Abstract. Subduction zones represent the only major pathway by which continental material can be returned to the Earth’s mantle. Constraining the sediments mass flux through subduction zones is important to the understanding of both petrogenesis of continental crust, and the recycling of volatiles and continental material back into the mantle over long periods of geologic time. When sediments are considered, convergent Observations of sediments at subduction margins appear to fall into one of divide them into two classes: accretionary and erosive. Accretionary margins are dominated by accretion of thick piles of sediments (>1 km) from the subducting plate, while tectonic erosion is favored in regions where the sedimentary cover is <1 km. However, as data help define geometry of the global subduction system, the The consequences of the two styles of margins on subduction dynamics remain poorly resolved.

In this study, we run systematic 2-D numerical simulations of subduction to investigate how sediment fluxes low-viscosity sediments influence subduction dynamics and margin type through plate coupling. We vary the thickness and viscosity of the sediment layer entering subduction, the thickness of the upper plate, and the driving velocity of the subducting plate (i.e., kinematic boundary conditions). Diagnostic parameters are extracted automatically from numerical simulations to analyze the dynamics and differentiate between modes of subduction margin. Our results show three geometry modes of subduction interface: a) Tectonic erosion margin(high viscosity sediment layer), b) Low-angle accretionary wedge margin(low viscosity, thin sediment layer), and c) High-angle accretionary wedge margin(low viscosity, thick sediment layer). We find that the properties of the sediment layer modulate the extent of viscous coupling at the interface between the subducting and overriding plates. When the viscous coupling is increased, an erosive style(high viscosity, thin layer of sediments), an erosive margin will be favored over an accretionary style margin. On the other hand, when the viscous coupling is reduced (low viscosity), sediments are scrapped-off the subducting slab to form an accretionary wedge. Diagnostic parameters are extracted automatically from numerical simulations to analyze the dynamics and differentiate between these modes of subduction margin. Models of tectonic erosion margins show small radii of curvature, slow convergence rates and thin subduction interfaces, while accretionary margins show large radii of curvature, faster convergence rates and dynamic accretionary wedges. These diagnostics parameters are then linked with observations of present-day subduction zones.
1 Introduction

Sediment subduction at convergent plate boundaries has long been recognized to play an important role in the dynamics of our planet as they can provide direct feedbacks between plate tectonics, climate, and life. Quantifying the sediments mass flux through subduction zones is important for understanding: i) generation of arc magmas and the problem of petrogenesis of continental crust (e.g., Plank and Langmuir (1998); Kelemen and Manning (2015)), ii) whether large volumes of existing continental crust are ever recycled back into the mantle over long periods of geologic time, and iii) cycling of volatiles from Earth’s crust and atmosphere to its deep interior (e.g., Hawkesworth et al. (1997); Plank and Langmuir (1998); Dasgupta and Hirschmann (2010)). Regarding the latter, carbon and water global cycles in particular depend greatly on the amount of subducted sediments (e.g., Plank and Manning (2019); Dutkiewicz et al. (2018); Merdith et al. (2019)), which in turn have important implications for climate stability (Kasting, 1989), biogeochemical cycles (Husson and Peters, 2017), and the rheology of the mantle (Hirth and Kohlstedt, 1996).

Sediments are also fundamental to the dynamics of subduction zones and plate tectonics. The lubricating effect of sediments at the plate interface (referred here as the domain between the lower and upper plates, as defined in Agard et al. (2018)) was recognized more than thirty years ago (i.e., Shreve and Cloos (1986)), and is critical for the mechanism of plate tectonics (e.g., Tackley (2000); Bercovici (2003); Bercovici and Ricard (2014); Sobolev and Brown (2019)). On a regional scale, sediments influence patterns of deformation by controlling the morphologies of subduction interfaces, accretionary prisms and forearc basins (Clift and Vannucchi, 2004; von Huene and Scholl, 1991b; Melnick and Echtler, 2006; Simpson, 2010). Moreover, sediments occupying the shallow seismogenic subduction interface, for example, appear to influence seismic coupling and the frequency of megathrust earthquakes (e.g., Moore and Saffer (2001); van Rijsingen et al. (2018); Heuret et al. (2012); Brizzi et al. (2020)).

However, how sediments influence subduction zone deformation and evolution remains unclear. The force balance during subduction includes the potential energy change of the negative buoyancy of the subducting slab, viscous dissipation in the mantle, bending of the lithosphere, and plate interface (e.g., Conrad and Hager (1999)). Most of the Considerable effort in subduction dynamics studies focused on quantifying dissipation due to slab bending (e.g., Conrad and Hager (1999); Becker et al. (1999); Capitanio and Morra (2012); Garel et al. (2014a)). That is because slabs were assumed to be strong (3000-5000 times stiffer than the mantle) and sediments weak, implying a low coupling degree (low shear stresses) at the interface (Conrad and Hager, 1999; Duarte et al., 2015; Billen and Hirth, 2007). Analytical models and a range of observations Laboratory and numerical models, instead, suggest that slabs may be weaker (only 150-500 times stiffer than the mantle) (Funiciello et al., 2008; Moresi and Gurnis, 1996; Zhong and Davies, 1999), implying a more prominent role for plate interface dissipation than previously thought. Recent simplified energy balance calculations by Behr and Becker (2018) also suggest that sediment-subduction may modulate plate speeds, with sediment-lubricated plates subducting faster than slabs with metabasaltic (i.e., exposed mantle rocks) interfaces.

The lubricating effect of sediments has largely been considered an implicit assumption in previous large-scale subduction dynamics studies. The subduction interface in numerical models is typically implemented by imposing either a fixed interface layer (i.e., subduction channel or weak fault) or a layer at the top of the subducting plate (i.e., weak crust) that is advected with
the flow and continuously entrained into the decoupling region. In this way, the weakening effect of sediments, or any other deformation-localizing processes such as damage, grain size reduction, and fabric development, is parameterized by setting a low viscosity or low friction coefficient of the weak interface material (Gerya et al., 2002). This is a necessary model component for stable asymmetric subduction (Petersen et al., 2017; Cramer and Tackley, 2015; Gerya, 2009; Sandiford and Moresi, 2019) and has become an increasingly common strategy in the last decade (Babeyko and Sobolev, 2008; Capitanio et al., 2010; Magni et al., 2012; Chertova et al., 2012; Cizkova and Bina, 2013; Garel et al., 2014b; Pusok and Kaus, 2015; Agrusta et al., 2017; Pusok and Stegman, 2019). However, maintaining an asymmetric subduction and constant interface thickness through time has been the sole aim of subduction interface approaches in the past (i.e., Sandiford and Moresi (2019)).

In reality, however, Indirect observations suggest subduction interfaces are not discrete isosurfaces separating two plates but are rather exemplified by melange zones (Shreve and Cloos, 1986; Vannucchi et al., 2008; Agard et al., 2018), which means that subduction interfaces that incorporate material from the subducting plate, the accretionary prism, and the upper plate (Menant et al., 2020; Angiboust et al., 2021). Moreover, when sediments are considered at the trench, convergent margins appear to fall into one of two classes: accretionary and erosive (i.e., Clift and Vannucchi (2004), Supplementary material, Figure S1). Accretionary margins are dominated by accretion of thick piles of sediments (>1 km) from the subducting plate, while tectonic erosion is favored in regions where the sedimentary cover is <1 km and showing long-term landward retreat of the trench.

Accretion occurs as develop from an accumulation of material from the subducting plate is transferred into being transferred onto the overriding plate, either by frontal off-scraping at the trench axis or by underplating of the forearc wedge above the decollement at greater depths. These tend to be in areas of rapid sediment delivery from the continental interior, often from large rivers draining mountainous continental sources (Silver et al., 1985; von Huene and Scholl, 1991a). Accretion is generally favored by slow convergence (<7.6 cm/yr) (Clift and Vannucchi, 2004; Syracuse et al., 2010), while fast convergence favors larger volumes of sediment to be dragged down at the interface. Depending on the sediment type, accretionary margins can also differ. Fast accretionary margins are often close to mountainous continental interiors that can deliver large volumes of coarse sandy sediment to the trench axis (e.g., Alaskan, Aleutian, Chilean, and Java margins). In comparison, the slower converging Makran, Aegean, and southern Lesser Antilles systems do not have mountainous hinterlands, and thus they have muddier, thicker trench sediments (Clift and Vannucchi, 2004).

