Abstract. Thermochronology data is key for quantifying the exhumation history and dynamics of mountain belts. Here we present a new analytical solution for the steady-state exhumation of an orogenic wedge that undergoes transport along a basal detachment, uniform internal deformation, basal and frontal accretion. The solution predicts an increase in exhumation towards the interior of the wedge, with the rate of increase dependent on the degree of internal deformation. Application of the solution to a cross section in the Himalayas shows that in spite of its simplicity the solution provides a good fit to thermochronology data, with a coefficient of determination (R^2) of 0.75. This implies that, although the solution does not capture the effects of individual faults and folds, at a large scale deformation can be described by uniform compression and transport. The results also imply that this part of the Himalayas may be in steady-state. The equations presented here can be used to quantify exhumation, deformation and shortening rates in mature orogens that are in steady-state.

10 1 Introduction

Thermochronology has increased our knowledge of the thermal and exhumation history of mountain belts (Reiners and Brandon, 2006). Numerical models that include faulting, erosion and heat flow enable the use of thermochronology data to quantify deformation (ter Voorde et al., 2004; Lock and Willett, 2008; Braun et al., 2012). Such models have for example been used to quantify the geometry and slip rates of major faults (Herman et al., 2010; Robert et al., 2011). The combination of numerical models and deformation histories derived from balanced cross-sections has enabled more detailed reconstructions of deformation history (Erdös et al., 2014; McQuarrie and Ehlers, 2015). However, one drawback of using numerical models for the interpretation of thermochronometers in orogens is that they require significant resources in terms of computational cost, geological data and research time. Furthermore these approaches rely on the knowledge of the location of faults, which may not be complete and depends on the quality of geological mapping and exposure. In addition, the models often assume that the fault blocks in between behave as rigid blocks, and may not include internal deformation of faults blocks by small-scale faults and folds inside these blocks.

Analytical solutions could offer an alternative as they require few computational resources and provide insight into the relation between input parameters and results without having to resort to computationally expensive sensitivity analyses. However, to our knowledge no analytical solutions exist for the relation between deformation and exhumation of mountain belts. Interestingly, the problem of quantifying exhumation is somewhat analogous to the quantification of groundwater age, which deals with groundwater moving downward after infiltration instead of rock particles moving up to the surface. Analytical solutions for groundwater age have been published (Vogel, 1967), which suggests that the description of exhumation may be mathematically tractable.

Here we aim to develop a new closed-form analytical solution for the exhumation of an orogenic wedge that is in steady-state. The solution aims to include the main deformation mechanisms of orogenic wedges, internal deformation of the wedge, transport along a basal detachment, basal accretion and frontal accretion. In contrast to most numerical approaches we aim to represent a relatively simple system in which the orogenic wedge undergoes pervasive internal deformation, and we do not resolve individual faults. We evaluate how well this solution can represent thermal and deformation history by applying the equation to a well-studied cross-section in the Himalayas (Long et al., 2012; Coutand et al., 2014; McQuarrie and Ehlers, 2015), and by using the calculated exhumation histories to calculate thermochronometer ages and compare these to published data.

2 Conceptual model

Previous research has shown that at a first order the cross-sectional geometry of the brittle part of many orogens (i.e. until the basal detachment becomes aseismic, typically at 300 °C) can be approximated by a critical wedge (Buiter, 2012). After some amount of convergence the orogenic wedge reaches a steady-state that is formulated by the critical wedge theory (Davis et al., 1983; Chapple, 1978; Dahlen et al., 1984), whereby the topography of the wedge is a function of balance between the compressional force, the friction along a basal detachment and the gravitational force. Steady-state is maintained by the incorporation of new material by frontal (Platt, 1986), and basal accretion (Van Gool and Cawood, 1994), and the loss of material by erosion at the land surface. In addition the rocks in the wedge itself deform as a result of compressional forces.

Here we derive a model that describes the motion of rock particles inside an orogenic wedge that is in steady-state, i.e., the geometry of the wedge is fixed and the flow of material into the wedge is balanced by erosion. The model covers three mechanisms for the deformation of an orogenic wedge: 1) Transport of the wedge along a basal detachment, 2) internal deformation of the wedge and 3) frontal and basal accretion. These three processes are shown schematically in Figure 1. The geometry of the wedge and the parameters that are used in this manuscript are shown in Figure 2. The symbols in the figure are defined in Table 1.

Here we briefly summarize the way these processes are represented in the analytical solution that we derive below. The motion of material inside the wedge is described using the tip of the wedge as a fixed reference point.

1. Transport of the wedge along a basal detachment results in a uniform motion of the material in the wedge upward and towards the tip of the wedge, with velocity vectors parallel to the wedge. Because the shape of the wedge is kept constant,

- 55 transport along the detachment means that material is added on the right hand side of the wedge, and removed at the
same rate at the top of the wedge. The material added at the right hand side and removed from the top of the wedge due
to detachment transport are shown by blue and yellow areas respectively in Fig. 2a.
2. The internal deformation of the wedge is modelled as a uniform compression of the material inside the wedge. This is
the most simple way to represent the internal deformation of the wedge that in reality is accommodated by faulting and
60 folding inside the wedge. The equations are based on the assumption that each rock particle in the wedge is compressed
horizontally by exactly the same amount. This causes an expansion by the same amount for each particle. Note that
we assume here that there is no volume loss. These assumptions lead to a total amount of expansion in the wedge that
increases linearly from 0 at the tip of the wedge to a maximum at the right hand-side of the wedge. The linear correlation
between wedge thickness and exhumation is the result of more rocks being available to compress in a thicker wedge. The
65 shape of the wedge remains constant, and therefore the deformation caused by compression is compensated by adding
material on the right hand side of the wedge and by eroding an equal amount of material from the top of the wedge (Fig.
2b).
3. Frontal and basal accretion add material to the front and the base of the wedge, as shown in Fig 2c and Fig. 2d, respec-
tively. Given that we use the fixed geometry of the wedge as a reference frame, this causes a movement of rock particles
70 inside the wedge to the right and upward. Note that by itself frontal accretion as described in our simple conceptual
model will generate an unrealistic addition of material to the wedge above the land surface (Fig. 2c). Therefore frontal
accretion should only be used in combination with rates of detachment transport, compression or basal accretion that are
sufficient to balance out the material added with erosion at the land surface.

