO}_2$  in the semi-open setting to  
449 form carbonate precipitates. These cation concentration trends appeared strongly correlated with the permeability  
450 evolution and creep strength of the rocks. The experiment with  $\text{H}_2\text{O}+\text{CO}_2$  open showed a larger post-heating  
451 permeability decrease than the experiments with  $\text{H}_2\text{O}$  and  $\text{H}_2\text{O} + \text{CO}_2$  close and was stronger (Figures 3e and 6). The  
452 absolute creep rate was consistent for experiments with comparable fluid chemistry ( $\text{H}_2\text{O}$  and  $\text{H}_2\text{O} + \text{CO}_2$  closed) and  
453 about a factor of 3 faster than in the experiment where precipitation was dominant ( $\text{H}_2\text{O} + \text{CO}_2$  open) indicating that  
454 dissolution associated with fluid presence weakens the rock while precipitation reactions slightly strengthen the rock  
455 and partly compensate the effect of dissolution. This congruence of observations is a strong argument that precipitation  
456 occurred in the pore space of the  $\text{CO}_2$  open experiment. However, we could not directly resolve evidence of  
457 precipitation within the resolution of our microstructural observations and this requires further study. Interestingly,  
458 the strain rate sensitivity to stress was similar in all fluid-saturated experiments (Figure 3), implying that creep rate  
459 sensitivity to stress was not significantly influenced by the fluid chemistry.

460 Our chemical data support the idea that carbonation of basalt is a kinetically favored reaction and are consistent with  
461 the fast rate of carbonation observed during the CarbFix field tests (Matter et al., 2016). We interpret the difference  
462 between the  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  concentrations measured in the  $\text{H}_2\text{O}+\text{CO}_2$  open experiment and those in the  $\text{H}_2\text{O}$  and  
463  $\text{H}_2\text{O}+\text{CO}_2$  close experiments to be a result of the consumption of  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  in the formation of carbonate. This  
464 indicates that the supply of  $\text{CO}_2$  is more sufficient in the  $\text{H}_2\text{O}+\text{CO}_2$  open experiment and the rate-limiting factor during  
465 carbonation under our experimental condition was the net supply of  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  cations, which is associated with  
466 dissolution.

#### 467 **4.4 Permeability & Porosity Evolution**

468 Permeability was affected by both chemical and mechanical processes. The evolution of permeability during the  
469 experiments was generally consistent with previous observations of monotonic permeability decrease during

470 hydrostatic loading of samples of limestone, sandstone and Etna basalt (Brantut, 2015; Fortin et al., 2011; Zhu &  
471 Wong, 1997). Comparison of the dissolution dominated experiments (H<sub>2</sub>O and H<sub>2</sub>O+CO<sub>2</sub> close) and the precipitation  
472 dominated experiment (H<sub>2</sub>O+CO<sub>2</sub> open) shows that the carbonation reaction reduced permeability in our experiment.  
473 In low differential stress conditions, the samples compacted and this compaction was accompanied by a further  
474 permeability decrease, which was likely related to the pore volume reduction expected during compressive  
475 deformation. Shortly before failure strength was reached, volumetric dilation became dominant and coincided with  
476 permeability increase. Our observations of the permeability evolution demonstrate that, although the permeability  
477 might decrease owing to compaction, formation and propagation of cracks can mitigate the permeability loss and even  
478 lead to an increase with further cracking. The effect of creep deformation on the long-term permeability evolution of  
479 reservoir rocks is therefore non-negligible. Increase in permeability, combined with other observations such as  
480 increasing volumetric strain and acoustic emissions, could potentially be used as a warning sign for impending failure  
481 during the long-term monitoring of reservoirs' integrity in GCS applications.