On the other hand, tectonic erosion occurs in regions where the convergence rate exceeds 6 cm/yr and where the sedimentary cover is thin. Tectonic erosion is regarded as (Angiboust et al., 2021). Erosive margins develop from a strong coupling between overriding and subducting plates that results in the basal erosion of the underside of the upper plate, as indicated by margin truncation and forearc subsidence (von Huene and Scholl, 1991a; Clift and Vannucchi, 2004). Tectonic erosion is also known to steepen trench slopes (e.g., von Huene and Lallemand (1990)). However, processes that govern tectonic erosion are less well understood, and can include high friction abrasion, high fluid pressure, and/or avalanches of accretionary wedges (Dueea and Chapman, 2018). Hybrid margins have also been identified, where subducting seamounts may create local accretionary wedges in tectonic erosion margins (Clarke et al., 2018; Comte et al., 2019). Clarke et al. (2018) suggest that two main factors controlling whether a forearc will undergo subduction erosion or accretion are sediment volumes at the trench and topographic
highs on the subducting plate (von Huene and Scholl, 1991a; Clift and Vannucchi, 2004; Straub et al., 2020). Accretionary margins are dominated by accretion of thick piles of sediments (>1 km) from the subducting plate, while tectonic erosion is favored in regions where the sedimentary cover is <1 km and showing long-term landward retreat of the trench.

Both accretionary and tectonic erosion margins are widely distributed. Clift and Vannucchi (2004) classified the global subduction zones in the two categories based on their dominant mode in the last 10 Myr, and found that 43% of global subduction margin is accretionary, and 57% is tectonic erosion. The implications of this equally-distributed duality in margin type to the global subduction system has not been investigated. Convergence rates for the two types of margins seem to correlate well with sediment thickness, the taper angle and radius of curvature (i.e., Supplementary material Figure S1, replotted data from Clift and Vannucchi (2004) and Wu et al. (2008)). De Franco et al. (2008) also observe a correlation between the margin type and upper plate strain (i.e, proxy for back-arc extension). Lamb and Davis (2003) went further to suggest that the type of margin can affect mountain building, with tectonic erosion producing a higher degree of coupling between the subducting and upper plate. They argue that changes from a sediment-rich to sediment-starved subduction regime during Cenozoic climatic cooling may have been responsible for the rise of the Andean mountain belt.

It is clear that the consequences of the two styles of margins on large-scale subduction dynamics remain poorly resolved and have not been explored extensively with numerical models. The dynamics of accretionary Accretionary margins have been investigated in more details, but not in the same framework as erosion style margins (i.e., following the theory for critical Coulomb wedges by Dahlen (1984) and Dahlen et al. (1984), i.e., in analogue models such as Lallemand et al. (1994); Gutscher et al. (1998), numerical models such as the recent study by Ruh (2017)). Beaumont et al. (1999); Selzer et al. (2008); Ruh (2017); Menant et al. (2020)). However, accretionary margins have generally not been studied in the same framework as erosion style margins. Thus, we identify a number of outstanding questions regarding the influx of sediments to trenches and the style of margin that could be addressed with numerical models: Why some margins accrete sediments while others do not? How do sediment fluxes influence subduction dynamics and back? What is the feedback between sediment fluxes and subduction dynamics? How much sediment material gets subducted into the mantle? How should the subduction interface be treated in numerical models, while relaxing the assumption of an interface with constant thickness?

In this study, we run systematic 2-D numerical simulations of ocean-ocean subduction to investigate how sediment fluxes low-viscosity sediments influence subduction dynamics and the plate coupling. We aim to understand what causes convergent margins to either accrete material delivered by the subducting plate or, alternatively, to subduct the trench sediment pile and even erode the basement of the overriding plate. The purpose of the present work is not to model in detail the dynamics of accretionary or erosive margins, but rather, by carrying out numerical experiments on the effect of sediments in geometrically simple configurations of subduction, to further understand the occurrence and evolution of each style of margin.

We begin our investigation with a discussion of the numerical setup and model diagnostics. We then extract automatic diagnostics from our numerical results that can be compared to parameters available for the natural subduction system numerical results to evaluate regimes and compare to available observations in natural subduction zones. In particular, we considered a range of dependent and independent variables from statistical analyses of present-day subduction zones (Clift and Vannucchi, 2004; Lalleman.
constrain and validate the results of numerical models. This study intends to consolidate insights from numerical models of subduction with an integrated set of global observations.

2 Methods

**Numerical models presented below are purely mechanical.** We solve for the slow-creeping motion of solid materials over a timescale of million of years, known as Stokes equations. They are comprised of the equations of conservation of mass and momentum, assuming incompressibility and neglecting thermal diffusion, which are given by:

\[
\nabla \cdot \mathbf{v} = 0, \\
-\nabla P + \nabla \cdot \mathbf{\tau} + \rho \mathbf{g} = 0,
\]

where \( \mathbf{\tau} \) is deviatoric stress tensor, \( P \) is pressure, \( \rho \) density, \( \mathbf{g} \) is the gravity vector, and \( \mathbf{v} \) is velocity. Thus, the lithosphere and mantle materials are assumed to behave as a continuous medium deforming by steady state creep over long time intervals (Turcotte and Schubert, 2014). We use a variable viscosity constitutive relationship \( \tau_{ij} = 2 \eta \dot{\varepsilon}_{ij} \), where \( \eta \) is the Newtonian viscosity, constant for each material phase, \( \dot{\varepsilon}_{ij} = \frac{1}{2} \left( \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \) is the deviatoric strain rate tensor, and \( i, j \) represent spatial directions following the Einstein summation convention.

The above equations are solved using the parallel 3-D finite difference code LaMEM (Lithosphere and Mantle Evolution Model) (Pusok and Kaus, 2015; Kaus et al., 2016), capable of simulating lithospheric deformation while simultaneously taking mantle flow into consideration. We use a pseudo 2-D Cartesian domain in an approach similar to Pusok and Stegman (2019, 2020), meaning we consider infinite extension in the \( y \)-direction. A Lagrangian marker-in-cell method (Harlow and Welch, 1965; Gerya, 2009) is used for accurately tracking distinct material domains (Pusok et al., 2017) as they undergo extensive deformation due to creeping flow. We also employ an internal free surface, using the "sticky-air" approach (Schmeling et al., 2008; Crameri et al., 2012), with a free surface stabilization algorithm (Kaus et al., 2010) that allows for the development of topography. The details of the model setup follow below.

2.1 Model setup

We performed 2-D numerical simulations of ocean-ocean free-subduction (Table 1, Figure 1) to investigate the role of sediment fluxes on slab dynamics and topography. The model domain is 6000 km across and 1500 km deep. The computational domain has a variable grid spacing, with higher resolution in the upper mantle asthenosphere and close to the subduction trench (minimum and maximum grid spacings: \( \Delta x \in [1.73, 15.62] \) km, \( \Delta z \in [2, 16] \) km). Free-slip boundary conditions are imposed on all boundaries and a 60-km layer of "sticky-air" on top of the plates. Previous studies have shown that using a free surface (i.e., sticky-air method in this case) instead of a free-slip top boundary dramatically changes subduction style, with free surface cases being a more appropriate choice to model single-sided subduction (Kaus et al., 2010; Crameri and Tackley, 2015). Here, the rock-sticky-air interface represents an internal free surface formulation, from which topography is calculated.
The initial model setup and material parameters are similar to the ones used in Pusok and Stegman (2019, 2020). These models were used to investigate the dynamics of same-dip double subduction systems, and to explain dynamical processes leading to the fast convergence history between India and Eurasia in the Cretaceous. Here, we model a single subduction framework, but we keep the same plate structure and geometry as in these previous studies setting (Figure 1). The model consists of an oceanic plate subducting beneath another oceanic upper plate (i.e., ocean-ocean subduction). The length of both plates is 2500 km and they are not attached to the side walls, mimicking mid-ocean ridges at the trailing edge of the plate away from the trench. Additional experiments with a fixed upper plate to the wall are presented in the Supplementary material Figure S8. Additional experiments with a fixed upper plate to the wall are presented in the Supplementary material Figure S8.