Figure 1. Conceptual model of an orogenic wedge showing the material transport and deformation mechanisms that act on the wedge.

3 Development of the analytical solution

- 75 We first develop solutions for the velocity of rock particles in the wedge (section 3.1), and subsequently use these equations to
develop expressions for the trajectories of rock particles (section 3.2). We initially develop separate solutions for the transport
of the wedge and basal and frontal accretions, and a solution for the velocity field due to compression of the wedge. The latter

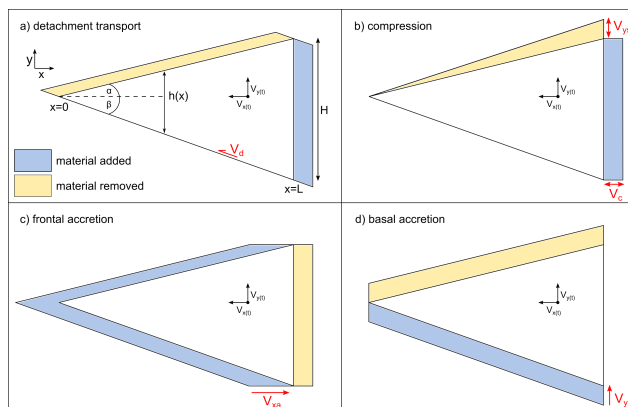

Figure 2. Conceptual model of an orogenic wedge as used in this study. The four panels show the four processes represented in the analytical solution, detachment transport (panel a), internal deformation represented by uniform compression (panel b), frontal (panel c) and basal accretion (panel d). The symbols listed in Table 1.

Table 1. Symbols and units

symbol	unit	description
L	m	width of the wedge
α	$m\ m^{-1}$	the slope of the land surface
β	$m\ m^{-1}$	the slope of the bottom of the wedge
H	m	maximum height of the wedge
$h(x)$	m	height of the wedge at any coordinate x
b	m	elevation of the bottom of the wedge above a reference point
$v_{x,a}$	$m\ s^{-1}$	horizontal velocity of particles due to basal and frontal accretion
$v_{y,a}$	$m\ s^{-1}$	vertical velocity of particles due to basal and frontal accretion
v_d	$m\ s^{-1}$	horizontal transport velocity of the wedge along a basal detachment
v_c	$m\ s^{-1}$	horizontal compression velocity of the wedge
$v_{y,s}$	$m\ s^{-1}$	vertical particle velocity at the top of the wedge
v_x	$m\ s^{-1}$	horizontal particle velocity in the wedge
v_y	$m\ s^{-1}$	vertical particle velocity in the wedge

is mathematically the most challenging process to represent. Subsequently we combine the solutions to first derive a simplified and finally a full analytical solution for particle trajectories inside an orogenic wedge resulting from compression, transport
 80 along a detachment and accretion, which is given by equations 10 and 12. The full derivation of the solutions is provided in appendix A for the equations of particle velocity and appendix B for the equations for particle trajectories. The solutions are

Table 2. Model parameters for the examples shown in sections 3 and 4

parameter	value, parameter set 1	value, parameter set 2
L	200 km	200 km
α	0.05 m m^{-1}	0.05 m m^{-1}
β	-0.15 m m^{-1}	-0.15 m m^{-1}
v_{xa}	0 m a^{-1}	$1 \times 10^{-3} \text{ m a}^{-1}$
v_{ya}	0 m a^{-1}	$1 \times 10^{-4} \text{ m a}^{-1}$
v_d	$-2 \times 10^{-3} \text{ m a}^{-1}$	0 m a^{-1}
v_c	$-2 \times 10^{-3} \text{ m a}^{-1}$	$-2 \times 10^{-3} \text{ m a}^{-1}$

demonstrated for two example cases, which represent a wedge undergoing compression and transport along a basal detachment and a wedge undergoing compression and basal and frontal accretion. The parameters for these example cases are shown in Table 2. The solution is also applied to a case study in the Himalayas, which is discussed in section 5.

85 3.1 Rock particle velocity

The combined horizontal and vertical particle velocity due to transport along a detachment and accretion is denoted as v_{xt} and v_{yt} , respectively:

$$v_{xt} = v_d + v_{xa} \quad (1)$$

$$v_{yt} = \beta v_x + v_{ya} \quad (2)$$

90 The horizontal and vertical components of the rock particle velocity due to compression are given by:

$$v_x = \frac{x}{L} v_c \quad (3)$$

and

$$v_{yc} = v_n (\epsilon y + \zeta x) \quad (4)$$

where ϵ and ζ are defined as:

$$95 \quad \epsilon = \left(-2 - \frac{\beta}{\alpha - \beta}\right) \quad (5)$$

$$\zeta = (2\beta + \frac{\alpha\beta}{\alpha - \beta}) \quad (6)$$

and v_n denotes normalized compression velocity, which is defined as:

$$v_n = \frac{v_c}{L} \quad (7)$$

The total velocity of rock particles can be found by combining the velocity due to transport (eqs. 1 and 2) and the velocity
100 due to compression (eqs. 3 and 4). For the horizontal component of velocity this yields:

$$v_x = v_{xc} + v_{xt} = v_n x + v_{xt} \quad (8)$$

And for the vertical component of velocity this yields:

$$v_y = v_n (\epsilon y + \zeta x) + v_{yt} \quad (9)$$

The combined velocity fields are shown in figure 3 and Fig. 4 for an example orogenic wedge. The parameters are shown in
105 Table 2. The first case shows a wedge undergoing compression and transport along a detachment, which results in an overall
rock particle motion towards the tip of the wedge and upward. Fig. 4 shows the velocity in a wedge undergoing compression
and accretion, which results in an overall particle motion towards the interior of the wedge and upward.

