**Abstract.** Middle-Late Jurassic high Sr/Y granitic intrusions are extensively exposed in the Liaodong Peninsula, in the eastern part of the North China Craton (NCC). However, the genesis of the high Sr/Y signature in these intrusions has not been studied in detail. In this study, we report results of zircon U-Pb dating, Hf isotopic analysis and zircon and whole-rock geochemical data for the Late Jurassic Zhoujiapuzi granite in the middle part of the Liaodong Peninsula. The Zhoujiapuzi granite is high-K (calc-alkaline) and peraluminous in nature, with high SiO<sub>2</sub> (68.1–73.0 wt %) and Al<sub>2</sub>O<sub>3</sub> (14.5–16.8 wt %), low in TFe<sub>2</sub>O<sub>3</sub> (1.10–2.49 wt %) and MgO (0.10–0.44 wt %), and with high Sr/Y (19.9–102.0) and La<sub>N</sub>/Yb<sub>N</sub> (14.59–80.40). Morphological and chemical studies on zircon grains show that there are two stages of zircon growth, interpreted as magmatic evolution in two distinct stages. The early stage of zircons (ESZ) reflects a crystallization environment of low oxygen fugacity and high T<sub>Zr-Ti</sub> (Ti-in-zircon thermometer values: 669–792°C); the late stage of zircons (LSZ) formed with high oxygen fugacity and lower T<sub>Zr-Ti</sub> (498–720°C). LA-ICP-MS U-Pb zircon dating yielded the formation ages of the ESZ and LSZ of ~162±1 Ma and ~158±1 Ma, respectively, with similar εHf(t) values in the range of -26.3– -22.8. Interpretation of the elemental and isotopic data suggests that the Zhoujiapuzi granite was a I-type granite derived from partial melting of basement in the region: ~2.17 Ga Liaoji granites. The high Sr/Y signature is most likely inherited from these source rocks. Based on the geochemical features and regional geological data, we propose that the Liaodong Peninsula in the Late Jurassic was part of a mature continental arc, with extensive melting of thick crust above the Paleo-Pacific subduction zone.

## 1 Introduction

The Liaodong Peninsula is located in the northeast of the North China Craton (NCC). The northeast NCC was influenced by three main tectonic regimes in the Mesozoic, related to the subduction of the Paleo-Asian, Paleo-Pacific and Mongol-Okhotsk oceans (Tang et al., 2018). The superposition of these different regimes resulted in changing tectonic and magmatic patterns over time.

Middle-Late Jurassic granitic rocks are extensively exposed in the northern parts of the Liaodong Peninsula, such as the

Yutun diorite, Xiaoheshan granodiorite, Heigou monzogranite (Wu et al., 2005), Wulong two-mica Monzogranite (Yang et al., 2018), and Huangdi biotite monzogranite (Xue et al., 2020). Most of these rocks are characterized by high Sr/Y, and plot within the adakite field on Sr/Y-Y and  $La_N/Yb_N$ - $Yb_N$  diagrams (Wu et al., 2005a; Yang et al., 2015a, 2018). Adakite and geochemically similar high Sr/Y igneous rocks have been proposed to represent several tectonic environments (Defant and Drummond, 1990; Castillo et al., 1999; Gao et al., 2004; Kamei et al., 2009; Ma et al., 2013; Ma et al., 2015; Ou et al., 2017; Yang et al., 2020). The Middle-Late Jurassic granitic rocks in the Liaodong Peninsula are commonly proposed to be the products of partial melting of thickened mafic crust with garnet in the residue (Wu et al., 2005a; Yang et al., 2015a, 2018; Tang et al., 2018).

In recent years, some studies have proposed that the high Sr/Y ratio in granitic rocks can be inherited from a high Sr/Y source (Kamei et al., 2009; Ma et al., 2015; Zhan et al., 2020). However, the source composition has not been fully considered in the petrogenesis of the high Sr/Y rocks in the Liaodong Peninsula. Hence, the petrogenesis of the Middle-Late Jurassic high Sr/Y rocks needs to be reevaluated, based on more detailed work and a consideration of possible sources. This petrogenesis is of significance for understanding the Jurassic tectonics of the Liaodong Peninsula, and the NCC in general.

In this paper, we examined the high Sr/Y Zhoujiapuzi granite from the Xiuyan area, in the middle of the Liaodong Peninsula. Zircons are analysed for U-Pb-Hf isotopes and trace element geochemistry, and by Raman spectroscopy. These results are integrated with whole-rock geochemistry. We focus on the zircons, because of their potential to reveal the origins of the pluton (Belousova et al., 2002; Wang et al., 2007; Breiter et al., 2014; Zhao et al., 2014), and so provide a case study for the evolution of plutonic magma systems in general. Based on observations of the CL images and chemical analysis, two zircon growth stages can be distinguished. We first determine the crystallization environments of the two zircon growth stages, and then decipher the petrogenesis, source characteristics and origin of the high Sr/Y signature of the pluton as a whole. Integrated with previous studies, our study provides insights into the tectonic evolution of the Liaodong Peninsula in the Late Jurassic.

## 2 Geological setting

The Zhoujiapuzi granite is located in the middle of the Liaodong Peninsula, at the northeastern margin of the NCC (Fig. 1). The Paleoproterozoic Liaohe Group is the basement in the study area, including the Lieryu, Gaojiayu, Dashiqiao and Gaixian formations. Although stratigraphic terms are used, these rocks are metamorphic, and the group consists of leptynite, leptonite, granulite, amphibolite, marble and phyllite. The protoliths of the Liaohe Group include marine volcanics, clastics, carbonates and claystones. The formation age of the metasedimentary rocks in the Liaohe Group is 2.0–1.9 Ga (Wan et al., 2006; Li et al., 2015). It is in unconformable contact with the overlying strata of the Mesoproterozoic Cuocaogou Formation and Xiaoling Formation.

In the Mesozoic, the region of the Liaodong Peninsula was influenced by the circum-Pacific tectonic regime, the Mongol-Okhotsk tectonic regime and the Paleo-Asian Ocean tectonic regime. The joint influence of multiple tectonic

65 regimes resulted in intensive magmatism during the Mesozoic (Fig. 1b). These Mesozoic magmatic rocks can be divided into three stages, namely: Triassic (233–212 Ma), Jurassic (180–156 Ma) and Early Cretaceous (131–117 Ma) (Wu et al., 2005b).