The subducting plate lithosphere has a thickness of 80 km with a 20 km thick core and 15 km combined weak crust and sediments. The crustal thickness represents a parameterization of the strength weakening of the lithosphere with depth due to hydration and weak sediment cover. Shear stresses in the subduction zone depend on the amount of subducted sediments, which are considered frictionally weak and/or with high fluid pressure (Behr and Becker, 2018). Therefore, within Behr and Becker (2018) estimate that metasediments and serpentinites can be more than two orders magnitude weaker than the reference asthenospheric mantle viscosity, while metabasalts are predicted to be of the same order of magnitude at temperatures between 600-800°C. In our model, we assume that the weak crust, we set a separate sediment layer is formed by a layer of highly-fractured metabasalts (dark green lithology in Figure 1a,b) overlain by a layer of metasediments (light green lithology in Figure 1a,b), which will affect interface properties and is free to deform. Thus, the viscosity structure for the combined weak crust and sediments represents a parameterization of the strength weakening with depth due to hydration and weak sediment cover. The combined initial thickness of sediments and crust remains the same for all simulations, and we investigate the deformation of this sediment layer and its effect on subduction dynamics.

Material parameters are the ones used in Enns et al. (2005) and Pusok and Stegman (2019), where the upper mantle asthenosphere has a reference density ($\rho_0 = 3300$ kg/m$^3$) and viscosity ($\eta_0 = 2.8 \times 10^{20}$ Pa.s), the plates are 85 kg/m$^3$ denser, and have a variable viscosity structure (slab: $500 \times \eta_0$, strong core: $5000 \times \eta_0$ and weak crust: $\eta_0$). The properties of the sediment layer (viscosity, thickness) are varied for each simulation and are given in Table 1. The transition to the lower mantle is marked by a viscosity jump of 50 in the reference models, consistent with previous estimates of the viscosity jump in the Earth’s mantle (Quinteros et al., 2010; Rudolph et al., 2015). For initial conditions, we impose a slab radius of curvature of 150 km and a subduction depth of 200 km, which is enough to initiate subduction. We vary the properties of the sediment layer (viscosity, thickness) and thickness of upper plate as explained below and in Table 1. All other parameters are kept the same among simulations. By not changing the density of the sediments or the slab geometry, the magnitude of initial slab-pull force is the same among simulations. We also consider constant sediment fluxes at the trench.

2.2 Input and diagnostics parameters

While previous studies investigated the role of upper plate and subduction plate parameters, such as thickness and strength (i.e., Holt et al. (2015); Brizzi et al. (2020)), we focus here on factors acting directly on the subduction interface. In particular, we use a result from Currie et al. (2007) and Cizkova and Bina (2019), which found that the effect of sediment...
buoyancy and viscous entrainment by the subducting plate are the main factors controlling the behaviour of slab and subducted sediments. Thus, we primarily vary the thickness and viscosity of the sediment layer and those of the upper plate. We also extract automatic diagnostics from our numerical models that can be compared to parameters available for the natural subduction systems. In particular, we considered a range of dependent and independent variables from statistical analyses of present-day subduction zones (i.e., Clift and Vannucchi (2004); Lallemand et al. (2005); Wu et al. (2008); De Franco et al. (2008); Heuret et al. (2012)) to constrain and validate the results of numerical models. These diagnostics include: margin style (erosive/accretionary), accretionary margin parameters (wedge angle and width), subduction parameters (radius of curvature, convergence rate, trench rate), and topography characteristics. Parameters discussed in this section are listed in Table 2.

We divide the potential factors to control the dynamics into three categories: slab, sediment, upper plate (Table 2). Furthermore, we make a distinction between input parameters (or control parameters) and diagnostic parameters (or system-response parameters). The input parameters remain constant over the length of a simulation, while diagnostics parameters are a result of the dynamics and are calculated at every timestep as they may evolve in time. In fact, their evolution (steady-state or transient) will constitute the basis of our parameter analysis in Section 3.3. Next, we discuss the individual input and diagnostic parameters used in this study.

**Input parameters.** For the Newtonian rheology used, the input parameters for each phase (viscosity, thickness, density) are categorized into three groups: 1) subducting plate (slab) parameters, 2) interface (sediments) parameters, and 3) upper plate parameters (Table 2). However, in order to reduce the number of simulations needed, and to derive a simple understanding, only the following parameters were varied: thickness and viscosity of sediments ($h_{sed} = [5, 10]$ km, $\eta_{sed} = [0.01\eta_0, 0.1\eta_0, \eta_0]$ Pa.s), and thickness of upper plate ($h_{UP} = [50, 80, 100, 150]$ km). Since the sediment construction is a parameterization of the strength of the oceanic lithosphere, the sediment viscosity is consistent with estimates from Behr and Becker (2018) and the variation in upper plate thickness mimics variable plate ages.

Global compilation studies show that sediment thickness goes from 0-12 km (e.g., Laske et al. (2013); Dutkiewicz et al. (2015); Straume et al. (2018)). Sediment thickness variation in our model setup is, thus, on the upper limit. However, a no-sediment case is still considered when the sediment viscosity is high (represented by high-sediment viscosity (i.e., higher proportion of crust at the interface). The thickness and viscosity of sediments will control the subduction interface shear stresses. High shear stresses will promote a strong mechanical coupling along the interface. All other parameters (dimensions, viscosity ratios, and density differences) are kept the same among simulations. By not changing the density of the sediments or other slab components, the magnitude of slab pull force remains the same among simulations. We also consider constant sediment fluxes at the trench, but future work should consider active surface processes such as erosion and sedimentation. All simulations performed are listed in Table 1.

**Diagnostics parameters.** The diagnostics or correlation (or system-response) parameters calculated from each simulation are also categorized into three groups: 1) subduction (slab) diagnostics, including convergence rate, radius of curvature, trench velocity, 2) interface (sediments) diagnostics, including wedge angle and width of the accretionary wedge, 3) upper plate diagnostics, including trench depth, maximum and mean topographic amplitude in the upper plate. These variables are compatible with parameters derived from statistical analyses of present-day subduction zones (i.e., Clift and Vannucchi (2004); Lalle-
mand et al. (2005); Wu et al. (2008); De Franco et al. (2008); Heuret et al. (2012)), which will be used for comparison of observations and numerical models in the Discussion. The diagnostics are extracted automatically from each simulation, and next we explain how they are calculated to constrain and validate the results of numerical models. Diagnostics parameters are calculated at every time step. Their evolution (steady-state or transient) will constitute the basis of our parameter analysis in Section 3.3.

A schematic of how slab parameters, such as plate convergence \( u_0 \), trench retreat \( u_T \), and radius of curvature \( R_C \), are calculated is shown in Figure 1b. The convergence velocity is calculated as the horizontal motion between the subducting plate and upper plate (i.e., motion between Marker 1 and Marker 3-2 in Figure 1a). The trench retreat is calculated as \( u_T = \frac{dx_T}{dt} \), where \( x_T \) is the trench position and \( t \) is time, starting from an initial trench position \( x_T = 0 \). In all simulations (ocean-ocean subduction), the trench is retreating, specific to ocean-ocean subduction.

The radius of curvature is one of the parameters that requires more careful inspection on how it is calculated. The issue of the radius of curvature is generally problematic, because it is derived from calculating a circular fit to the available earthquake data, which for natural subduction systems can be noisy, questionable, incomplete or subjective (Buffett and Heuret, 2011; Lallemand et al., 2005; Wu et al., 2008). For example, some analyses fit earthquake data for the first 100 km or less because the plate interface is clearly marked at high resolution. However, there are limits on the length of the arc of a circle that can reasonably fit a unique circle (i.e., see discussion in Val and Willenbring (2020)). For this reason, slab dip angle is often used as a metric for slab orientation. However, considering that slabs bend elastically, radius of curvature is more appropriate to describe slab deformation with depth, while slab dip represents only the tangent to curvature close to the surface.