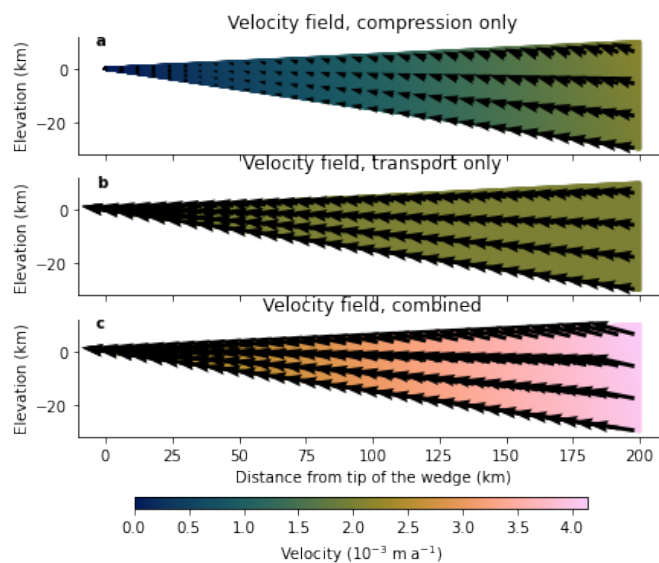

Figure 3. Particle velocity inside a wedge undergoing internal deformation and transport along a basal detachment, using parameter set 1 in Table 2. Panel a shows the velocity field resulting from compression of the wedge, panel b shows the velocity field resulting from transport of particles inside the wedge and panel c shows the velocity field due to both compression and transport.

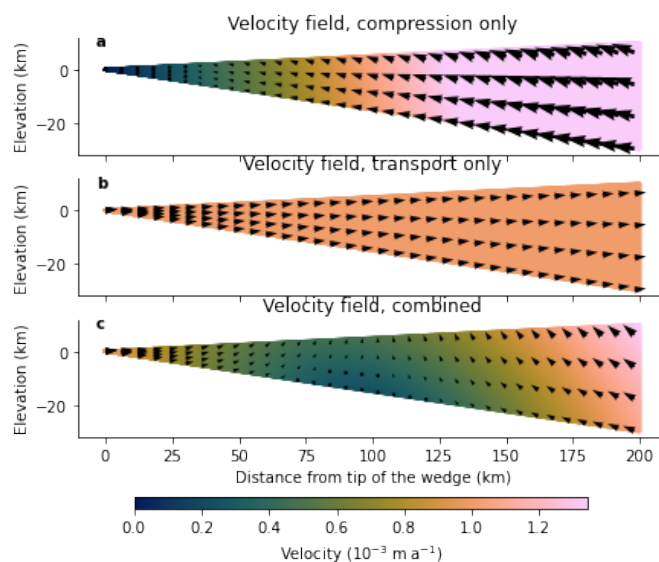

Figure 4. Particle velocity inside a wedge undergoing internal deformation and basal and frontal accretion, using parameter set 2 in Table 2. Panel a shows the velocity field resulting from compression of the wedge, panel b shows the velocity field resulting from transport of particles inside the wedge and panel c shows the velocity field due to both compression and transport.

3.2 Particle trajectories

The equation for the horizontal position of particles over time follows from integration of the velocity equations as:

$$110 \quad x = \left(x_0 + \frac{v_{xt}}{v_n} \right) e^{v_n t} - \frac{v_{xt}}{v_n} \quad (10)$$

Where x_0 is the horizontal position of the rock particle at $t = 0$.

The first solution for the vertical position is a simplified solution, where we take the depth below the surface for compression and for transport and add these two to get an expression for depth over time. This results in the following approximate solution for the depth of rock particles (d) over time:

$$115 \quad d = -v_{yt}t + (\alpha - \beta)x_0 (e^{v_n t} - e^{\epsilon v_n t}) \quad (11)$$

Combining the expression for x (eq. 10) and the vertical velocity (eq. 9) and integration of the equation yields the full solution of the vertical particle position in the wedge:

$$y = \left(\alpha x_0 + \beta \left(x_0 + \frac{v_{xt}}{v_n} \right) \left(e^{v_n(1-\epsilon)t} - 1 \right) - \frac{v_{yt} - \zeta v_{xt}}{v_n \epsilon} \left(e^{-v_n \epsilon t} - 1 \right) \right) e^{v_n \epsilon t} \quad (12)$$

This equation describes the vertical position of rock particles in a wedge (y) as a function of time (t), the initial position (x_0),
 120 the slope of the land surface (α) and the basal detachment (β), the normalized compression velocity (v_n), which is a function of the horizontal compression (v_c) and the length of the wedge (L) ($v_n = v_c/L$), the horizontal (v_{xt}) and vertical (v_{yt}) transport velocity, which are a function of basal and frontal accretion velocity and transport velocity along the basal detachment (eqs. 1 and 2) and the geometry parameters ϵ (eq. 5) and ζ (eq. 6), which are functions of α and β .

This equation can be adjusted to yield an expression for the depth of rock particles below the land surface (d), instead of the
 125 vertical position:

$$d = \alpha x_0 - \left(\alpha x_0 + \beta \left(x_0 + \frac{v_{xt}}{v_n} \right) \left(e^{v_n(1-\epsilon)t} - 1 \right) - \frac{v_{yt} - \zeta v_{xt}}{v_n \epsilon} \left(e^{-v_n \epsilon t} - 1 \right) \right) e^{v_n \epsilon t} \quad (13)$$

4 Validation of analytical solutions

The simplified analytical solution for rock particle trajectories (eqs. 10 and 11) and the full solution (eq. 10 and 12) were
 130 verified using numerical particle tracking using the velocity fields described by the equations for particle velocity (eqs. 8 and 9). A number of particles were placed at the surface at $t = 0$. The velocity of these particles were calculated using these equations. In turn the velocities were used to calculate new particle positions at $t - \Delta t$ where Δt is a time increment and the procedure was repeated. This procedure provides a history of depth versus time for each particle that can be used to verify the

analytical solutions for particle depth over time, i.e. to explore whether the solution is consistent with the velocity fields that were derived in section 3.1.

135 The comparison between the numerical model and the simplified and full analytical solutions shows that the full solution matches the numerical results perfectly for example cases dominated by transport along a basal detachment (Figs. 5) and basal and frontal accretion (Fig. 6). The maximum difference of the full solution and the numerical results is 0.12 %. The simplified solution deviates from the numerical and the full solution for both cases. The maximum difference with the full solution is 30 %.

140 The error increases with depth (Fig. 5d, 6d). This means that the simplified solution may still be useful to predict particle trajectories for the more shallow and low-temperature domains of the wedge. However, this is not the case for samples that are close to the tip of the wedge for models with significant basal and frontal accretion (Fig. 6d), where the deviation from the full solution is relatively large.