The Triassic magmatic rocks are less exposed, mainly alkaline rocks, diabase, diorites and granites (Wu et al., 2005b). Among them, the granites mainly have A-type affinity, and may have formed in an extensional setting (Tang et al., 2018; Wang et al., 2019). Magmatism has been related to either the subduction of the Paleo-Pacific slab, closure of the Paleo-Asian  
70 Ocean, or the collision between the NCC and the Yangtze Craton (Tang et al., 2018; Wang et al., 2019). The majority of the Jurassic magmatic rocks are monzogranite, tonalite and granodiorite, which are generally calc-alkaline I-type granites, and show characteristics of adakite-like rocks. Some of them, exposed near later extensional structures, have undergone regional ductile deformation. These Jurassic magmatic rocks are generally considered to relate to the subduction of the Paleo-Pacific slab (Li et al., 2004; Zhai et al., 2004). In the Early Cretaceous, basic-acidic-alkaline rocks were widely developed. Among  
75 them, the granites have mainly A- and I-type affinities. These rocks are generally considered to have formed in an intense extension environment, which is connected with either the rollback or low-angle subduction of the Paleo-Pacific slab (Wu et al., 2005c; Zheng et al., 2018).

### 3 Samples and petrography

The Zhoujiapuzi granite is located to the east of Xiuyan City, in the middle of the Liaodong Peninsula (Fig. 1b). It intruded  
80 into the Lieryu Formation of the Liaohu Group. Eight samples of the Zhoujiapuzi granite were collected at locations shown in Fig. 1c.

The Zhoujiapuzi granite is generally grey in colour and with fine-grained texture (Fig. 2a). The mineral assemblage contains K-feldspar (~50 %), quartz (~25 %), plagioclase (~20 %) and biotite (~5 %) as well as accessory minerals such as zircon, ilmenite, magnetite and apatite. K-feldspar are euhedral or subhedral, always exhibit cross-hatched twinning (Fig. 2b).  
85 Quartz is usually xenomorphic, and have indented boundaries and wavy extinction (Fig. 2b-d). Plagioclase always exhibits polysynthetic twinning and have sericitization in places (Fig. 2c). Biotite mainly fills in the interstices between the other minerals (Fig. 2c, d).

### 4 Analytical methods

The cathodoluminescence (CL) images of zircon were obtained by the Chengpu geological Testing Co. Ltd, Langfang, China  
90 using the TIMA analysis. The LA-ICP-MS zircon U-Pb analyses were performed using an Agilent Technologies 7700x ICP-MS with a Teledyne Cetac Technologies Analyte Excite laser-ablation system at Nanjing FocuMS Contract Testing Co. Ltd. The analyses were carried out with a 35 µm spot size at 8 Hz repetition rate for 40 seconds. The raw ICP-MS data were processed using ICPMSDataCal software (Liu et al., 2010). Date reduction were completed using the Isoplot4.15 (Ludwig, 2003). The instrument description and analytical procedure are described in detail by Zeng et al. (2018).

95 The in-situ Lu-Hf isotopic analyses of zircon were performed by LA-MC-ICP-MS using a Teledyne Cetac laser-ablation system and a Nu Plasma II MC-ICP-MS at Nanjing FocuMS Contract Testing Co. Ltd. The 193 nm ArF excimer laser was focused on zircon surface with fluence of 6.0J/cm<sup>2</sup>. The ablation protocol employed a spot diameter of 50 μm at 8 Hz repetition rate for 40 seconds. A more detailed description of the method was described by Zeng et al. (2018).

100 Zircon Raman analyses were carried out using an RM2000 laser Raman spectrometer at the State Key Laboratory of Nuclear Resources and Environment, East China University of Technology. The selected incident wavelengths were 532 and 785 nm in order to clearly identify the luminescence bands due to low concentration impurities. The beam power was 20 mW. The Leica 50× objective was employed.

105 Six fresh rock samples were selected for geochemical analysis. The elemental analyses were conducted at Analytical Chemistry & Testing Services (ALS) Chemex (Guangzhou) Ltd. Major oxides were analyzed using wave-dispersive X-ray fluorescence (XRF) (ME-XRF26). Analytical precision was better than ± 0.01%. Trace element abundances were measured by the lithium borate dissolution method and ICP-MS (ME-MS81). The analytical uncertainties of the rare earth element (REE) and high field strength element (HFSE) are <5%. Analytical uncertainties are in the range of 5%–10% for the other elements. Detailed analytical procedures refer to Zhang et al. (2019) and Nash et al. (2020).

## 5 Analytical results

110 The data for major and trace elements, Raman microprobe data, zircon trace elements, zircon U-Pb ages, and zircon Hf isotopes are shown in Tables S1, S2, S3, S4 and S5, respectively.

### 5.1 Whole-rock major and trace element compositions

115 SiO<sub>2</sub> contents ranging from 68.11 wt.% to 73.02 wt.% (average 71.71 wt.%). Contents of Na<sub>2</sub>O and K<sub>2</sub>O are 3.81–4.65 wt.% and 4.32–4.71 wt.%, respectively, with Na<sub>2</sub>O/K<sub>2</sub>O ratio of 0.82–1.08 and total alkalis (Na<sub>2</sub>O + K<sub>2</sub>O) of 8.38–8.97. All samples plot in the field of granite in the TAS classification except one (Fig. 3a). These samples have Al<sub>2</sub>O<sub>3</sub> contents of 14.49–16.83 wt.% (average 15.09 wt.%), CaO contents of 1.04–1.98 wt.% (average 1.38 wt.%) and A/CNK values of 1.05–1.10 (average 1.07). In the A/NK–A/CNK diagram (Fig. 3b), all samples plot in the peraluminous field (Fig. 3b). The granite samples have low TFe<sub>2</sub>O<sub>3</sub> (TFe<sub>2</sub>O<sub>3</sub> = all Fe calculated as Fe<sub>2</sub>O<sub>3</sub>) contents and MgO contents ranging from 1.10–2.49 wt % and 0.10–0.44 wt %, respectively, with Mg# (Mg#=100\*molar Mg/(Mg+Fe)) values of 15–26.