We calculated the radius of curvature after Petersen et al. (2017) (Figure 1c), in the following way: we extract the upper surface of the core of the slab (black) and fit a circle to an arc defined by the inflection point where the plate starts bending (red dot-point below A), and the point on the surface corresponding to 150 km depth (red point next to C). The slab core is the most appropriate feature for the fitting algorithm to calculate the radius of curvature of the slab, as its strength controls the bending of the slab. Moreover, the upper layers (weak crust and sediments) may deform strongly during subduction and introduce noise into the circle-fitting algorithm. This algorithm remains robust throughout the evolution of a simulation (see movies in data repository). Therefore, our calculations of the radius of curvature are approximately 30 km less than total radius of curvature which includes the crust and sediments, but are more robust. By extracting the radius of curvature, we are also interested in understanding whether the radius of curvature is a good metric for subduction dynamics, as compared to slab dip (as used in Lallemand et al., 2005).

Sediments reaching the trench may either subduct into the mantle or accumulate into an accretionary wedge. We quantify whether a margin is tectonic erosion (TE) or an accretionary wedge (AW) by calculating two diagnostics for the accretionary wedge at the trench: the angle \( \alpha_{\text{wedge}} \), and the width \( W_{\text{wedge}} \) (Figure 1c). These parameters are not equivalent to the ones calculated in the taper wedge theory (Dahlen, 1984; Dahlen et al., 1984), which are more difficult to derive from numerical results, and the extract as current numerical resolution is too coarse (i.e., the surface topography variations of the wedge in our models in the wedge are too small).
The algorithm to calculate both the wedge angle and width is the following: 1) isolate the sediment markers (grey material in Figure 1c), 2) determine wedge points (A,B,C): point A is the inflection point of the slab at the surface, point B is the end point to the right of the surface of sediments, and point C is at the base of the upper plate. We then connect ABC into a triangle, and calculate \( \alpha_{\text{wedge}} = \angle A\!C\!B \), and \( W_{\text{wedge}} = AB \). Supplementary material shows that the algorithm works well in the majority of cases (Supplementary material, movies in data repository). It is important to note that the wedge angle is non-zero even in tectonic erosion margins, as there is a finite thickness of the sediments (i.e., points A, B will not overlap).

The effect of sediments on topography is also investigated. Lamb and Davis (2003) suggested that changes from a sediment-rich to sediment-starved subduction regime during Cenozoic climatic cooling may have been responsible for the rise of the Andean mountain belt, high topography in the Andes. They argue that tectonic erosion favours more coupling with the upper plate, while accretionary wedges favour decoupling, thus lower topographic amplitude. We investigate these hypotheses by extracting three diagnostics related to topography: trench depth \( h_{\text{trench}} \), maximum topographic amplitude in the upper plate \( h_{\text{max}} \), and mean topographic amplitude in the upper plate \( h_{\text{mean}} \). The choice of last two are is motivated by the study of Pusok and Kaus (2015), which shows that the two parameters can describe a number of topographic expressions for convergent margins.

### 3 Results

The 2-D numerical experiments below aim to understand what causes convergent margins to either accrete material delivered by the subducting plate or, alternatively, to subduct the trench sediment pile and even erode the basement of the overriding plate. We primarily varied the thickness and viscosity of the sediment layer and those of upper plate (Table 1). This is an initial set of models in which the driving force (i.e., slab pull) remains constant in all simulations by not varying the density, and investigate how sediments can affect the plate interface and control subduction dynamics. In the first part of results, we describe end-member models of margin styles (accretionary or tectonic erosion) and the corresponding reference model results. In the second part, we analyse results from all numerical models and investigate parameter correlations using the diagnostics presented above.

#### 3.1 Margin styles and reference models

The outcome of each simulation is classified into three regimes: tectonic erosion (TE), low-angle accretionary wedge (low-AW), high-angle accretionary wedge (high-AW) (Figure 2, Table 1). The end-member division was done both qualitatively (i.e., formation of the accretionary wedge as seen in Figure 2, left column) and quantitatively using the evolution of diagnostics parameters (transient versus steady state) which is shown in Figure 3. We explain the individual classification below. Details of each model evolution are included in the Supplementary material, as they have been extensively investigated and described in previous studies (i.e., adjustment of the model to initial conditions and development of slab curvature, formation of accretionary wedge, interaction of slab with the lower mantle).

We focus here on characterizing overall model outcomes from incipient subduction to slab consumption. The time taken for subduction to consume the slab varies for each model because the velocity field (i.e., subduction velocity, convergence rate)
**Figure 1.** Model setup. a) The model consists of an oceanic plate (SP) subducting beneath an oceanic upper plate (UP). Both plates are 2500 km long and have an upper mantle lithosphere component with a 20 km strong core. Additionally, the subducting plate contains a weak crust and sediments (combined 15 km, weak crust - dark green, and sediments - light green lithologies in panel b). The parameter values are listed in Table 1 and are relative to the reference density ($\rho_0 = 3300$ kg/m$^3$) and viscosity ($\eta_0 = 2.8 \times 10^{20}$ Pa.s) of the mantle asthenosphere. The red markers (Marker1 and Marker2) are located in the strong cores of the subducting and upper plate to track the convergence of the plates. The domain has free-slip boundary conditions on all sides, and a 60 km "sticky-air" layer on top of the plates. Subduction is initiated by prescribing an initial slab depth of 200 km, and an initial radius of curvature of 150 km. The dynamics is entirely controlled by the negative buoyancy (slab-pull) of the subducting slab (i.e., main driving force is slab pull). b) Zoom area on the subduction interface and illustrating the convergence rate ($u_0$), trench rate ($u_T$), and the radius of curvature ($R_C$). c) Phase markers used to calculate the radius of curvature (core markers - black), and wedge properties such as angle and width (sediment markers - grey).

Table 1. Simulations performed in this study. Margin type: TE - tectonic erosion, low-AW - low-angle accretionary margin, high-AW - high-angle accretionary margin, u-AW - unstable accretionary margin. Reference viscosity is \( \eta_0 \) = 2.8 \times 10^5 \text{Pas} (upper mantle viscosity). Diagnostics (mean values): \( \theta_w \) - wedge angle, \( \psi \) - wedge depth, \( h_{\text{max}} \) - maximum topographic amplitude in the upper plate, \( \rho_w \) - mean topographic amplitude in the upper plate.
of the system is controlled by interface processes, in turn controlled by material parameters (see dependence of end time and average time step of a simulations on convergence rate in Supplementary material, Figure S7). In consequence, time step size is not anymore an independent variable of the model. For this reason and for uniformity, we plot instead generic timesteps, we use a characteristic time ($t_{\text{char}} = t/t_{\text{final}}$) to highlight the entire model evolution in several figures (i.e., Fig. 3). Initial model time corresponds to $t_{\text{char}} = 0$, while final time $t_{\text{final}}$, corresponding to $\sim 2500$ km slab consumption, becomes $t_{\text{char}} = 1$. Every model simulation has an initial adjustment period of 5-10 generic timesteps ($t_{\text{char}} \sim 0.1$) in which the subduction system acquires a natural curvature, and a final stage $t_{\text{char}} \sim 0.9$ in which the slab is consumed (grey intervals in Figure 3). These two initial and final condition stages are excluded in our further analysis or calculation of diagnostics parameters, since they are a result of initial and final conditions. Details of typical subduction processes in numerical models are not included in this study, as they have been extensively investigated and described in previous studies (i.e., adjustment of the model to initial conditions and development of slab curvature, interaction of slab with the lower mantle).

For the rest of this study, we also adopt a color code for the regimes each regime: purple for tectonic erosion, yellow for low-angle accretionary wedge, and orange for high-angle accretionary wedge. Each reference case is described separately below.

**Tectonic erosion margin (TE).** A Figure 2a shows a typical simulation outcome that resulted in a tectonic erosion margin shown in Figure 2a (model SubdSed03, with thin cover $h_{\text{sed}} = 5$ km and high viscosity of sediments). In all tectonic erosion models, the sediment wedge parameters and subduction parameters remain relatively constant throughout the model evolution (i.e., $h_{\text{sed}} = h_0$). Evolution of diagnostics parameters is shown in Figure 3, and additional model evolution snapshots are shown in Supplementary material, Figure S3.