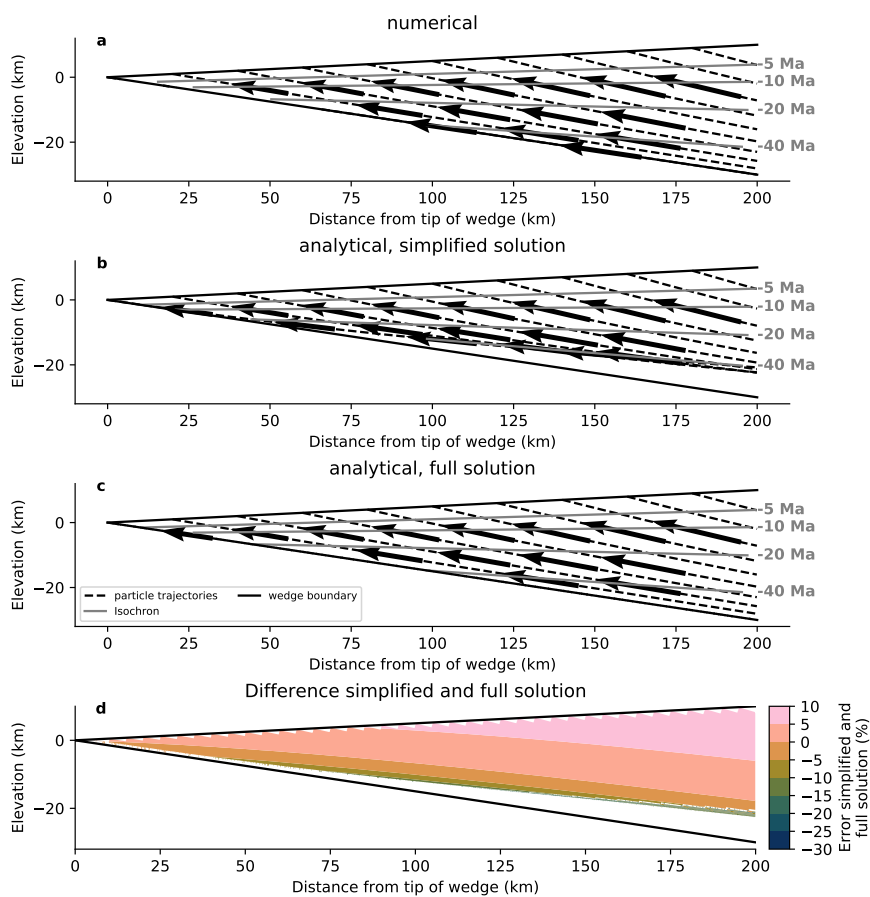

Figure 5. Comparison of analytical and numerical solutions for particle trajectories in a wedge undergoing internal deformation and transport along a basal detachment. Panel a shows the numerical solution for particle trajectories, panel b shows the simplified analytical solution (eq. 10 and 11), panel c shows the full solution (eq. 10 and 12), and panel d shows the difference between the simplified and full solution. The particle trajectories were calculated using parameter set 1 in Table 2.

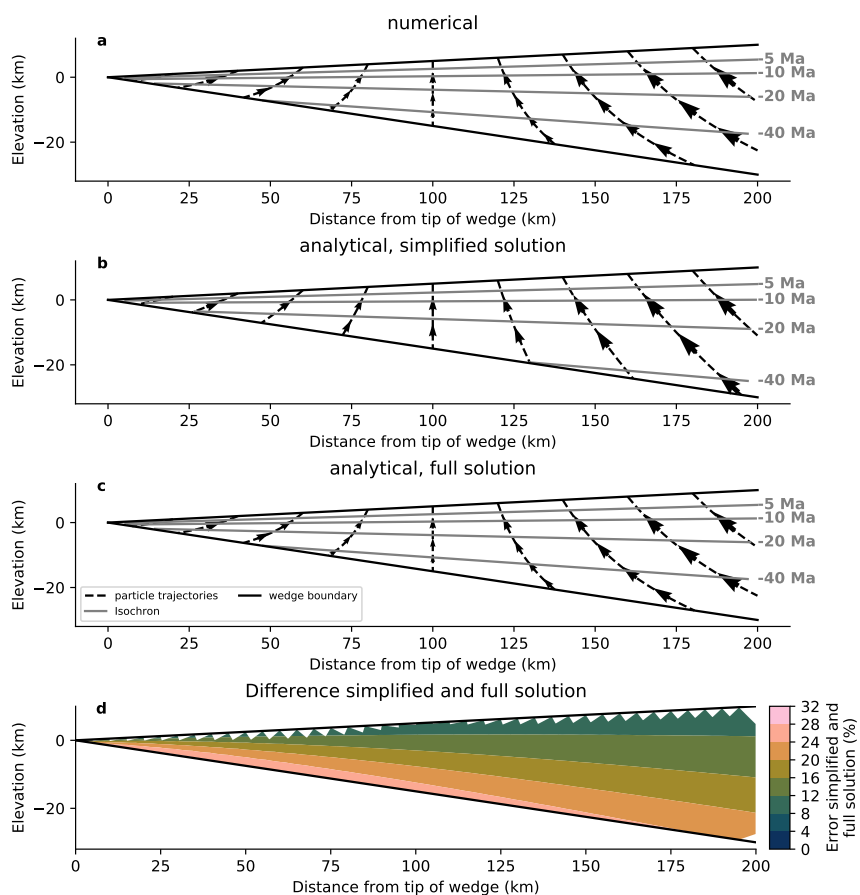

Figure 6. Comparison of analytical and numerical solutions for particle trajectories in a wedge undergoing internal deformation and basal and frontal accretion. Panel a shows the numerical solution for particle trajectories, panel b shows the simplified analytical solution (eq. 10 and 11), panel c shows the full solution (eq. 10 and 12), and panel d shows the difference between the simplified and full solution. The particle trajectories were calculated using parameter set 2 in Table 2.