120 The samples of the Zhoujiapuzi granite exhibit variable REEs, with total REEs ranging from 59 to 302 ppm. The La<sub>N</sub>/Yb<sub>N</sub> values of the Zhoujiapuzi granite range from 14.59 to 80.40 (average 38.27), showing right-declined REE patterns (Fig. 4a). The samples have Eu/Eu\* of 0.62–1.94 and Ce/Ce\* of 0.94–1.16. In the primitive mantle-normalized trace element diagram (Fig. 4b), the samples show negative anomalies of HFSEs (e.g., Nb, Ta, Ti and P) and positive anomalies of La and LILEs (e.g., K, Rb, Ba, U, La, Ce). The Zhoujiapuzi granite is characterized by high contents of Sr (309–551 ppm) and low contents of Y (5.01–15.5 ppm) and Yb (0.43–1.40 ppm), with high Sr/Y ratios of 19.94–102.04 (average 65.50).

## 5.2 Zircon CL images, Raman spectra and REE elements

CL images of zircons from the Zhoujiapuzi granite are shown in Fig. 5. Zircons commonly have crystal sizes between 120 and 200  $\mu\text{m}$ , and have length/width ratios of 2:1–4:1, with euhedral, stubby to elongate prisms. According to the CL images, there were two stages for zircon growth, and the zircons can be divided individually and collectively into: the early stage of zircon (ESZ) and the late stage of zircon (LSZ). The ESZ is characterized by bright CL intensity and widely-spaced oscillatory zoning patterns. The LSZ is characterized by extremely low CL emission and narrowly-spaced oscillatory zoning patterns.

Six ESZ spots and six LSZ spots were analyzed for Raman spectra. The ESZ have antisymmetric stretching vibration ( $B_{1g}$ ) of the  $\text{SiO}_4$  tetrahedra ( $\nu_3$  ( $\text{SiO}_4$ )) Raman band of 1005–1007  $\text{cm}^{-1}$  and half-width of the  $\nu_3$  ( $\text{SiO}_4$ ) Raman band ( $b$ ) values of 6.0–8.1  $\text{cm}^{-1}$ , while the LSZ have  $\nu_3$  ( $\text{SiO}_4$ ) Raman band of 1004–1007  $\text{cm}^{-1}$  and  $b$  values of 5.4–9.0  $\text{cm}^{-1}$ .

Twenty ESZ spots and eighteen LSZ spots were analyzed for trace and rare earth elements. The ESZ spots have lower U content (28–677 ppm) than that of the LSZ spots (U=641–3842 ppm). In the chondrite-normalized REE element diagram (Fig. 6a, b), both the ESZ and LSZ characterized by HREE enrichment relative to LREE with positive Ce anomalies and negative Eu anomalies. The ESZ spots have  $\Sigma\text{REE}$  of 49–1115 ppm (average 390 ppm),  $\Sigma\text{LREE}$  of 3–72 ppm (average 14 ppm) and  $\Sigma\text{HREE}$  of 46–1100 ppm (average 377 ppm), whereas the LSZ spots have  $\Sigma\text{REE}$  of 327–1632 ppm (average 895 ppm),  $\Sigma\text{LREE}$  of 2–14 ppm (average 6 ppm) and  $\Sigma\text{HREE}$  of 325–1627 ppm (average 889 ppm). Hence, the REE content of the ESZ is significantly lower than that of the LSZ, and the difference between the two is mainly in HREE content. The ESZ spots have  $\delta\text{Eu}$  of 0.07–0.60 (average 0.28) and  $\delta\text{Ce}$  of 1.26–166.54 (average 45.49). The LSZ spots have  $\delta\text{Eu}$  of 0.08–0.24 (average 0.13) and  $\delta\text{Ce}$  of 4.23–271.90 (average 94.37). These results indicate that the ESZ have a weaker negative Eu anomaly and a weaker positive Ce anomaly than those of the LSZ.

Some zircons have inherited cores, which have corroded and rounded shapes, such as the 1# in XY-001 and 6# and 41# in XY-008 (Fig. 5). These inherited zircons have oscillatory zoning in CL images. The inherited zircon spots have  $\Sigma\text{REE}$  of 602–1517 ppm, and show depletion of LREE, enrichment of HREE, a positive Ce anomaly ( $\delta\text{Ce}$  of 1.52–216.08) and a negative Eu anomaly ( $\delta\text{Eu}$  of 0.07–0.13) (Fig. 6c).

## 5.3 Zircon U–Pb and Hf isotope composition

Seventy-seven spots were analysed for U–Pb isotope composition from samples XY-001 and XY-008. In the U–Pb Concordia diagram (Fig. 7a, d), both the ESZ and LSZ spots are clustered on the Concordia curve. Overall, the ages of LSZ are generally older than those of ESZ (Fig. 8). On a single zircon, the  $^{206}\text{Pb}/^{238}\text{U}$  age of the ESZ is older than that of the LSZ (Fig. 5). In sample XY-001, 13 spots from ESZ define a weighted mean  $^{206}\text{Pb}/^{238}\text{U}$  age of  $160.8 \pm 1.3$  Ma ( $1\sigma$ , MSWD=0.62; Fig. 7b), and 19 spots from LSZ define a weighted mean  $^{206}\text{Pb}/^{238}\text{U}$  age of  $157.8 \pm 0.8$  Ma ( $1\sigma$ , MSWD=0.42; Fig. 7c). In sample XY-008, 19 spots from ESZ define a weighted mean  $^{206}\text{Pb}/^{238}\text{U}$  age of  $161.5 \pm 1.1$  Ma ( $1\sigma$ , MSWD=0.32; Fig. 7e), and 16 spots from LSZ define a weighted mean  $^{206}\text{Pb}/^{238}\text{U}$  age of  $157.8 \pm 0.9$  Ma ( $1\sigma$ , MSWD=0.39; Fig. 7f). The other 10 spots with

160 distinctly older ages ( $^{207}\text{Pb}/^{206}\text{Pb}$  ages ranging from 2494 to 2132 Ma) were obtained on inherited cores. Their ages are discordant, suggesting that these inherited cores were variably influenced by lead loss. Among these, 9 spots define a discordia line with an upper intercept age of  $2167 \pm 12$  Ma (MSWD=0.59) (Fig. 7g), which is concordant with the weighted mean  $^{207}\text{Pb}/^{206}\text{Pb}$  ages of  $2167 \pm 12$  Ma ( $1\sigma$ , MSWD = 0.54; Fig. 7h).