#### 482 **4.5 Effect of Sample Heterogeneity**

483 As our samples are taken from drill cores collected at depth at the CarbFix carbon mineralization site, the heterogeneity  
484 is larger than in rocks typically used in rock mechanics experiments. The samples investigated in this study exhibit  
485 variations in their initial porosity (5-15%, see Table 1), failure strength (55-130 MPa) and Young's modulus (12-28  
486 GPa). We observed a correlation between the failure strength and the elastic modulus of the samples where stiffer  
487 samples reach higher peak strengths, consistent with previous reports of an empirical relationship between the  
488 unconfined compressive strength and the elastic modulus of sedimentary rocks (see review in Chang et al., 2006). The  
489 peak strength however varied inversely with porosity; the dry sample (OR5), which has the highest initial porosity  
490 (15%), shows a higher failure strength (>105 MPa) and exhibits the lowest creep rate compared to the fluid-saturated  
491 experiments where porosity measurements were available (H<sub>2</sub>O and H<sub>2</sub>O+CO<sub>2</sub> close). Remarkably, the stress  
492 sensitivity of the creep strain rate shows consistency ( $\epsilon^{0.02 - 0.03 \sigma}$ ) in all the fluid saturated experiments (H<sub>2</sub>O and  
493 H<sub>2</sub>O+CO<sub>2</sub> open and close) in spite of these variations in porosity, stiffness and failure strength. Moreover, the creep  
494 rate at individual stress steps is consistent for experiments with comparable fluid chemistry (H<sub>2</sub>O and H<sub>2</sub>O + CO<sub>2</sub>  
495 closed) despite a variation in porosity by a factor of 2 in between the samples (Figure 3 and Table 1). These results  
496 are a strong argument for the operation of chemical processes that contribute to creep. While variations in porosity  
497 resulted in variation in peak strength, they did not seem to affect the absolute creep rates or the sensitivity of creep  
498 rate to stress.

#### 499 **5 Conclusions**

500 Through the experimental study of long-term creep deformation of Iceland Basalt, we have demonstrated that:

- 501 • Transient creep occurred at stress levels as low as 11% of the failure strength.
- 502 • Presence of an aqueous pore fluid exerted first order control on the creep deformation of the basaltic rocks,  
503 while the fluid composition had only a secondary effect under our experimental conditions. At similar  
504 differential stress level, the creep rates in fluid-saturated experiments were much higher than the rates in the  
505 dry experiment.

- 506 • A close system tended to favor dissolution over precipitation during carbonation in our experimental setting,  
507 whereas precipitation played a more important role in an open system with continuous CO<sub>2</sub> supply.
- 508 • Larger amount of dilation was observed in fluid saturated experiments than in the dry experiment, as  
509 evidenced by both volumetric strain data and micro-structural observations.
- 510 • Larger low-to-high amplitude ratios of the AE events and higher AE rates were observed during the phase II  
511 creep of the fluid-saturated experiments than the dry experiment, indicating that aqueous fluids promoted  
512 stress corrosion processes.
- 513 • The mechanism governing the creep deformation was brittle, time- and stress-dependent, and could likely be  
514 identified as sub-critical dilatant cracking.

515 Overall, our results emphasize the non-negligible role that the creep deformation can potentially play in the long-term  
516 deformation of rocks even under low pressure and temperature conditions and calls for more attention to time-  
517 dependent processes such as sub-critical micro-cracking in GCS applications. Under our experimental conditions, the  
518 creep deformation and the associated fracture development were affected by the presence of aqueous fluids, implying  
519 that reactive fluids could potentially alter the fracture patterns and allow mineralization in a greater rock volume during  
520 GCS applications. Further detailed studies on the creep deformation under chemically active environment are required  
521 to better understand the long-term deformation of rocks in natural systems.

## 522 **Acknowledgments, Samples, and Data**

523 The authors benefited from discussions with Ben Holtzman, Yves Bernabé, Brian Evans, Bradford Hager and Brent  
524 Minchew. The author would like to thank Yves Bernabé for his copy editing of this paper. The author would also like  
525 to thank Edward Boyle and Richard Kayser for their help with the ICP-MS analysis. Funding by the MITe's Carbon  
526 Capture, Utilization and Storage Center, Scotiabank's Net Zero Research Fund and NSF funding for CORD laboratory  
527 technician support (EAR-1833478 and EAR-2054414) are gratefully acknowledged. The x-ray tomographic images  
528 were obtained at the Center for Nanoscale Systems (CNS), a member of the National Nanotechnology Coordinated  
529 Infrastructure Network (NNCI), which is supported by the National Science Foundation under NSF award no.  
530 1541959. CNS is part of Harvard University. The cores used in this study were generously provided by Sandra  
531 Snæbjörnsdóttir and Kári Helgason. The authors declare no conflict of interest. The underlying data is available at  
532 [http:// doi.org/10.5281/zenodo.4926587](http://doi.org/10.5281/zenodo.4926587). The authors would like to thank Phillip Benson and the anonymous reviewer  
533 for their constructive and detailed reviews, and also thank editor David Healy and Federico Rossetti for the handling  
534 of this manuscript.