5 Application to the exhumation of a mountain belt

5.1 Introduction

145 We used equations 10 and 12 to calculate particle trajectories for a case study based on a published cross-section in the
Himalayas, the Kuru-Chu cross-section (Long et al., 2012; Coutand et al., 2014; McQuarrie and Ehlers, 2015). The cross-
section is located in Bhutan in the central Himalayas and runs perpendicular to the strike of the Himalayas and the main faults.
The cross-section and the wedge geometry that was adopted based on this cross-section are shown in Fig. 7. The cross-section
was chosen because of the abundance of thermochronology data that covers both low-temperature (apatite fission track) and
150 high temperature (muscovite Ar-Ar) thermochronology. In addition, the high convergence rate in the Himalayas makes it likely
that exhumation is governed by the processes that are represented in the equations that we derived. Comparison of long-term
(i.e. million year), intermediate (100-10 kyr) and short term (yrs) erosion rate estimates indicates that the study area is in
steady state (Ganti et al., 2016). This implies that other processes such as glacial erosion and isostatic compensation that are
not captured by the equations are likely to be relatively minor. Note that the goal here is not to provide a detailed geological
155 case study, but to demonstrate the use of the equation to calculate deformation and exhumation rates.

5.2 Wedge geometry

The tip of the wedge was based on the location of the southernmost thrust fault in this part of the Himalayas, the main frontal
thrust. The geometry of the wedge is based on published geological cross-sections (Long et al., 2012; Coutand et al., 2014;
McQuarrie and Ehlers, 2015), with a surface slope (α) of 0.034 m m⁻¹, an average slope of the basal detachment (β) of -0.17
160 m m⁻¹ and a total length of 200 km.

5.3 Thermochronology data and cooling ages

There is a large set of thermochronometer data available for the cross-section, including 17 apatite fission track samples (Grujic
et al., 2006; Long et al., 2012; Coutand et al., 2014), 23 zircon (U-Th)/He samples (Long et al., 2012; Adams et al., 2013) and
8 muscovite Ar-Ar samples (Long et al., 2012).

165 Particle trajectories were converted to thermal history using a uniform geothermal gradient of 15 C km⁻¹, which is based
on a gradient of 10 to 20 C km⁻¹ reported by Coutand et al. (2014). Surface temperature was calculated using a surface
temperature at sea level of 24 °C and a atmospheric lapse rate of 7 °C km⁻¹ (Coutand et al., 2014). Cooling ages were
calculated using the thermal history and assumed resetting temperatures of 110 °C, 180 °C and 325 °C for the apatite fission
track, for zircon (U-Th)/He and muscovite Ar-Ar thermochronometers, respectively (McQuarrie and Ehlers, 2018). Note that
170 we aim for a simple model setup and do not include more complex calculation based either on a more formal definition of
cooling ages (Dodson, 1973; Fox et al., 2014) or fission track annealing models or diffusion models of He or Ar, which we
reserve for follow up work. Ages for samples that originated in the foreland of the wedge and that did not reach resetting
temperatures in the wedge were calculated using an assumed exhumation rate of 1×10^{-4} m a⁻¹. This was done to give these

175 samples arbitrary high ages that approximate the typically higher ages found in foreland basins of orogenic wedges. Note that we did not calculate ages for samples that originated in the hinterland of the wedge, because it is difficult to make assumptions about their thermal history and initial age prior to entering the wedge.

5.4 Model calibration and parameter space exploration

180 The optimal values of the model parameters v_c , v_d , v_{xa} , v_{ya} were found using the downhill simplex algorithm (Nelder and Mead, 1965), as implemented in the Python module *scipy* (Virtanen et al., 2020), to minimize the mean absolute error (MAE) of the calculated thermochronometer ages.

185 In addition to model calibration we also ran a set of models with different parameter combinations to explore the sensitivity of the model fit to the parameter values. For the parameters v_c and v_d the values were varied from the calibrated value $-4 \times 10^{-3} \text{ m a}^{-1}$ to $+4 \times 10^{-3} \text{ m a}^{-1}$ with steps of $1 \times 10^{-3} \text{ m a}^{-1}$. For parameter v_{xa} we tested the calibrated value plus $1 \times 10^{-3} \text{ m a}^{-1}$ and $2 \times 10^{-3} \text{ m a}^{-1}$, respectively, and for v_{ya} we evaluated the calibrated value plus $1 \times 10^{-4} \text{ m a}^{-1}$ and $2 \times 10^{-4} \text{ m a}^{-1}$, respectively.

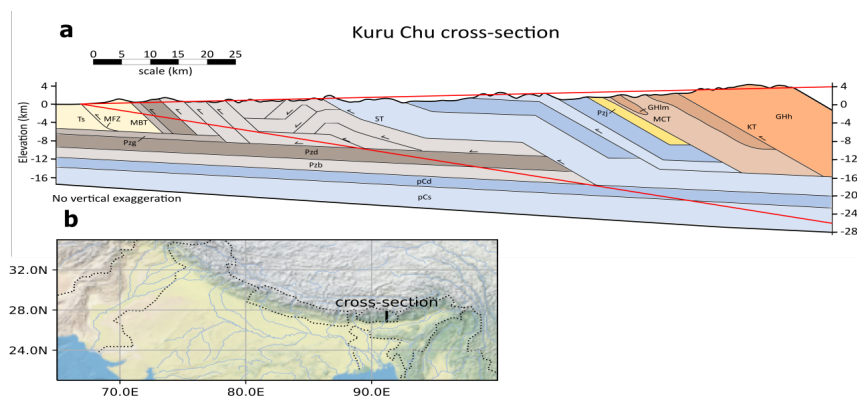

Figure 7. Geological cross-section in Bhutan that was used as a case study and the geometry of the wedge as used for the calculation of particle trajectories and exhumation (panel a) and location of the cross-section (panel b). The cross-section was modified from Long et al. (2012). MFT denotes the main frontal thrust, MBT the main boundary thrust, MCT denotes the main central thrust and KT the Kakhtang thrust. The tectonostratigraphic units are denoted as follows: GHh: Greater Himalaya GHm: Greater Himalaya metasedimentary unit, Pzj: Jaishinda formation, pCs: Shumar formation, pCd: Daling formation, Pzb: Baxa group, Pzd: Diuri Formation, Pzg: Gondwana succession, Ts: Siwalik Group.