We classified simulations as tectonic erosion when the evolution of the radius of curvature, convergence rate, wedge angle and width, and trench rate are in steady-state (Figure 2a and Figure 3) (constant) throughout the simulation (purple lines,

*Table 2.* Input and diagnostics parameters. Input parameters represent parameters that are prescribed at the beginning of each simulation and stay the same throughout the evolution, while diagnostics are parameters that are the result of the dynamics of the system, and are calculated during model evolution. Input parameters: $\rho$ - density, $\eta$ - viscosity, $h$ - thickness, and subscripts represent: SP - subducting plate, sed - sediments, UP - upper plate. Diagnostics: $u_0$ - convergence velocity between subducting plate and upper plate (horizontal motion between Marker 1 and Marker 3 in Figure 1), $u_T$ - trench motion, $R_C$ - radius of curvature, $\alpha_{\text{wedge}}$ - angle of accretionary wedge, $W_{\text{wedge}}$ - width of accretionary wedge, $h_{\text{trench}}$ - trench depth, $h_{\max}$ - maximum topography in the upper plate, $h_{\text{mean}}$ - mean topography in the upper plate.
Figure 3 and Supplementary material Figures S13-S15). The radius of curvature remains small as seen in Figure 2a, with a steeply-dipping slab means (dotted purple lines) follow closely the evolution diagnostics.

The low convergence velocity and trench retreat rate maintained throughout the simulation (Figure 3b) suggests, e) suggest a high degree of coupling between the subducting slab and upper plate. This is also observed in the velocity field, where Figure 2a-B shows that the motion between subducting and upper plate in tectonic erosion margin is accommodated in the middle of the sediment layer is an integrated part of, a region of high strain-rates. Instead, very low strain-rates just below the slab suggest a rigid-body rotation of the slab in order to maintain a constant radius of curvature. The radius of curvature remains small as seen in Figure 2a-C, with a steeply-dipping slab.

Entrainment of sediments within upper plate material at the interface (Figure 2a-A) is indicative of some erosion of the subducting slab and is eroding the upper plate. All simulations with high viscosity sediments show this behaviour (Supplementary material, Figures S13-S15, cases with \( \eta_{\text{sed}} = \eta_0 \)), which could be regarded as having a stronger interface (i.e., a more mafic cover and/or lack of weak unconsolidated sediments).

We classified simulations as tectonic erosion cases when the evolution of the radius of curvature, convergence rate, wedge angle and width, and trench rate are in steady-state (constant) throughout the simulation (Figure 3 and Supplementary material Figures S13-S15). The algorithm for calculating wedge parameters provides non-zero angles and widths in all simulations, and that is because of geometrical constraints, however, in case of tectonic erosion they remain small and constant, and no further wedge growth is registered over time (as compared to accretionary wedge margins described below). Topographic signals (Topographic signals in tectonic erosion (trench depth, maximum and minimum topography in the upper plate) show more variability in Figure 3, which will be discussed later.

Accretionary Wedge margin (AW). When the viscous coupling is reduced, sediments are scrapped off the subducting slab to form an accretionary wedge (Figure 2b-c). We identify two types of accretionary margins: low and high angle low- and high-angle accretionary wedges, primarily controlled by the thickness of sediments for low viscosity of sediments, in cases of low-viscosity sediments. Evolution of diagnostics parameters is shown in Figure 3 (yellow and orange lines), and additional model evolution snapshots are shown in Supplementary material, Figures S4-S5.

The distinction between the two cases comes from the behaviour of the slab: low-angle accretionary margins have increasing radii of curvature, wedge properties, but fairly constant convergence rate (Figure 3b), while high-angle accretionary margins result in flat slab subduction with large radii of curvature and irregular behavior of the convergence rate. In high-angle accretionary margin simulations, in a first stage of evolution, sediments accumulation lubricate the interface and promote fast convergence rates, but once the wedge reaches a critical size and slab curvature is too large (i.e., subduction needs to accommodate horizontal slab motion), subduction rate is inhibited. When this stage is reached, plate convergence may happen at slower rates than in tectonic erosion simulations.

Accretionary margins models are favoured by higher sediment thickness and lower viscosities lower viscosities \( \eta_{\text{sed}} = 0.01 \times \eta_0 \). By increasing the thickness of the sediments, more sediment is available to create a thicker wedge (high angle and width). The larger the wedge angle, the larger the radius of curvature, suggesting that wedge geometry has a control on slab bending (Figure 3a-d).
The interface dynamics is also different with increasing availability of weak sediments. The motion between subducting and upper plate in tectonic erosion margin is accommodated in the middle of the sediment layer, while in accretionary wedge margins, the motion is accommodated at the base of the sediment wedge. The velocity field at the subduction interface suggests internal counter-clockwise flow inside accretionary wedges, detached from both corner flows in the mantle (Figure 2b-e). Plate motion is also accommodated at the base of the sediment wedge, indicated by high strain-rates. Despite the unrealistically large geometry of the wedge, Figure 2c-B shows that the accretionary wedge can impede motion within the upper plate. However, we are not concerned here with further details of internal wedge dynamics compared to numerous previous studies because we also lack the numerical resolution required (i.e., Ruh (2017); Menant et al. (2020)).

A third margin style is also observed, which is highly unstable accretionary wedge and of a highly- unstable accretionary wedge is shown in the Supplementary material (e.g., results of SubdSed04_100 in Figures S6, S13-S15). In these cases, the accretionary wedge quickly reaches a maximum size and critical angle, and instead of moving laterally, the wedge, material is being expelled down the subduction channel. Afterwards, the wedge will continue to deform and grow again until it reaches a new critical angle. This unstable mode occurs in simulations with thick upper plate thickness, which acts as a deformable backstop, in combination with accumulating weak and thick sediments. This margin style is a consequence of the density model chosen here, in which sediments have the same density as the rest of the lithosphere.

Clearly, this is an overestimated effect.

3.2 Major Impacts on Subduction Dynamics

Although material within the weak layer of the plate interface (i.e., between the subducting and upper plates) is a volumetrically insignificant component of the larger plate-mantle coupled system, we observe this small feature can exert a profound influence on the emergent regional-scale subduction dynamics. Figures S10 and S11 show models with the strongest sediment layers (\( \eta_{sed} = \eta_b \)) have sub-vertical slab morphologies, smaller values of \( R_C \), and slower trench retreat rates than similar models with weaker sediment layers (\( \eta_{sed} = 0.01 \times \eta_b \)). Stronger sediment layers also stabilize the subduction system as seen in Figure S12, in which much larger variations in \( R_C \) occur for models in column A than column C, where values remain approximately constant. The steady-state values of \( R_C \) can vary by more than a factor of two due to the viscosity of the sediments, with model SubdSed06_50 having 400 km while models SubdSed04_50 and SubdSed05_50 both evolve such that \( R_C \) exceeds 800 km. For these models, a similar increase of more than a factor of 2 can also be observed in convergence rate (Figure S14) and trench motion (Figure S15).