165 Twenty-four zircons were analyzed for Lu-Hf isotope composition. The variation in Hf isotopic data is limited, between 9 spots from ESZ and 8 spots from LSZ. 17 spots exhibit a range of  $^{176}\text{Hf}/^{177}\text{Hf}$  ratios from 0.281921 to 0.282030, which converts to  $\epsilon\text{Hf}(t)$  values between -26.3 to -22.8 (Fig. 9), and two-stage Hf model ( $T_{\text{DM}2}$ ) ages of 2650 to 2889 Ma by using the U-Pb age for each zircon. Six analytical spots, which define the Concordia upper intercept age of 2167 Ma, show  $^{176}\text{Hf}/^{177}\text{Hf}$  ratios and  $\epsilon\text{Hf}(t)$  values of 0.281443 to 0.281496 and -0.7 to 1.2, respectively, with  $T_{\text{DM}2}$  age of 2646 Ma to 2788 Ma by using the upper intercept age.

## 6 Discussion

### 6.1 Significance of the two stages of zircon

170 Generally, zircon with high U content can easily break down into the metamict state because of the radiation damage to the lattice caused by  $\alpha$ -particles originating from the decay of uranium (Mezger and Krogstad, 1997). The physical and structural changes often lead to the loss of Pb and addition of trace elements such as LREE. In this study, the LSZ are characterized by high U content. Hence, the metamictization degree of the zircons must be taken into consideration. Data from LSZ spots plot on the Concordia curve, indicating no obvious Pb loss. The internal structure of LSZ is relatively intact, with obvious  
175 oscillatory zoning, and few cracks, implying that the physical and structural of the LSZ remained unchanged. Nasdala et al. (1998) suggested that the metamictization of zircon can be well characterized by Raman spectroscopy. The half-width of the  $\nu_3(\text{SiO}_4)$  Raman band ( $b$ ) of  $10\text{ cm}^{-1}$  and  $20\text{ cm}^{-1}$  are proposed to approximately distinguish well-crystallized, intermediate and metamict zircons (Nasdala et al., 1998). The LSZ have  $b$  values of 5.4–9.2, characterizing them as well-crystallized. Therefore, the above features indicate that the LSZ are not metamict. Consequently, it can be concluded that the U-Pb  
180 isotope and trace element systematics of the LSZ have not been changed by metamictization.

Both the ESZ and LSZ have oscillatory zoning patterns, and their chondrite-normalized REE patterns are characterized by steeply positive slopes from the LREE to HREE with strong negative Eu anomalies and pronounced positive Ce anomalies. The above characteristics are consistent with those of igneous zircon (Hoskin and Schaltegger, 2003). Although hydrothermal zircon can also have oscillatory zoning patterns similar to magmatic zircons, there are obvious differences in  
185 trace elements between the magmatic and hydrothermal zircon (Hoskin et al., 2005). In the discrimination diagram (Fig. 10), both the spots of ESZ and LSZ fall in or near the magmatic field, which is obviously different from hydrothermal zircon. Hence, the above characteristics indicate that both the ESZ and LSZ from the Zhoujiapuzi granite have a magmatic origin.

The ESZ was overgrown continuously by the LSZ. In addition, the contact between the ESZ and LSZ is euhedral. Such core-mantle overgrowth relationships indicate that both the ESZ and LSZ formed in two stages of the same magmatism (i.e.

190 the ESZ are not xenocrysts or inherited zircons). Furthermore, the similar Hf isotopic data of the ESZ and LSZ is also consistent with this interpretation. The obvious difference in internal structure and trace element composition between the ESZ and LSZ could be due to significant and abrupt changes in their crystallization environments (Wang et al., 2007).

Watson and Harrison (2005) found that the Ti content of zircon has a strong dependence on temperature (T), and obtain a Ti-in-zircon thermometer ( $T_{Zr-Ti}$ ). Since then, Ferry and Watson (2007) suggested that the solubility of Ti in zircon depends  
195 not only on T and activity of  $TiO_2$  ( $a_{TiO_2}$ ) but also on the activity of  $SiO_2$  ( $a_{SiO_2}$ ), and revised the  $T_{Zr-Ti}$ . We use the  $T_{Zr-Ti}$  from Ferry and Watson (2007) and the recommended values ( $a_{SiO_2}=1$ ,  $a_{TiO_2} = 0.6$ ) for the activity of  $SiO_2$  and  $TiO_2$ , due to the presence of ilmenite and quartz and lack of sphene and rutile in the Zhoujiapuzi granite. The  $T_{Zr-Ti}$  from the ESZ and LSZ are 669–792 °C (average 734 °C) and 498–720°C (average 621 °C), respectively, i.e. the ESZ formed at higher temperatures than the LSZ. The U content shows a significant negative correlation with T (Fig. 11a).

200 Cerium exists in magmas as both  $Ce^{3+}$  and  $Ce^{4+}$ . Because the 0.84-Å radius of the  $Zr^{4+}$  ion is more closely matched by the  $Ce^{4+}$  (0.97-Å radius) than the  $Ce^{3+}$  (1.143-Å radius) (all ionic radii are from Shannon, 1976),  $Ce^{4+}$  is more compatible in the zircon structure than the  $Ce^{3+}$ . Hence, zircon  $Ce^{4+}/Ce^{3+}$  ratio is a useful tool for evaluating the oxygen fugacity condition of crystallization environment (Ballard et al., 2002). In this study, the  $Ce^{4+}/Ce^{3+}$  ratio of the ESZ and LSZ are 6.30–153.36 (average 32.51) and 21.81–5773.06 (average 787.39), respectively (the calculation method after Ballard et al., 2002). As  
205 shown in the  $Ce^{4+}/Ce^{3+}$ -U diagram (Fig. 11b), U has a significant positive correlation with  $Ce^{4+}/Ce^{3+}$ . This result implies that the LSZ formed in a higher oxygen fugacity environment than the ESZ.