5.5 Results

The the best-fit parameter values show a relatively good fit of the calculated thermochronometer ages to the measured ages in the cross-section (Fig. 8a), with a coefficient of determination of 0.75. The calibrated parameters values indicate that transport

190 along the basal detachment and internal deformation are equally important mechanisms driving exhumation of the wedge, with a calibrated value of the transport (v_d) and compression velocity (v_c) of $5.0 \times 10^{-3} \text{ m a}^{-1}$ and $4.8 \times 10^{-3} \text{ m a}^{-1}$, respectively (Table 3). Frontal and basal accretion play an insignificant role in this cross-section, with a best-fit value of $1.7 \times 10^{-6} \text{ m a}^{-1}$ for the horizontal component (v_{xa}) of the accretion vector, and a value of 0.0 for the vertical component (v_{ya}).

The exploration of parameter space show a relatively small area with a good fit (Fig. 9). A reduction in detachment transport velocity can to some extent be taken up by an increase in compression velocity and vice versa. However, both processes results
195 in fundamentally different exhumation and cooling age curves, with a straight line for models dominated by transport over a detachment only (Fig. 10a, b), and a curved line for models that include compression (Fig. 10c, d). This means that the degree of curvature of cooling ages along a cross-section and the rate of decrease in ages towards the interior of the wedge can be used to quantify the rate of internal deformation of orogenic wedges.

Note that Coutand et al. (2014) report that the geothermal gradient varies systematically in their model experiments from 10
200 C km^{-1} at the tip of the wedge to 20 C km^{-1} in the hinterland. This is caused by high advection rates in the hinterland and the cooling effects of the subducting footwall plate in the foreland. Our results do not include a spatially varying geothermal gradient, and could therefore have underestimated geothermal gradients and overestimated thermochronometer ages for the samples furthest away from the wedge. With such a spatially variable geothermal gradient our model would have required less internal deformation to reproduce the decrease in thermochronometer ages towards the interior of the wedge. However, the
205 magnitude of this effect is difficult to constrain given the lack of subsurface temperature or heat flow data in this part of the Himalayas.

5.6 Comparison with published numerical models

Comparison of our results with published thermochronometer model ages by McQuarrie and Ehlers (2015) shows a better fit of the analytical solution to the data (Fig. 11). Note that some of the misfit of the McQuarrie and Ehlers (2015) data may be
210 due to errors introduced by digitizing the model results from their publication. Nonetheless the comparison shows that the new analytical solution fits as well or better than a more sophisticated numerical model that included the activity of individual thrust faults based on balanced cross-sections. This suggests that, for this cross-section, deformation of the wedge can be better represented by uniform deformation.

The sum of the best-fit values of internal deformation and transport along the detachment results in a total shortening rate
215 of 10 mm a^{-1} . This is comparable to previous findings. Inverse numerical models by Coutand et al. (2014) found the best fit an overall convergence rate of 22 mm a^{-1} . Roughly half the convergence rate is accommodated by underthrusting, and the convergence taken up by the wedge itself was found to be 10 to 11 mm a^{-1} , which is equal to our estimate. McQuarrie and Ehlers (2015) found slightly lower total convergence rate of 18 mm a^{-1} . However, the rate of over and underthrusting were not reported separately. Coutand et al. (2014) and McQuarrie and Ehlers (2015) also included models with variable convergence
220 rates over time. However, in Coutand et al. (2014) the reported misfit for models with variable convergence rates was similar to models with steady convergence rates. McQuarrie and Ehlers (2015) reported a highly variable convergence rate through time. However, the extent to which these inferred changes in convergence rate improved the model fit statistics was not reported.

In contrast, the good fit of the thermochronometer ages predicted by the steady-state deformation and exhumation equation (Fig. 8) suggests that instead this part of the Himalayas may be in steady-state. This is corroborated by the finding that erosion rates determined on shorter averaging timescales reproduce thermochronological data within error, as expected for steady state landscapes (Ganti et al., 2016). The distributed nature of internal shortening of the wedge is supported by the deep exhumation of Himalayas southern slope as demonstrated by erosional remnants of the once continuous MCT thrust sheet overlying rocks of the Lesser Himalaya (Yin, 2006). This supports the idea that, over long timescales, internal shortening is distributed in nature and does not only occur by large offsets on a few major faults.

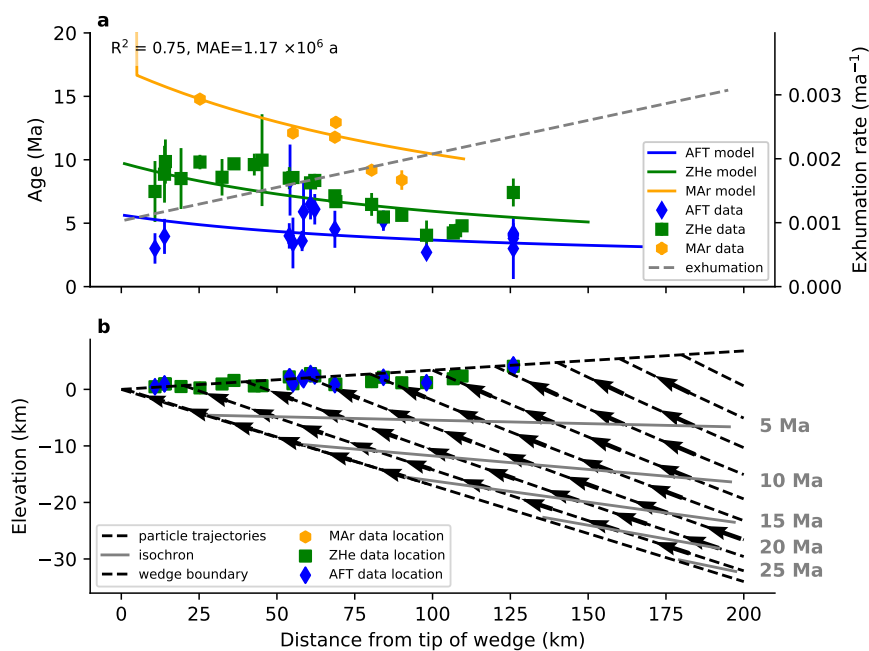

Figure 8. Comparison of calculated thermochronometer ages and published ages for a cross-section in the Himalayas for the best-fit model. Panel a shows calculated and published apatite fission track (AFT), zircon (U-Th)/He (ZHe) and muscovite Ar-Ar ages (MAr), and the exhumation rate at the surface. Panel b shows the particle trajectories that were used to calculate the cooling ages, along with the isochrons. The calibrated parameter values used for this model run are shown in Table 3.