762 are made by combining RGB channel where the individual channels contain element concentration. a) Backscattered  
763 electron (BSE) images of the starting material; b) Elemental composition of Na K and Ca; c) Elemental composition  
764 of Mg and Fe; d) Elemental composition of Al and Si.  
765

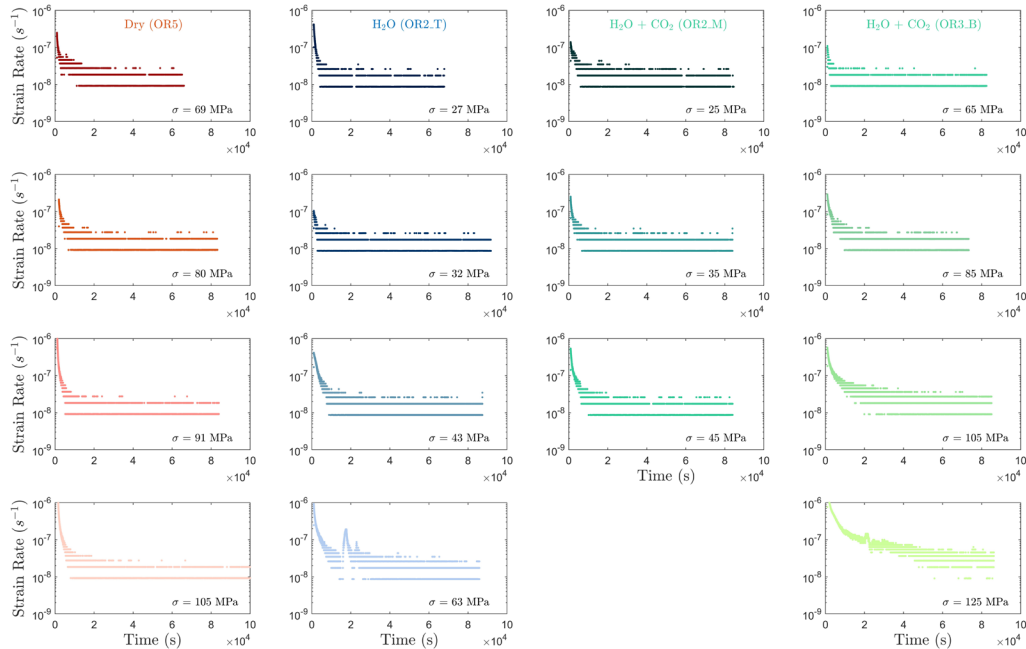

766 **A.2 Experimental Procedures**

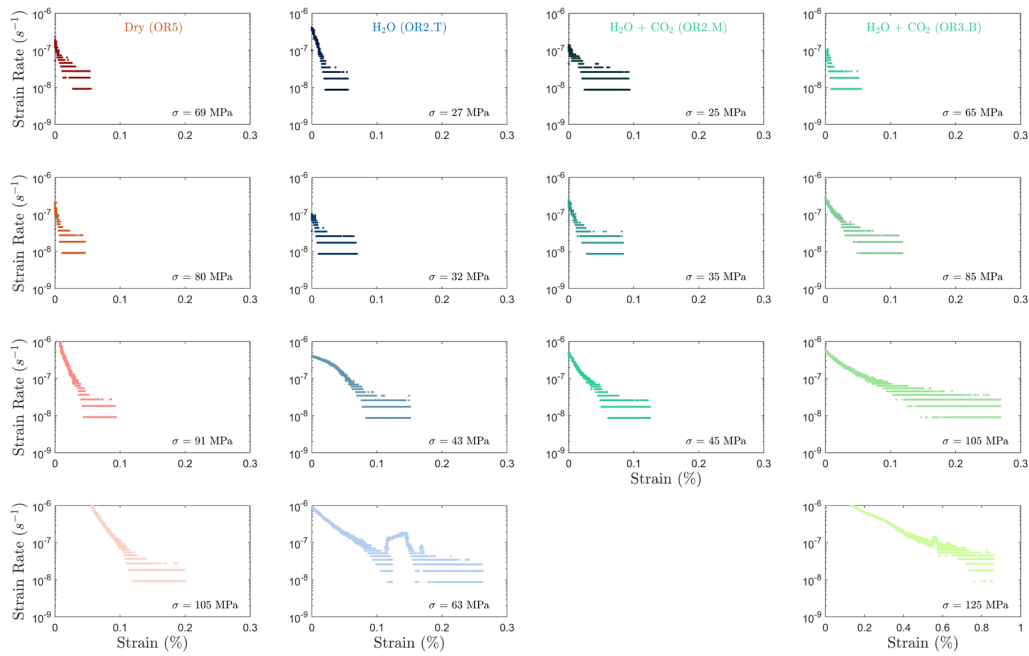

767  
 768 **Figure A2** a) Differential stress vs time plot of experiments conducted at temperature of 78°C. The dry experiment  
 769 (red) was ceased before dynamic failure occurred in the sample. b) A temporary stress drop was observed (highlighted  
 770 by the dashed rectangle in a)) during the primary creep of the dry experiment at creep stress of ~90 MPa accompanied  
 771 by the occurrence of high amplitude AEs.

772 **A.2 Phase I to Phase II Transient Creep Transition**

773 Selection of the phase II transient creep from the mechanical data is based on the calculated strain rate using first  
 774 derivative of the strain curve vs. time at different stress levels (Figure A2). The plot of strain rate vs strain further  