The Zr/Hf ratio in zircon has a negative correlation with the degree of fractionation in the parent melt (Breiter et al., 2014). The Zr/Hf ratios of the ESZ (39–56) are obviously higher than those of the LSZ (21–40) (Fig. 11c). Hence, the above features reflect that the LSZ crystallized from a later and more evolved magma. The lowest Zr/Hf value of the LSZ is less  
210 than 25, which indicates that the Zhoujiapuzi granite finally evolved into a highly fractionated granite due to crystallization differentiation. It is consistent that all the samples of the Zhoujiapuzi granite are characterized by relatively high  $SiO_2$  and total alkali contents, low  $TFe_2O_3$ , MgO and CaO contents, and enrichment of Rb, Th and U (Xiao et al., 2014).

The absence of enclaves and disequilibrium textures in the Zhoujiapuzi granite and uniform  $\epsilon_{Hf}(t)$  values of the ESZ and LSZ do not support magma mixing and wall-rock assimilation. Consequently, the abrupt change between the  
215 crystallization environment of the ESZ and LSZ is not due to the magma mixing or contamination during magma evolution. Therefore, we propose that the ESZ was formed in a relatively deep magma chamber, which had low oxygen fugacity, low Zr saturation and high temperature. The low Th, U and REE, and widely-spaced oscillatory zoning patterns indicate a low growth rate of zircon (Hoskin and Schaltegger, 2003; Wang et al., 2011). In contrast, the LSZ was formed during the ascent and/or at the emplacement location of the magma. At this stage, the oxygen fugacity significantly increased, the temperature  
220 decreased, and Zr saturation increased due to the crystallization differentiation. In this environment, the crystallization rate of zircon significantly increased, forming the zircons with a higher content of Th, U and REE elements, low CL emission and narrowly-spaced oscillatory zoning patterns. As shown in the  $U\text{-}^{206}Pb/^{238}U$  age diagram (Fig. 11d), the  $^{206}Pb/^{238}U$  ages of the ESZ are relatively scattered, while the  $^{206}Pb/^{238}U$  age of the LSZ are mainly concentrated around 157–158 Ma. This

phenomenon indicates that the cooling rate of magma in the deeper magma chamber was relatively slow, thus the zircon  
225 crystallized continuously over a relatively long period. The magma finally solidified in a relatively short period, so the zircon  
crystallized rapidly.

Zircon U-Pb dating is the most commonly used method in magmatic rock dating. A weighted mean age or upper  
intercept age is usually obtained to represent the emplacement time of a magmatic rock. However, this study shows that  
zircons in magmatic rocks record two different magmatic evolution stages: in the deeper magma chamber and in the ascent  
230 passage or/and emplacement site. Previous studies, such as Wang et al. (2007), Zhao et al. (2014) and Chen et al. (2020),  
also show that zircons can crystallize continually or intermittently in a single phase of magmatism, showing several growth  
zones of clearly different internal structure and distinct time difference. Some scholars even regard that the age difference of  
different stages can be more than dozens of Ma (Wang et al., 2007). Therefore, if the zircon ages in the same magmatic rock  
have a large range of variation, this could be caused by the zircons recording different stages in magmatic evolution, related  
235 to different levels of magma within the crust and/or different temperature regimes. It is notable that the bulk petrology and  
geochemistry of the host pluton does not record and reveal this two-stage magmatic evolution, which can only be detected in  
the zircon analysis.

## 6.2 Genetic type: I-type affinity

The samples of the Zhoujiapuzi granite have  $A/KNC < 1.1$ , relatively high  $Na_2O$  (3.96–4.65 wt.%) and lack peraluminous  
240 minerals (e.g. cordierite, andalusite, muscovite and garnet), which are clearly different from S-type granites (Chappell and  
White, 1992). With the rise of the degree of crystallization,  $P_2O_5$  contents (generally  $>0.1$  wt.%) increase in S-type granites,  
accompanied by an increase/immobility in  $SiO_2$  (Wolf and London, 1994). However, the Zhoujiapuzi granite samples have  
low  $P_2O_5$  contents (0.02–0.08 wt.%), and decrease with increasing  $SiO_2$  (Fig. 12a), which is also inconsistent with the  
characteristics of S-type granite (Chappell and White, 1992). Additionally, Rb has a negative correlation with Y (Fig. 12b),  
245 which has been considered as an indicator of I-type granite rather than S-type granite (Jiang et al., 2018). Thus, the  
Zhoujiapuzi granite is not an S-type granite.

Although the samples of the Zhoujiapuzi granite have high  $10000Ga / Al$  ratios of (2.74–3.13) akin to A-type granites,  
the low Zr (113–242 ppm) and  $Zr+Nb+Ce+Y$  (152.0–382.6 ppm) contents are distinct from the diagnostic features of A-type  
granites (Whalen et al., 1987). This observation is consistent with the Zhoujiapuzi granite lacking alkaline mafic minerals  
250 (Zhang et al., 2017). Wu et al. (2017) suggested that a high formation temperature is one of the most important  
characteristics of A-type granite. Zircon saturation thermometry ( $T_{Zm}$ ) and Ti-in-zircon thermometer ( $T_{Zr-Ti}$ ) are two methods  
for estimating magma temperatures. As discussed before,  $T_{Zr-Ti}$  is negatively correlated with the U content, which indicates  
that the crystallization temperature of zircon gradually decreases with magma. Hence, the initial magma temperature should  
be greater than or equal to the highest Ti temperature (792 °C). Zircon saturation thermometry was introduced by Watson  
255 and Harrison (1983) and is suitable for non-peralkaline crustal source rocks. The calculated  $T_{Zrn}$  values for the Zhoujiapuzi  
granite are in the range of 803–870 °C. Because the Zhoujiapuzi granite contains abundant inherited zircons, the initial

magma temperature should be lower than or equal to the lowest  $T_{Zm}$  (803 °C) (Miller et al., 2003). Therefore, the initial magma temperature of the Zhoujiapuzi granite was at a range of 792–803 °C, which is significantly lower than that of the typically A-type granite (>900 °C, Skjerlie and Johnston, 1992; Douce, 1997). Furthermore, the Zhoujiapuzi granite samples show similar trends to the Late Jurassic granitoids in the Liaodong peninsula, which are typical I-type granites (Fig. 12). Therefore, we conclude that the Zhoujiapuzi granite is a highly fractionated I-type granite.