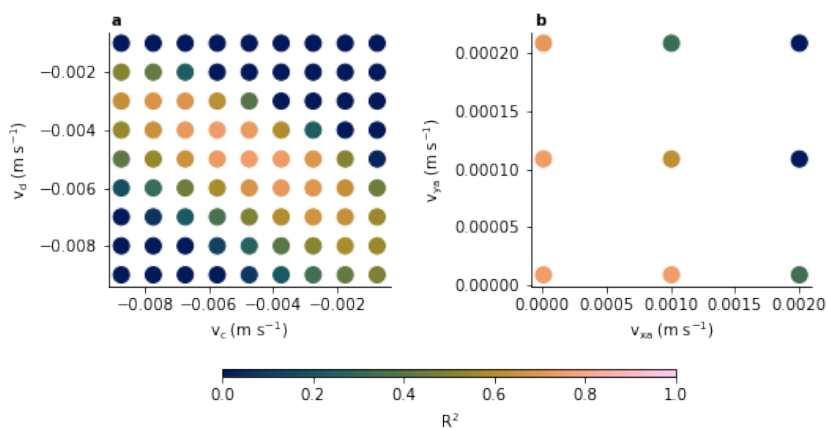

Figure 9. Fit of the calculated thermochronometer ages to the measured ages for a range of values for compression velocity (v_c), detachment transport velocity (v_d), horizontal and vertical accretion velocity (v_{xa} , v_{ya})

Table 3. Calibrated model parameters for the best-fit model shown in Fig. 8 and two additional model experiments shown in Fig 10. The numbers in bold denote calibrated values, non-bold numbers were fixed.

parameter	unit	best-fit	experiment 1	experiment 2
v_{xa}	$m a^{-1}$	1.7×10^{-6}	0	0
v_{ya}	$m a^{-1}$	0	0	0
v_d	$m a^{-1}$	-5.0×10^{-3}	-8.8×10^{-3}	0
v_c	$m a^{-1}$	-4.8×10^{-3}	0	-14.4×10^{-3}

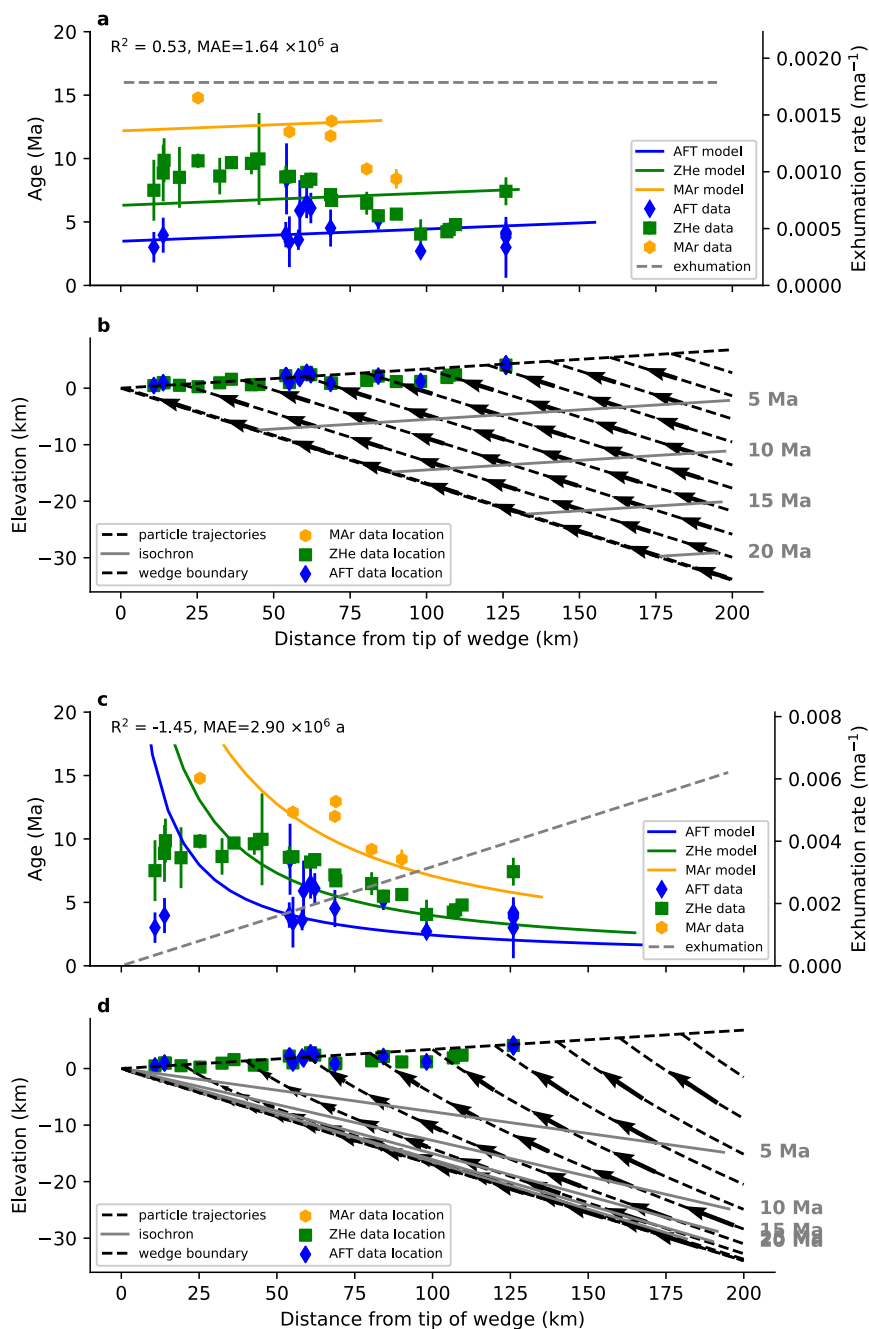

Figure 10. Comparison of calculated thermochronometer ages and published ages for the cross-section in the Himalayas for two model experiments that demonstrate the effect of shortening taken up only by transport along the basal detachment (panels a,b) and shortening taken up only by internal deformation (panels c, d). The parameters for these model runs can be found in Table 3.