 775 supported that the strain rate evolution slows down during the identified phase II creep.

776  
 777 **Figure A3** Strain rate evolution calculated from the first derivative of the strain vs. time data. It can be observed that  
 778 the strain rates generally become constant 10,000 s (≈2.8 h) after the load stepping in most steps.

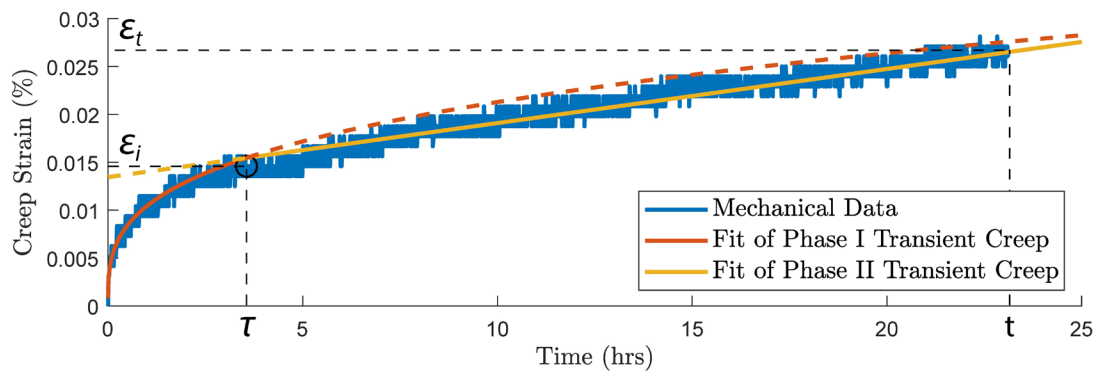

779

780

**Figure A4** Plot of strain rate evolution vs. strain.

781 To consistently analyze the transition between phase I and phase II of the transient creep, we fit the evolution of phase  
 782 I creep strain over time using a power-law function and the phase II creep strain as a linear function (Figure A3 a).  
 783 The measured strain data point that is the closest to the intersection of the two fitting functions is selected as the  
 784 inflection point, i.e., the transition from phase I to phase II transient creep deformation. Figure A3 b and c shows the  
 785 logarithmic and power-law fitting methods used for the time evolution of creep strain ( $\epsilon$ ). With the 24 hrs observation  
 786 window of our experiment.