It is not just the low strength of the sediment layer that influences the system, but also the thickness of the upper plate. The dynamics of the plate interface depend on the total length of contact area between the two plates as well as the thickness and strength of the material between them Beall et al. (2021). Comparisons of models that are otherwise identical except for having different upper plate thicknesses (Figure S11, columns a-A and b-A) exhibit more shallow-angled and variable slab morphologies for those models with thinner upper plates.
We calculate the mean value (Figure 3, dotted lines) and the variability during evolution (minimum and maximum values). The initial (time to form natural curvature) and final (consumption of slab) conditions in Figure 3 are excluded from our calculations of the mean value. The means in TE models remain close to the evolution curves, which are in steady state (i.e., less variability, and the mean is steady-state with the mean close to the min/max values). In AW models, the means differ significantly from

Figure 2. Margin style end-member results. a) Tectonic erosion margin (TE, reference model SubdSed03), b) Low-angle accretionary margin (AW, reference model SubdSed01), c) High-angle accretionary margin (AW, reference model SubdSed04). The A. Left column on the left shows model snapshots at 27 Ma. B. Middle column shows second invariant of strain rate, $\hat{\varepsilon}^{II} = (\hat{\varepsilon}_{ij}\hat{\varepsilon}_{ij})^{1/2}$ and velocity field as arrows in an enlarged area of the subduction interface, and C. The Right column on the right shows the core and sediment markers, together with calculated radii of curvature, wedge angles and widths. Tectonic erosion margin shows low-angle wedges and small radius of curvature. When an accretionary wedge forms, in cases of lower sediment viscosity, the wedge angle and width increases over time, together with the radius of curvature. The motion between subducting and upper plate in tectonic erosion margin is accommodated in the middle of the sediment layer, while in accretionary wedge margins, the motion is accommodated at the base of the sediment wedge. In high angle accretionary margins (c), episodes of flat slab may occur, and strongly influence plate bending. Time evolution of diagnostic parameters for the reference cases are shown in Figure 3.

3.3 Parameter analysis

We summarize all simulation results by analyzing correlations between the means of the diagnostic parameters for all simulations (Figures 4 and 5). They the diagnostics parameters can then be compared to similar parameters observed in the global subduction system (see Discussion).
Figure 3. Evolution of diagnostic parameters for end-member reference models: Tectonic erosion - SubdSed03 (purple), low-angle accretionary margin - SubdSed01 (yellow), high-angle accretionary margin - SubdSed04 (orange). a) Radius of curvature, b) convergence rate, c) wedge angle, d) wedge width, e) trench rate, with positive values indicating trench advance and negative values indicating trench retreat, f) trench depth, g) Maximum topographic amplitude in the upper plate (hmax), h) Mean topographic amplitude in the upper plate (hmean). Continuous lines represent model data, while dotted lines represent the mean over entire simulation time. Time axis is generic for all simulations because the model Characteristic time \( t_{\text{char}} \) is dependent on defined in the velocity scale of the system (Fig. main text, S7). Grey portions represent initial and final conditions, corresponding to the system forming its natural slab curvature, and to the last stage of slab consumption. The two stages are excluded from calculating the means.
the evolution curves, so. Therefore, the min/max values during time evolution highlight reflect this larger variability (grey bars in Fig. 4 and 5). Diagnostic means are given in Table 1 and evolution curves are shown in Supplementary material (Figures S13-S18).

Figure 4 shows correlations between subduction and sediment diagnostic parameters for all simulations, while Figure 5 shows correlations between sediment and topography diagnostic parameters. In both figures, each colored point represents the mean value in that a simulation, and the grey bars represent variability intervals (min/max values). The colorscale represents the margin type, identified as in the previous section. TE simulations (purple) immediately have smaller variability bars, also emphasizing steady-state. On the other hand, AW models have larger variability bars (largest for high-angle AW) suggesting transient evolution for that diagnostic.

We find clear strong correlations between sediment parameters and subduction parameters in 2-D numerical models (Figure 4). Convergence rate correlates well with radius of curvature, wedge angle and width (panels a-c). TE models have low convergence rates, radii of curvature, but also small accretionary wedge properties (angle and width). As seen in previous section, with increasing sediment availability (thickness) and/or decreasing sediment viscosity, wedges are more readily to form form more readily. Figure 4 shows that AW models register higher convergence rate, higher radii of curvature and larger wedge properties. The results here show that sediments lubricate the subduction interface, promoting faster convergence rates. The rate of trench motion is also influenced by the dynamics of subducting sediments, with sediment-rich AW trenches retreating faster (panel d).

Figure 5 suggests weaker correlations between sediment and topography parameters. In panels 5b-5j, we observe a tendency of tectonic erosion models b-j. TE models tend to produce higher maximum topography and deeper trench depths (i.e., extreme amplitudes), while accretionary wedge AW models produce lower extreme signals, but higher mean values, suggesting that sediments also help transmit and disperse stresses in the upper plate more efficiently. The weaker correlation of sediments diagnostics with topographic signals could be due to a lesser influence of the sediments on topography, but also it could be due to the is likely due to the nature of the upper plate (i.e., oceanic/continental, free/attached plate to side walls). In our set of simulations with ocean-ocean subduction and unattached upper plate, stresses accumulated at the plate interface are accommodated in trench motion, instead of upper plate deformation. Topographic signals for simulations with a fixed upper plate are shown in Figure S9, which are higher and more distinct for end-member models, as any convergence motion is subduction is now accommodated more in deformation of the upper plate, and less in trench motion. Topography also builds faster in continental lithosphere compared to oceanic lithosphere (due to less resistance against gravity) (Pusok and Kaus, 2015). This could be the case in our models, where we only consider ocean-ocean subduction in this set of experiments. (Pusok and Kaus, 2015).

Investigation of the effect of sediments on topography signals in with a continental upper plate is reserved for a future study.

Thus, to summarize, tectonic erosion models suggest a stronger coupling at the plate interface, yielding lower radii of curvature, slower convergence rates and higher topographic signatures. TE margins also retreat slower compared to AW margins. These correlations and simulation snapshots suggest that geometry dynamics of the wedge controls the bending of the slab and the radius of the curvature.
Figure 4. Subduction versus sediment diagnostic parameters. Each point represents the evolution mean of the given parameter in a simulation, and the grey bars represent the variability intervals (see Figure 3 on how the mean is calculated). Initial and final stages of the evolution are removed from calculations. Tectonic erosion models (purple) have lower variability in diagnostics than accretionary wedge models (yellow/orange). a) Radius of curvature and convergence velocity. Small radii of curvature are correlated with small convergence velocities. b-c) Small wedge properties (angle and width) are also correlated with low convergence rates and radii of curvature. We observe clear correlations between margin types and diagnostics. Tectonic erosion margins have low convergence velocities, small radii of curvature, and wedge properties. This is indicative of a stronger coupling between subducting and upper plates. Accretionary wedge models have higher radii of curvature, faster convergence velocities and larger wedge properties. This is indicative of decoupled dynamics between subducting and upper plates, modulated by the deformation and growth of the accretionary wedge.
Figure 5. Sediment versus topography diagnostic parameters. Each point represents the evolution mean of the given parameter in a simulation, and the grey bars represent the variability intervals (see Figures 3 and 4). Initial and final stages of the evolution are removed from calculations. There is a weaker correlation between sediment parameters and topography/upper plate parameters. Tectonic erosion models still yield smaller trench depths and mean topography, and higher maximum topography in the upper plate. These indicate a higher degree of coupling at the subduction interface in tectonic erosion models. The weaker correlations are due to the nature of the upper plate, which is considered oceanic and unattached to the right boundary, so any topographic signal is smaller than it would be for continental upper plate lithosphere. Topographic signals for simulations with fixed upper plate are shown in Figure S9, which are higher and more distinct for end-member models, as any convergence motion is accommodated more in deformation of the upper plate, and less in trench motion.
4 Discussion

Our results show three modes of subduction interface: tectonic erosion margin, low-angle accretionary wedge margin, and high-angle accretionary wedge margin. We find that the properties of the sediment layer modulate the extent of viscous coupling at the interface between the subducting and overriding plates. When the viscous coupling is increased, an erosive style margin will be favored over an accretionary style. On the other hand, when the viscous coupling is reduced, sediments are scraped off the subducting slab to form an accretionary wedge.

We obtain a diverse response in subduction geometry to just a few varied input parameters: sediment viscosity and thickness, and upper plate thickness. The focus of our analysis is solely on the effect of sediments on large-scale subduction dynamics. Other parameters have also been shown to be important (i.e., density of sediments, age of slab, thermal structure, upper plate structure) that will be discussed below.

The viscosity of sediments represents the critical parameter, and thickness as a secondary parameter in our simulations. High-viscosity sediments lead to tectonic erosion margin, while low-viscosity sediments lead to accretionary wedge margins (Table 1). Sediment thickness controls the availability of sediments to be accumulated in accretionary wedges. A detailed analysis of Figures S10-S18 shows that the thickness of the upper plate plays an important role in determining the subduction interface length and the depth at which sediments can be locked into an accretionary wedge.