### 6.3 Petrogenesis of the high Sr/Y granite

The samples of the Zhoujiapuzi granite have high Sr/Y and  $(La/Yb)_N$  ratios and low Y and Yb contents (Fig. 13a) consistent with the geochemical signatures of modern adakites (Defant and Drummond, 1990). However, other geochemical parameters of the Zhoujiapuzi granite, such as the high  $K_2O / Na_2O$  ratio (0.93–1.22), low  $Al_2O_3$  content (14.49–15.02%, except one) and Sr content (in half of the samples lower than 400 ppm), are obviously different from typical adakites ( $K_2O/Na_2O \leq 0.42$ ,  $Al_2O_3 \geq 15\%$ ,  $Sr > 400$  ppm, Defant and Drummond, 1990; Drummond et al., 1996, Martin et al., 2005). A variety of petrogenetic models have been proposed for the origin of high Sr/Y magmatic rocks, such as partial melting of subducting oceanic crust (Model A, Defant and Drummond, 1990), delaminated lower continental crust (LCC) (Model B, Kay and Kay, 1993; Xu et al., 2002), differentiation of basaltic arc magma (Model C, Castillo et al., 1999), magma mixing between mantle-derived mafic and crust-derived silicic magmas (Model D, Ma et al., 2013), partial melting of thickened basaltic LCC (Model E, Gao et al., 2004; Ou et al., 2017), or melting of a high Sr/Y (and La/Yb) source (Model F, Kamei et al., 2009; Ma et al., 2015).

#### 6.3.1 Model A: Partial melting of subducting oceanic crust

The partial melting of the young, hot and hydrated subducted oceanic slab in the garnet stability field is the classical formation model of adakite (high Sr/Y rock) (Defant and Drummond, 1990). Studies have shown that the rock with this genetic model generally has the characteristics of high mantle components (such as MgO, CaO and Cr) because of the involvement of mantle magma (Wang et al., 2018). However, this phenomenon was not seen in the Zhoujiapuzi granite. In addition, the Zhoujiapuzi granite has high  $K_2O/Na_2O$  ratios (0.92–1.22, average 1.13), which is inconsistent with the slab-derived adakites ( $K_2O/Na_2O = \sim 0.4$ , Martin et al., 2005). Moreover, the low  $\epsilon_{Hf}(t)$  values (-26.3 to -22.8) of the Zhoujiapuzi granite are also inconsistent with the magmas derived from the partial melting of oceanic crust, which generally have depleted isotopic character (Zhan et al., 2020). In summary, the Zhoujiapuzi granite is difficult to explain by Model A.

#### 6.3.2 Model B: Delaminated lower continental crust (LCC)

High-density, garnet-bearing mafic lower crust delaminating or foundering into the asthenosphere mantle and subsequent interaction with mantle peridotite could produce high Sr/Y magmas (Kay and Kay 1993). Because the melt formed by partial melting of the delaminated lower crust would interact with mantle peridotite during magma ascent, the high Sr/Y magmas

related to this petrogenetic model generally have high MgO (>1.5 %) and Mg# (>50) (Gao et al., 2004; Ou et al., 2017). The MgO (0.10– 0.44) and Mg# (15– 26) values of Zhoujiapuzi granite are significantly lower than the above values. Due to the high temperature of the asthenosphere (1200 °C, Parsons and McKenzie, 1978; King et al., 2015), rocks formed by partial melting of the delaminated lower crust should possess a high-temperature fingerprint. As mentioned before, the initial magma temperature of the Zhoujiapuzi granite was ~800 °C, which is markedly lower than the temperature of the asthenosphere. Therefore, the petrogenetic model of delaminated lower continental crust (Model B) is also inconsistent with the Zhoujiapuzi granite.

### 6.3.3 Model C: Differentiation of basaltic arc magma

Low-pressure fractional crystallization (involving olivine + clinopyroxene + plagioclase + amphibole+ titanomagnetite) or high-pressure fractional crystallization (involving garnet) from basaltic magmas have been proposed as two ways to generate adakitic characteristics (Castillo et al., 1999; Macpherson et al., 2006). As shown in the La/Sm versus La diagram (Fig. 14a), increasing La content with constant La/Sm shows that fractional crystallization rather than partial melting is the main factor controlling the composition of the Zhoujiapuzi granite. Hence, the samples of Zhoujiapuzi granite displayed variable Eu and Sr contents, implying that the plagioclase is likely a fractional phase. Separation of titanomagnetite could explain the positive in  $\text{TFe}_2\text{O}_3$  with increasing  $\text{TiO}_2$  content (Fig. 14b), consistent with the occurrences of magnetite in some studied rocks. This possible mineral assemblage of fractional crystallization is also reflected by the chemical variations in the Sr/Y-Y diagram (Fig. 13b).

However, fractionation of olivine and clinopyroxene is inconsistent with the depletion of HREE (e.g., Yb) given their low distribution coefficients for these elements in mafic-intermediate magmas (Dunn and Sen, 1994). Moreover, the crystallization of amphibole would result in a negative correlation between the  $(\text{Dy}/\text{Yb})_N$  and  $(\text{La}/\text{Yb})_N$  (Davidson et al., 2007), which is not seen in the Zhoujiapuzi granite (Fig. 14c). No positive correlations between Dy/Yb and Sr/Y ratios and  $\text{SiO}_2$  contents (Figure 14d, e) suggest that fractional crystallization of garnet was not a significant process for the Zhoujiapuzi granite (Macpherson et al., 2006). Therefore, both the low-pressure and high-pressure crystallization fractionation of basaltic melts could be ruled out for the negligible fractional crystallization of olivine, clinopyroxene, garnet and amphibole.

In addition, crystal fractionation of basaltic melts can only form minor volumes of granitic melts, the ratio of the two is about 9:1 (Zeng et al., 2016). However, in the Liaodong Peninsula, most of the Middle-Late Jurassic magmatic rocks are acidic, mafic-ultramafic rocks are only reported in the Huaziyu area (lamprophyre dikes, Jiang et al., 2005), and cover a much smaller area than the Zhoujiapuzi granite. For these reasons, it is highly improbable that Zhoujiapuzi granite was derived by differentiation of basaltic magma (Model C).