787

788 **Figure A5** illustration of the method used to pick up the transition (circle) from phase I to phase II transient creep  
 789 deformation. a) Two phase model for the time evolution of creep strain. The transition (circle) from phase I to phase II  
 790 creep deformation is selected based on the intersection of the power-law fit function of phase I creep (red) and linear  
 791 fit function of the phase II creep (yellow).

792 **A.3 Creep Strain/Stress Models**

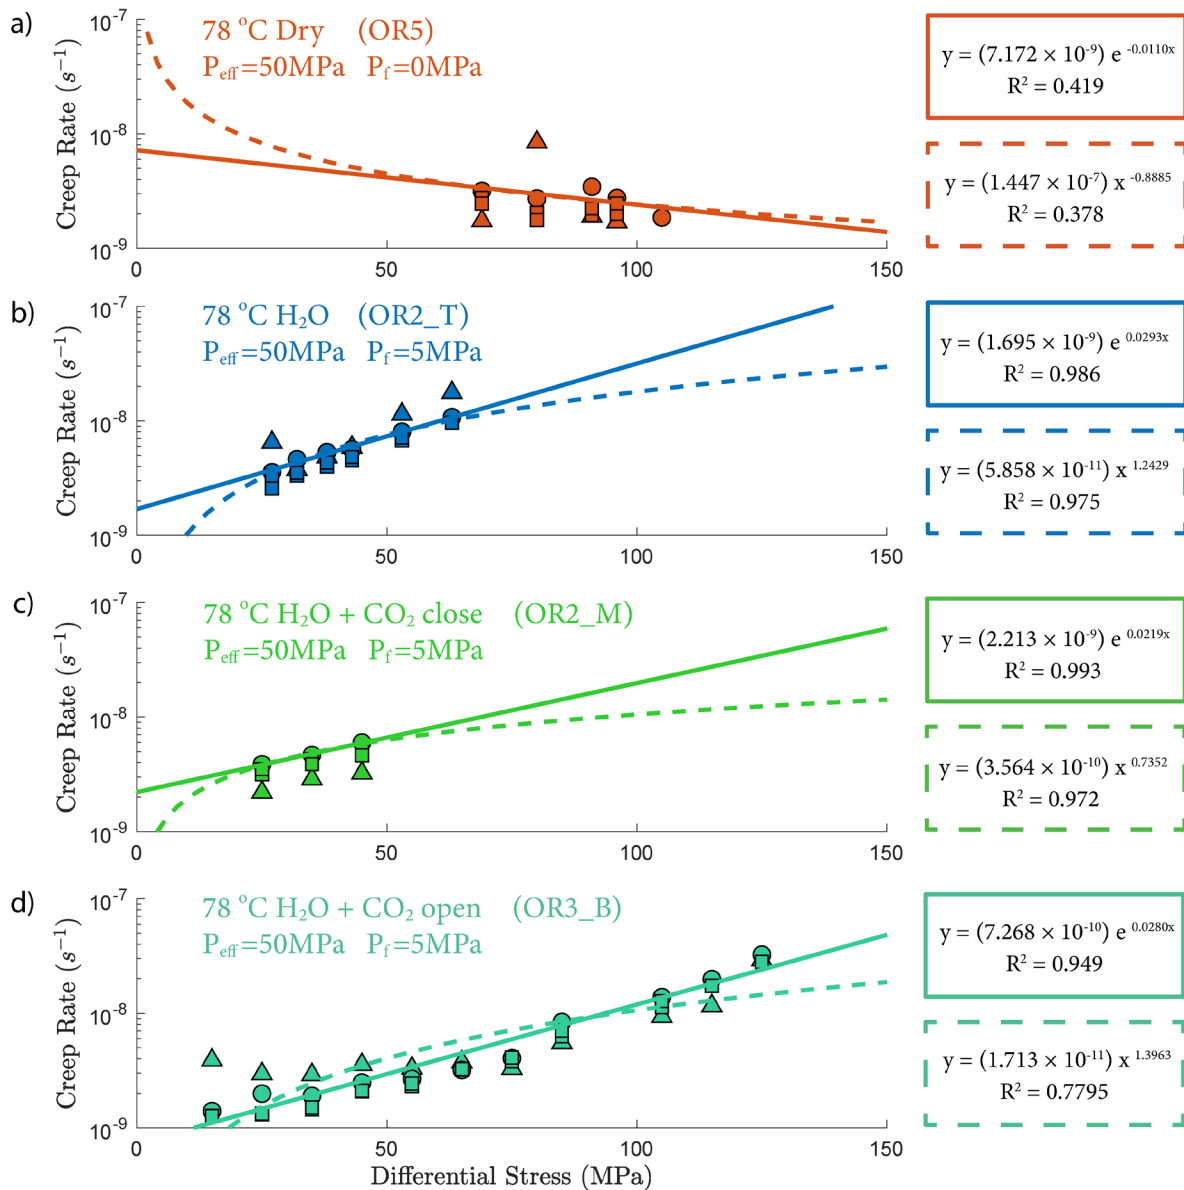

793 The strain rate during phase II creep deformation is generally described using the power law form (e.g. Atkinson,  
794 1984; Meredith and Atkinson, 1983):

795 
$$d\varepsilon/dt = A\sigma^n \tag{Eq. A1}$$