For the same influx-thickness of sediments, when the upper plate is thinner, the accretionary wedge is also shallower and wider volumetrically smaller, but wider and with high wedge angle, while for a thick upper plate, sediments are distributed across the entire interface into a thinner layer with a small wedge angle, leading to tectonic erosion (i.e., compare results of SubdSed02_50 for 50 km thick upper plate, and SubdSed02_150 for 150 km thick upper plate in Figure S11).

4.1 Parameter correlation and observations

In this section, we discuss the results of our findings in relation to observations of the global subduction system. A common approach to constrain the effect of different parameters that control subduction dynamics has been done considering the statistical analysis of present-day subduction zones (Supplementary material, Figure S2) (Clift and Vannucchi, 2004; Lallemand et al., 2005; Wu et al., 2008; De Franco et al., 2008; Heuret et al., 2012). Our diagnostic parameter analysis in Section 3.3 attempts to create a bridge between these studies and numerical models, as diagnostics from numerical models are often not comparable with those from statistical analyses. However, there remain a number of fundamental differences between our results and these studies. Present-day subduction parameter correlation represent only current snapshots and do not always account for the evolution stage of a given subduction system. Our analysis considers the entire evolution of a subduction system and evolution averages. Moreover, natural subduction zones are far from ideal, have variable sediment influxes, changing boundary conditions and other changes to the system are the norm multi-phase physics. On the other hand, the numerical model setup is ideal and simplified, which is further discussed below.

Despite these differences, we succeed in obtaining subduction margins that accrete sediments, and ones that are erosive. Our results agree with findings in Clift and Vannucchi (2004). Accretionary margins form in simulations with thicker and
weaker sediment covers entering the trench, while tectonic erosion margins form in simulations with less sediment cover (high viscosity sediments are representative of a stronger crust and mantle component at the slab surface). Replotted data from Wu et al. (2008) and using the margin classification from Clift and Vannucchi (2004) (Supplementary material, Figure S2), shows that accretionary margins also tend to have larger radii of curvature, which is consistent with our numerical results. Since many studies do not separate data into margin type, and the statistical data in Clift and Vannucchi (2004) and Wu et al. (2008) have different subduction segment resolution, the margin classification is not be highly accurate in Figure S2. A recent study obtained similar correlations between margin style and convergence rate and radii of curvature (Brizzi et al., 2021).

Our findings using slab curvature are consistent with observations on slab dip. Diversity of subduction zones is generally investigated through the perspective of slab orientation (i.e., Beall et al. (2021); Riel et al. (2018)). Many analogue and numerical studies used slab dip as the preferred diagnostic for slab orientation instead of slab curvature (i.e., Heuret et al. (2007), Section 2.2). They suggest that slab dip (plate bending) and the upper plate deformation depend both depends on properties of the subducting plates (velocity, thickness, buoyancy, strength), mantle properties or slab/mantle interactions (stratification, regional mantle flow, slab anchoring), overriding plate properties (nature, velocity, strength, thickness), or plate, mantle, overriding plate, and the coupling between the subducting and overriding plate (e.g., Bellahsen et al. (2005); Heuret et al. (2007); Billen and Hirth (2007); Schellart et al. (2007); Funiciello et al. (2008); Babeyko and Sobolev (2008); Duarte et al. (2013); Riel et al. (2018)). Our findings using slab curvature are consistent with these observations on slab dip. We find that coupling at the plate interface due to sediment influxes can strongly influence convergence rate and bending of the slab (radius of curvature).

TE models have small $R_C$ (large dip), while AW models have large $R_C$ (small dip). The nature of upper plate (oceanic or continental), however, will further influence these correlations by changing the load on subduction interface, which should be investigated further. We consider the radius of curvature is a better metric for slab orientation in subduction dynamics studies, as slab dip represents only the tangent to curvature close to the surface (Petersen et al., 2017).

Topographic signals have been incorporated less in both statistical and numerical studies of subduction zones, despite the fact that topography is a direct and easily acquirable observable (i.e., Pusok and Kaus (2015); Riel et al. (2018)). In our free higher resolution models, Menant et al. (2020) found that deep accretion processes influence forearc topography over time, but did not compare the effect in both accretionary and erosion margins. In our ocean-ocean subduction, we see a lesser control of sediments on topographic diagnostics, with tectonic erosion margin margins yielding deeper trenches. However, the influence effect increases when the upper plate is attached to the right wall (Supplementary material, Fig. S9). This is because the subduction interface stresses are transferred in the upper plate (i.e., topography build-up) rather than accommodated in trench motion retreat.

### 4.2 Convergence rate and margin type

Results from numerical models suggest strong correlations between margin type and convergence rate (Figure 4). Convergence rates in AW models are faster than in tectonic erosion models, as sediments help lubricate the interface and reduce coupling between subducting and upper plate. A special case could be the high-angle AW model results (Figure 3b), where the convergence rate is faster in the growing-stage of the accretionary wedge, but once it reaches a critical value, the convergence
rate becomes slower than in the case of tectonic erosion. Behr and Becker (2018) use energy balance calculations to also and Brizzi et al. (2021) obtain similar predictions, in which weaker (lower viscosity) sediments promote faster convergence rates. However, observations suggest an inverse correlation between convergence rate and margin type (see Supplementary material, Figure S2), with tectonic erosion margins subducting faster than accretionary wedge margins. Most likely, this inverse correlation between convergence rate and margin type shown in data (Figure S2) suggests that we do not capture all complex processes happening at the subduction interface (von Huene et al., 2004).

The plate interface has to be intrinsically weak to accommodate mantle convection during millions of years, but also strong enough to build up stress that is released during recurring mega-earthquakes at the human time scale (Agard et al., 2018). However, the dominant mechanisms governing accretionary and tectonic erosion margins are different. The style of deformation within accretionary wedges is thin-skinned, that is, associated thrusts and folds are uncoupled from the underlying oceanic crust by a basal decollement with a large amount of displacement (Weiss et al., 2018). The dynamics of accretionary wedges can become more complex if one considers multiple types of sediments, fluid pressure and deformation mechanisms (Ruh, 2017). Accretionary wedges are generally modelled separate of subduction dynamics, while subduction dynamics models include a thin interface (Sandiford and Moresi, 2019).

In accretionary margins, ocean sediments are available to lubricate the interface, while little sediments enter tectonic erosion margins. However, in tectonic erosion margins, the subducting plate may erode the basement of the upper plate, and create further debris along the plate interface (von Huene et al., 2004). In any given system, both processes may be occurring simultaneously, either in time and space or at the same time in different parts of the subduction zone (Clarke et al., 2018; Comte et al., 2019; Ducea and Chapman, 2018; Straub et al., 2020). We do not account for these detailed processes in our numerical models.

Moreover, it is unclear whether sediment influxes affect convergence rate, or convergence rate affects sediment accumulation at trench, or both. Accretion is generally favored by slow convergence (<7.6 cm/yr) (Clift and Vannucchi, 2004; Syracuse et al., 2010) while fast convergence favors larger volumes of sediment to be dragged down at the interface, thus lubricating the interface.

We tested this hypothesis requires different experimental setups: one in which convergence rate evolves dynamically due to sediments input, and second, in which the convergence rate is prescribed and sediments deform accordingly. Here, we tested the first scenario, where the convergence rate is the dynamic response of the system due to incoming sediments at the trench. We briefly tested the second scenario in Supplementary material, Figures S8-S9, with changing boundary conditions (i.e., free subduction versus kinematic boundary conditions). Imposed convergence with a fixed upper plate reduces the amount of trench retreat, and the variation of diagnostic parameters is smaller among end-member cases, but the correlations remain valid. Menant et al. (2020) investigated the dynamics of accretionary margins as a function of convergence rate to find that more sediment and crustal material is subducted at higher convergence rates.
4.3 Sediment fluxes to trench and to depth

Sediment fluxes to depths below the lithosphere influence the amount of volatiles recycled into the mantle (Plank and Langmuir, 1998; van Keken et al., 2011; Plank and Manning, 2019). The type of margin may also affect how much sediment gets subducted into the mantle. It has been proposed that tectonic erosion margins can subduct higher percentages of sediment influx, however, large volumes of continental crust are subducted at both erosive and accretionary margins (von Huene and Scholl, 1991a; Clift and Vannucchi, 2004). Clift and Vannucchi (2004) calculated that accretion is a relatively inefficient process for cleaning sediment off the oceanic basement and that 70% of the sediment column is likely subducted to great depths below the forearc.