### 6.3.4 Model D: Magma mixing between mantle-derived mafic and crust-derived silicic magmas

The Zhoujiapuzi granite has high  $\text{K}_2\text{O}/\text{Na}_2\text{O}$  ratio (>1) and A/CNK value (>1), together with the absence of mafic

320 microgranular enclaves (MMEs), felsic xenocrysts and melting texture of plagioclase, implying that the mantle-derived  
magma is unlikely to have played an important role in the genesis of the Zhoujiapuzi granite (Castro et al., 1991). In addition,  
the Zhoujiapuzi granite is characterized by the development of biotite, but lacks amphibole and pyroxene. These features,  
coupled with the high A/CNK value, are consistent with an origin as a crust-derived granitoid, but obviously different from  
the granitoids formed by crust-mantle-derived magma mixing (Barbarin, 1990). Moreover, granites formed by magma  
mixing generally have variations in  $\epsilon\text{Hf}(t)$  values, high MgO,  $\text{TFe}_2\text{O}_3$ , CaO and Cr contents and low  $\text{SiO}_2$  content (Ma et al.,  
325 2013; Wang et al., 2018). These features are obviously inconsistent with the Zhoujiapuzi granite in this study. Hence, magma  
mixing of mantle-derived and crust-derived magmas (Model D) is also unlikely to have produced the Zhoujiapuzi granite.

### 6.3.5 Model E: Partial melting of thickened basaltic LCC

Experimental studies have shown that the partial melt of basaltic LCC in the garnet stabilization zone ( $> 40$  km, i.e.  $\sim 1.2$   
GPa) can produce magma with a high Sr/Y ratio (Rapp et al., 2003 and references therein). In these scenarios, high Sr/Y and  
330 overall adakitic affinity are caused by leaving garnet as residual phases (e.g. Gao et al., 2004). Based on geochemical data  
for the Zhoujiapuzi granites, partial melting of thickened basaltic LCC is also unlikely to account for the high Sr/Y  
Zhoujiapuzi granite (Model E). This conclusion is based on the following observations:

(1) This ratio of  $(\text{Gd}/\text{Yb})_N$  is the most important feature to judge whether garnet is involvement in magma genesis (Ma  
et al., 2012). If the  $(\text{Gd}/\text{Yb})_N$  ratio of the source is similar to the average value of the LCC (1.71, Rudnick and Gao, 2003),  
335 partial melting of these crustal materials controlled by garnet at high pressure can produce melt with  $(\text{Gd}/\text{Yb})_N$  of 5.8 (Huang  
and He, 2010). In contrast, the  $(\text{Gd}/\text{Yb})_N$  values (1.22–5.06, average 2.69) of the Zhoujiapuzi granite are relatively low. (2)  
Melt in equilibrium with a garnet-rich residue will result in positive correlations between the Dy/Yb and Sr/Y ratios and  $\text{SiO}_2$   
contents. However, these phenomena were not seen in the Zhoujiapuzi granite (Fig.14 d, e). (3) Studies of lower-crustal  
xenoliths show that garnet may not be a common mineral in the lower crust of the NCC (Huang et al., 2004; Ma et al., 2012).  
340 (4) As shown in the discrimination diagrams of granite sources (Fig. 14f, g), all samples fall in the range of metagreywacke-  
derived melts. Therefore, the Zhoujiapuzi granite was considered to have been derived from crustal anatexis of  
metagraywacke (or intermediate-acid igneous rock with similar mineral composition), rather than basaltic lower crust.

### 6.3.6 Model F: Melting of a high Sr/Y (and La/Yb) source

Studies have shown that when a source rock has a high Sr/Y ratio, the high Sr/Y signature of the derived magma can inherit  
345 from their source, regardless of pressure (Kamei et al., 2009; Moyen, 2009; Ma et al., 2015). The Zhoujiapuzi granite has  
similar  $\text{K}_2\text{O}/\text{Na}_2\text{O}$  ratios and  $\text{Al}_2\text{O}_3$  contents to the Tsutsugatake intrusion (Fig. 14h), which is explained by partial melting of  
arc-type tonalite or adakitic granodiorite (Kamei et al., 2009). We suggest that partial melting of high Sr/Y Liaoji granite was  
most probably the origin of the high Sr/Y Zhoujiapuzi granite, as discussed below (Model F).

Among the inherited zircons from Zhoujiapuzi granite, the  $^{207}\text{Pb} / ^{206}\text{Pb}$  ages of all the spots are between 2132 and 2200  
350 Ma, except one, and yield a Concordia upper intercept age of 2167 Ma. Both assimilation of country-rocks and incomplete

melting of source rocks can explain the genesis of inherited zircon in granite. Due to the similar  $T_{DM2}$  of syn-magmatic zircons (ESZ and LSZ) and the  $\sim 2.17$  Ga inherited zircon, the  $\sim 2.17$  Ga inherited zircons most likely come from the source of the Zhoujiapuzi granite. In the study area, meta-sedimentary rocks and meta-volcanic rocks of the South Liaohe Group,  $\sim 2.17$  Ga mafic rocks, as well as the Liaoji granites, have  $\sim 2.17$  Ga zircon. In spite of an age peak of  $\sim 2.17$  Ga in detrital  
355 zircon age spectra of the metasediments from the South Liaohe Group, melting of a sediment-dominated source is unlikely to have occurred, as it would have also introduced other age peaks such as  $\sim 2.03$  Ga and  $\sim 2.09$  Ga (Li et al., 2015). In addition, given the I-type characteristics of the Zhoujiapuzi granite, derivation from an igneous precursor is more plausible rather than a metasedimentary origin (Chappell and White, 1992). Therefore, these  $\sim 2.17$  Ga zircon from Zhoujiapuzi granite is unlikely to come from the South Liaohe Group. As shown in the host rock discrimination diagrams (Fig. 15, introduced by Belousova  
360 et al., 2002), all the  $\sim 2.17$  Ga inherited zircons from Zhoujiapuzi granite fall into the granitoid area (Fig. 15), precluding that these  $\sim 2.17$  Ga zircon come from the  $\sim 2.17$  Ga mafic rocks. In addition, the  $\sim 2.17$  Ga inherited zircons from Zhoujiapuzi granite and the zircons from the Liaoji granites lie in a similar area in the  $\epsilon Hf(t)$ -age (Ma) diagram (Fig. 9). Hence, the  $\sim 2.17$  Ga inherited zircon most likely come from the Liaoji granites.