796 or the exponential form (e.g. Charles and Hillig, 1962):

797 
$$d\varepsilon/dt = Be^{\eta\sigma} \tag{Eq. A2}$$

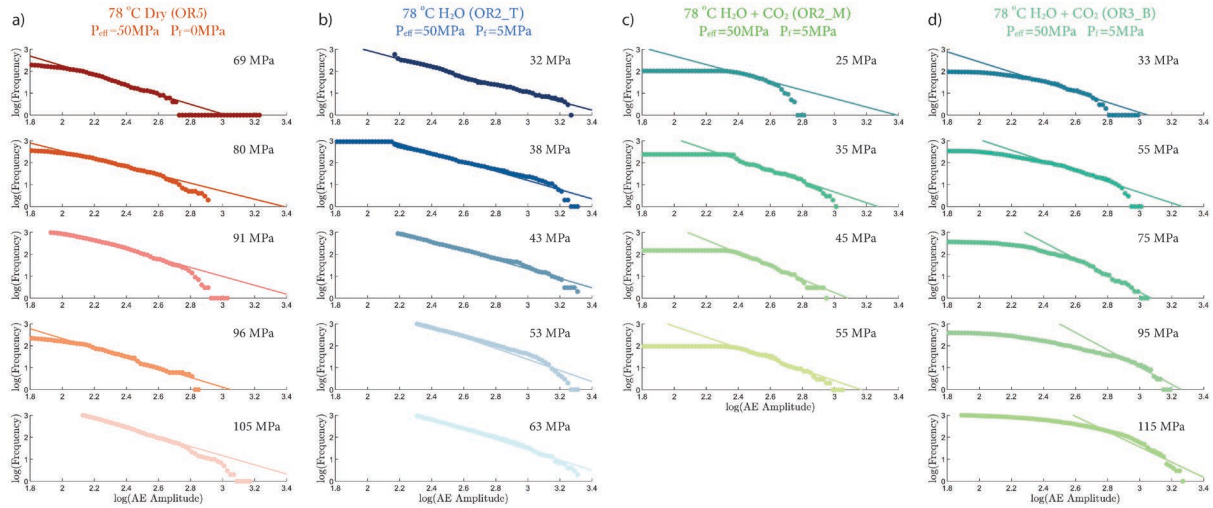

798 where  $\varepsilon$  is the creep strain and  $\sigma$  is the differential stress.  $A$ ,  $B$ ,  $n$  and  $\eta$  are constants. Both models have described our  
799 laboratory data well. The exponential model seems to be slightly better than the power law model when comparing  
800 the  $R^2$  factors.

801  
802 **Figure A6** Power-law (dash line) and exponential (solid line) fit of creep rate/stress relationship. The strain rates are  
803 calculated from strain measurement from main ram displacement (circle), strain gauge (triangle) and LVDTs (square).