Here, we calculate the volume fraction of sediments accreted and subducted in the mantle below the lithosphere in our reference models (Figure 6). We find that tectonic erosion margin subducts higher percentage of influx sediments than accretionary margins. The total percentage of sediments subducted right before the slab was consumed in tectonic erosion margin was 60%, while in accretionary margins the percentage remains at ~10%. However, considering that tectonic erosion margins have a smaller sediment cover (and influx), accretionary margins may in total subduct a larger volume of sediments. For example, both 50% of a 1 km column of influx sediments and 10% of a 5 km column of influx sediments give 500 m column of subducted sediments. We conclude that both tectonic erosion margins and accretionary wedges can subduct a high volume of sediments, but at different rates relative to influx material.

This is, however, a simplistic view of sediment subduction to depth. As sediments are transported to subduction zones, the possible destinations of trench-accumulated sediments are: approach the trench, they can be accreted in the trench, subducted into the mantle, accreted structurally to the bottom of the upper plate after initial downward transport, and returned to the upper plate either via magmatism with partial melting of the downgoing sediment or some other form of diapirism or partially-molten upward transport (Gerya and Yuen, 2003; Currie et al., 2007; Tian et al., 2019). To model all these processes requires future development of multi-physics models that is beyond the scope of this study.

In this study, we considered a steady-state (constant) sediment flux to the trench. However, sediment subduction is neither a steady-state nor a globally averaged process (Plank and Manning, 2019) and can have major implications for subduction dynamics. Modern oceanic sediments cover 70% of the planet’s surface, but sediment distribution and lithology occur in drastically different proportions globally (Dutkiewicz et al., 2015, 2018). Moreover, the oceanic lithosphere is covered by various sediment types depending on the depth, proximity to continental margins, and interactions with the oceanic currents and biosphere. For example, an abundant carbonate cover is subducted at the Central American margin, while little sedimentary carbonate is subducted along the Tonga, Central Aleutian and Kuriles–Kamchatka trenches (Plank and Langmuir, 1998; Plank and Manning, 2019). The global sedimentary cover also varies in both space and geological time, with greatest volume in the geologically recent and decreasing exponentially with increasing age (Peters and Husson, 2017).

We expect the abundance and lithology of sediments at trenches to influence the mode of occurrence of margin styles in space and geologic time. The abundance and lithology of sediments at trenches will influence the density and viscosity at the interface. The subduction interface structure and properties (i.e., lithology, geometry, thickness, rheology, and how these change with depth) are sensitive to the composition of the material that is being subducted (Behr and Becker, 2018). Our
Figure 6. Total Evolution of total volume fraction of sediments accumulated in accretionary wedge and subducted to depth in the mantle for the three reference cases: a) Tectonic erosion (SubdSed03), b) low-angle Accretionary wedge (SubdSed01), c) high-angle Accretionary wedge (SubdSed04).
results cover broadly the end-member scenarios. The degree to which variability in these influxes impacts long-term subduction dynamics remains debated (Cloos and Shreve, 1988; Duarte et al., 2015; Behr and Becker, 2018) and should be studied with further numerical modelling.

Global compilations of sediment thickness also show that sediment thickness goes from 0-12 km (e.g., Laske et al. (2013); Dutkiewicz et al. while mean thickness in the oceans is 920m, in the deep ocean 400m, and on continental margins 3km (Straume et al., 2019). Our model setup tested sediment thicknesses between 5-10km.

4.4 Model limitations

In order to be able to address the points above, a number of model improvements are needed. The models shown here provide an initial experiment on the viscosity of sediments, where we considered constant sediment fluxes at the trench. Future work should explore the effect of other material parameters (i.e., density, lithology of sediments, as in Currie et al. (2007)), and active surface processes such as erosion and sedimentation (for potential delivery of continental sediments to the trench). Thinner. The effect of sediments is overestimated in some of our model outcomes, especially in models with unrealistically large wedges. Thinner and lighter sediment covers require higher resolutions at the trench, which could also help connect results with those from high-resolution accretionary wedge models (Menant et al., 2020).

Despite our simplified model, mechanical coupling between plates should not just be investigated only in variations in subduction velocity or dynamics, as most of previous numerical efforts focused, but also in the type of margin: accretionary or erosion. The definition of subduction interface in numerical models could also be relaxed. A recent methodological analysis (Sandiford and Moresi, 2019) investigated the emergence of significant spatial and temporal thickness variations within the interface zone, with the sole focus of maintaining a constant thickness through time. Instead, Beall et al. (2021); Riel et al. (2018) also investigated variations in interface thickness as potential controlling factor of dynamics. All these studies, in fact, highlight the tendency for the subduction interface to develop spontaneous thickness variation as the models evolve. The interface widens near the trench, building a prism-like complex, and thins at depths beyond the brittle–ductile transition. This pattern was also noted in the boundary element models of Gerardi et al. (2019), who attributed a down-dip thickness variation to lubrication layer dynamics. However, natural observations suggest that variable subduction fluxes enter the subduction trench, questioning this approach of constant thickness interface layer.

5 Conclusions

Systematic 2-D numerical simulations of ocean-ocean subduction are run to investigate how sediment fluxes influence subduction dynamics and plate coupling. The aim is to understand what causes convergent margins to either accrete material delivered by the subducting plate or, alternatively, to subduct the trench sediment pile and even erode the basement of the overriding plate. We obtain end-member cases that are governed primarily by sediment viscosity and thickness: accretionary and tectonic erosion margins. We find that the properties of the sediment layer modulate the extent of viscous coupling at the interface between the subducting and upper plate. When the viscous coupling is increased, an
erosive style of margin is favoured. On the other hand, when the viscous coupling is reduced, sediments are scrapped off the subducting slab to form an accretionary wedge. The geometry of the wedge controls the bending of the slab and the radius of the curvature. We perform an automated analysis of diagnostic parameters to differentiate between the two end-member modes of margin type and to better understand fundamental differences between them. Strong correlations between sediment, subduction diagnostics and margin type are observed. Tectonic erosion margins have smaller radii of curvature, wedge parameters and slower convergence rate, while accretionary margins are dominated by larger sediment wedges that can strongly influence subduction dynamics.

However, a more detailed study on the effect of sediments is needed, especially on buoyancy of sediments. The margin type, accretionary or tectonic erosion, is intimately linked to earthquakes. The amount of sediments filling the trench was proposed to facilitate seismic rupture (Heuret et al., 2012; van Rijssingen et al., 2018; Brizzi et al., 2020). Subduction zones with large amounts of trench sediments positively correlate with the occurrence of great interplate earthquakes.

**Code and data availability.** The Bitbucket version of the numerical code (LaMEM) used can be found here: https://bitbucket.org/bkaus/lamem/branch/cvi_test, and the repository containing the input parameters files to reproduce the data can be found here: https://adina@bitbucket.org/adina/rep-msubdsed.git. The full simulation data (> 100Gb) presented in this study can be provided on request from AP.

**Author contributions.** AP and DS designed the study, AP built the numerical model and performed the analysis, MK helped run and analyze part of the simulations during REU internship. AP wrote first draft of manuscript, all authors contributed equally to the revision of this manuscript.

**Competing interests.** The authors have no competing interests.

**Acknowledgements.** A.E.P. is grateful for postdoctoral research funding from the the Cecil H. and Ida M. Green Foundation, UCSD. In addition, all authors are grateful for support from the National Science Foundation Grant No. EAR-1255040. The numerical simulations were performed on Comet (San Diego Supercomputing Center) within the Extreme Science and Engineering Discovery Environment (XSEDE), which is supported by National Science Foundation grant number ACI-1053575. We thank two anonymous reviewers for their instructive comments that helped improve the manuscript.