Some of the Liaoji granites, such as the Muniuhe granite (comprising granodiorite and syenogranite with no distinct  
365 boundary between the two), have adakitic signatures, and similar REE and trace element patterns as the Zhoujiapuzi granite (Fig. 4). Based on a model of modal batch melting (Shaw, 1970) using the experiments of Conrad et al. (1988), the high Sr/Y characteristic of the Zhoujiapuzi granite can be explained by partial melting of Muniuhe granitic pluton leaving amphibole as the main residue (Fig. 13b). In this model, we choose the XY-005 sample to approximately represent a primitive melt composition because the fractional crystallization of plagioclase decreased of Sr content and Sr/Y ratio (Fig. 13a). To find  
370 the best matching experimental melts, we have compared the major elements of the XY-005 sample with that of experimental melts, coupled with the initial magma temperature of  $\sim 800$  °C and the characteristics of no garnet residue discussed above. Results are shown in Fig. 13b. The Sr and Y compositions of the starting material used in these experiments resemble those of the average composition of the Muniuhe granitic pluton (Sr=475 ppm, Y=9.77 ppm), if the residue contains a large volume of amphibole (>90 %). However, if more plagioclase is retained in the residue (e.g. 18.3 %), a  
375 source region with a higher Sr content is required. Therefore, a similar high Sr/Y Liaoji granite to the Muniuhe granitic pluton can produce the high Sr/Y signatures of the Zhoujiapuzi granite.

A large number of Yanshanian adakites (or high Sr/Y rocks) are developed in the NCC, which are generally considered to be derived from the thickened basaltic LCC (e.g. Gao et al., 2004; Wu et al., 2005; Ma et al., 2013). Zhang et al. (2001, 2003) suggested that these so-called “C-type adakites” indicated a large-scale crustal thickening event, so it was speculated  
380 that a Mesozoic plateau once existed in the eastern China. However, according to the studies on the Triassic and Jurassic adakitic rocks near the Pingquan area, the northern part of the NCC, Ma et al. (2012, 2015) suggested that the adakitic signatures of these rocks are inherited from their source rocks. Similar results have been obtained by studying the late Jurassic Zhoujiapuzi granite in the Liaodong Peninsula in this study. Therefore, we suggest that melting of a high Sr/Y (and La/Yb) source is an important process for the generation of Yanshanian high Sr/Y rocks in the NCC. This kind of high Sr/Y

385 granite does not need to be formed in the garnet stability field.

#### 6.4 Tectonic implications

A large number of Early Jurassic arc-like igneous rocks occur in the northeast part of NCC- Korean Peninsula-Hida belt, which belong to the middle-high K calc-alkaline series and are characterized by the enrichment in LILE and depletions in HFSE (Wu et al., 2007; Tang et al., 2018 and references therein). In addition, the Early Jurassic accretionary complexes in  
390 the eastern margin of the Eurasian continent and the Japan islands, such as the Heilongjiang complex, the Khabarovsk complex and the Mino-Tamba complex, are considered to be related to subduction (Wu et al., 2007; Tang et al., 2018 and references therein). It is generally accepted that the Paleo-Pacific slab subducted westwards in the Early Jurassic (Tang et al., 2018; Zhu and Xu, 2018).

In the middle-late Jurassic, I-type granites are dominant in the Liaodong Peninsula, such as the Zhoujiapuzi granite (this  
395 study), Heigou pluton, Gaoliduntai pluton (Wu et al., 2005a), Waling granite (Yang et al., 2015b) and Sanguliu granite (Yang et al., 2018). There are not A-type granites, and mantle derived magmatism is extremely rare. These granites were formed by partial melting of crustal materials without obvious contribution of mantle derived magma (Wu et al., 2005a; Yang et al., 2015b, 2018; Xue et al., 2020). In addition, WNW-ESE compression during 157-143 Ma was widespread in the Liaodong Peninsula (Yang et al., 2004; Zhang et al., 2020). It not only mylonitized the granite plutons in middle-lower crust  
400 levels, but also intensely deformed the thick sedimentary cover in the upper crust (Qiu et al., 2018; Ren et al., 2020). Low angle subduction will lead to the separation of lithospheric mantle and asthenospheric mantle, which will lead to tectonic compression, a cold orogeny and a lack of mafic magmatism (Zheng et al., 2018). Hence, the Late Jurassic magmatism in the Liaodong peninsula is most likely to be related to the thinning of the NCC mantle lithosphere, itself triggered by the subduction of the Paleo-Pacific plate (Zheng et al., 2018). A likely setting is a mature continental arc, with crust previously  
405 thickened by compressional tectonics, related to both the oceanic subduction and the earlier Mesozoic collisions at the north and south margins of the NCC. There is a potential resemblance to the modern arc of the Central Andes (Allmendinger et al., 1997), where crustal thickening and plateau growth has developed over the Cenozoic (Scott et al., 2018), and melting of older basement has taken place during subduction of the Nazca plate (Miller and Harris, 1989).

#### 7 Conclusion

410 (1) LA-ICP-MS zircon U-Pb dating indicates that the Zhoujiapuzi granite in the Liaodong Peninsula formed during the Late Jurassic (158–162 Ma).

(2) Zircon growth in Zhoujiapuzi granite can be divided into two distinct stages, the ESZ and LSZ. The ESZ was formed in a deeper, hotter, magma chamber, which had low oxygen fugacity and high temperature. Whereas, the LSZ formed from later, more evolved, magma. Oxygen fugacity significantly increased and the temperature decreased at this

415 stage. The Zhoujiapuzi granite is a case study of multistage generation and emplacement of magma, revealed by zircons, where no signals are discernible in the bulk petrology or geochemistry.

(3) The I-type Zhoujiapuzi granite originated from partial melting of the ~2.17 Ga Liaoji granites. The high Sr/Y compositions are inherited from their source rocks, rather than being a direct indication of deep crustal melting, or any other common mechanism for generating adakitic signatures.

420 (4) The Late Jurassic tectonic setting of the Liaodong Peninsula and the eastern NCC resembled the modern orogenic plateau of the Central Andes, where silicic magmatism may occur by partial melting of older continental crust in a compressional environment related to the subduction of the Paleo-Pacific plate.