804 **A.4 Gutenberg-Richter b-value**

805 Figure A6 shows the fitting of the Gutenberg-Richter b-value from different experiments at various stress levels.

806 **Figure A7** Statistics of AE amplitudes for Gutenberg-Richter b-value calculation from a) dry, b) H<sub>2</sub>O c) H<sub>2</sub>O+CO<sub>2</sub>  
 807 close and d) H<sub>2</sub>O+CO<sub>2</sub> open experiments.

809 **A.5 Samples after Deformation**

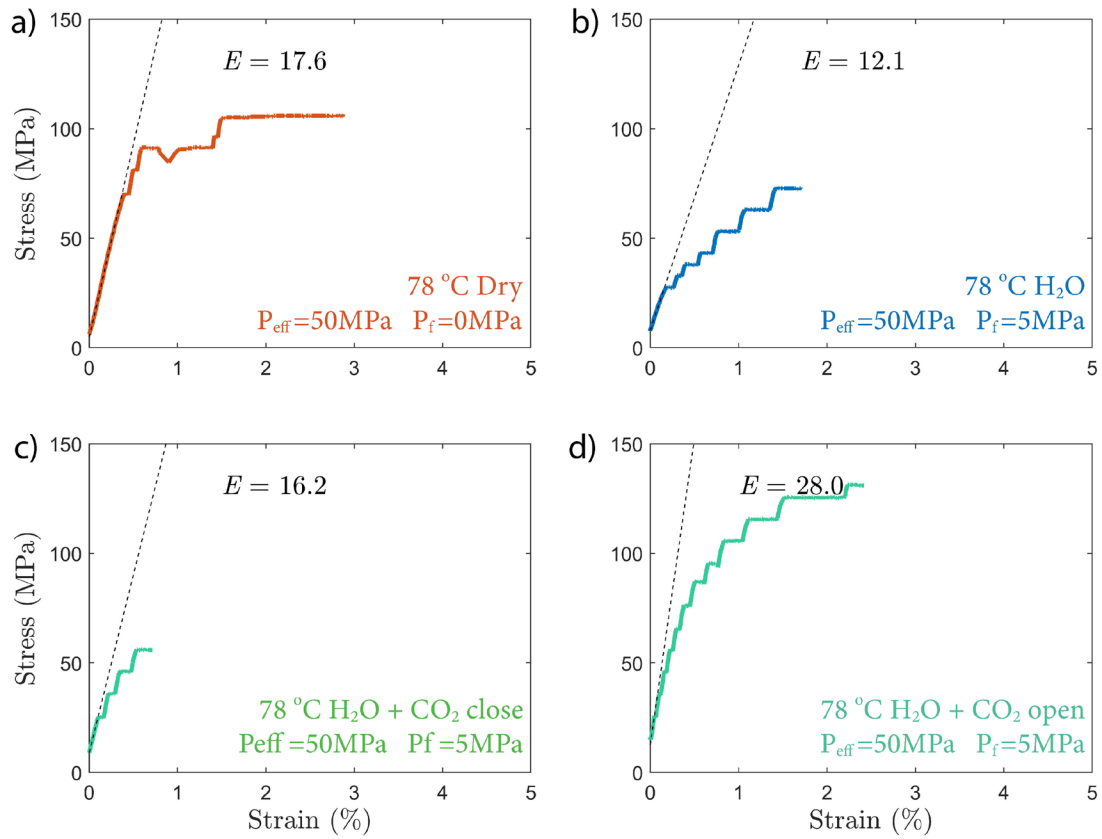

810 **Figure A8** Photo of samples after deformation. The dry sample did not reach the final dynamic failure before  
 811 experiment was halted.  
 812

813 **A.6 Elastic Modulus**

814 The Young's modulus ( $E$ ) of the sample is calculated based on the strain measurement during the elastic loading,  
 815 using the following equation:

816 
$$E = \frac{\Delta\sigma}{\Delta d/L} \quad (\text{Eq. A4})$$

817 where  $\Delta\sigma$  is the differential stress,  $d$  is the displacement of main ram piston and  $L$  is the length of the sample.

818

819 **Figure A9** Elastic modulus calculated from strain vs stress plots from a) dry, b) H<sub>2</sub>O c) H<sub>2</sub>O+CO<sub>2</sub> close and d)  
 820 H<sub>2</sub>O+CO<sub>2</sub> open experiments.