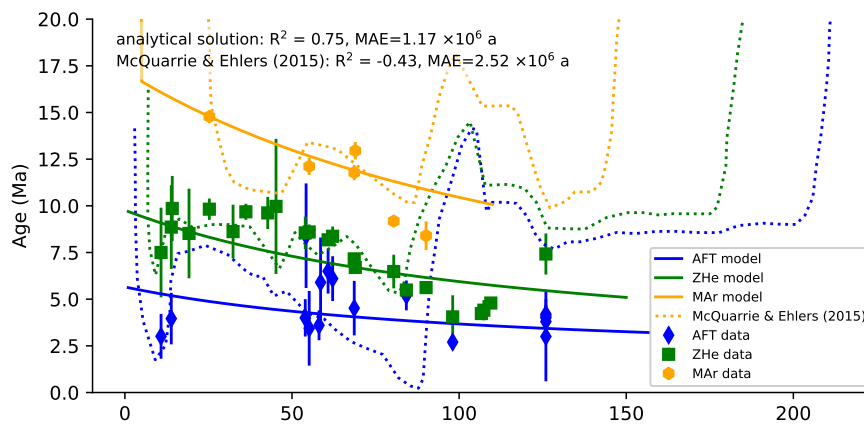

Figure 11. Comparison of published thermochronometer ages, the analytical solution presented in this study (solid lines), and published numerical model results by McQuarrie and Ehlers (2015) (dotted lines).

230 6 Conclusions

We have developed an analytical solution for rock particles trajectories in an orogenic wedge that is in steady-state and that undergoes uniform internal deformation, transport along a basal detachment, frontal accretion and basal accretion. The solution was validated using a numerical solution based on calculated velocity fields and numerical particle tracking. We also derived a simplified solution that provides a good approximation for the upper half of the orogenic wedge, and may therefore be useful to
235 quantify exhumation in the shallow and low-temperature part of orogenic wedges. The solution predicts that exhumation rates follow a curved line along the wedge, with an increase in exhumation rate and a decrease in thermochronometer ages towards the interior of the wedge. The degree of curvature depends on the rate of internal deformation of the wedge. Application of the equation to a published cross-section in the Himalayas show that the equation provides a very good fit to thermochronology data, with a coefficient of determination (R^2) of 0.75. This indicates that the Himalayas may be in steady-state and that, at
240 a large scale, the exhumation of mature mountain belts may be approximated by a relatively simple model of uniform and steady-state deformation, accretion and transport. The equations enable a direct estimate of deformation and shortening rates from thermochronology data in orogens.

Code availability. Jupyter notebooks that reproduce the workflow and the figures presented in this study have been published at Zenodo (Luijendijk, 2021) and are available at GitHub (<https://github.com/ElcoLuijendijk/wedgex>). The code is distributed under the GNU General
245 Public License, version 3. The notebook collection include a notebook that reproduces Fig. 5 and 6 that compare the equation to numerical results (https://github.com/ElcoLuijendijk/wedgex/blob/master/model_validation/wedgex_validation.ipynb) and a notebook that can be used to calibrate parameters and compare the results to thermochronometers (<https://github.com/ElcoLuijendijk/wedgex/blob/master/wedgex.ipynb>), which was used to produce Fig. 8 and 9. Wedgex depends on the Python modules Numpy (Harris et al., 2020), Scipy (Virtanen et al., 2020), Matplotlib (Hunter, 2007), Pandas (McKinney, 2010; Reback et al., 2021), scikit-learn (Pedregosa et al., 2011) and Scientific colour maps
250 (Crameri, 2021).

Appendix A: Derivation of equations for rock particle velocity

A1 Velocity due to wedge transport and accretion

For transport of the wedge along the basal detachment the additional horizontal velocity is constant everywhere and defined as v_d . The vertical transport velocity is the product of the slope of the basal detachment and the horizontal transport velocity:

$$255 \quad v_{yd} = \beta v_d \quad (A1)$$

Exhumation due to basal and lateral accretion is described by a constant term for the horizontal and vertical velocity of rock particles inside the wedge that represents the lateral and upwards movement of rock particles caused by accretion. These are denoted by v_{xa} and v_{ya} , respectively. The combined horizontal and vertical particle velocity due to transport along a detachment and accretion is denoted as v_{xt} and v_{yt} , respectively:

$$260 \quad v_{xt} = v_d + v_{xa} \quad (A2)$$

$$v_{yt} = \beta v_x + v_{ya} \quad (A3)$$

A2 Velocity due to internal deformation

A2.1 Horizontal velocity

The horizontal velocity due to internal deformation is represented by uniform compression that is assumed to increase linearly from 0 at the left-hand side to $v_x = v_c$ at the right hand side. This yields the following expression for velocity:

$$v_x = \frac{x}{L} v_c \quad (A4)$$

A2.2 Vertical velocity at the top of the wedge

For compression without any volume loss the volume balance of the wedge as shown in Figure 2 can be written as:

$$v_c H = \int_0^L v_{ys} L \quad (A5)$$

270 The velocity at the top of the wedge is assumed to increase linearly from $v_{ys} = 0$ at the left hand side to $v_{ys} = v_{ym}$ at the right hand side ($x = L$):

$$v_{ys} = \frac{x}{L} v_{ym} \quad (A6)$$

The area that the wedge extends at the top should be equal to the area that is compressed at the right hand side:

$$\frac{1}{2}Lv_{ym} = -Hv_c \quad (\text{A7})$$

275 which can be combined with the previous eq. to form:

$$\frac{L}{x}v_{ys} = -2\frac{H}{L}v_c \quad (\text{A8})$$

which can be reorganized as to write yield an expression of the particle velocity at the top of the wedge as a function of x , the height of the wedge (H), the length of the wedge (L) and the compression velocity (v_c):

$$v_{ys} = -2\frac{H}{L^2}xv_c \quad (\text{A9})$$

280 A2.3 Vertical velocity inside the wedge

We assume that the vertical velocity due to wedge compression (v_{yc}) at any point (x,y) increases linearly from v_b at the bottom of the wedge ($y=b$) to v_{ys} at the top of the wedge:

$$v_{yc} = fv_{yb} + (1-f)v_{ys} \quad (\text{A10})$$

which can be rearranged as:

$$285 \quad v_{ys} = \frac{(v_{yc} - (1-f)v_{yb})}{f} \quad (\text{A11})$$

where f is the relative vertical position of the rock particle in the wedge and is defined as : $f = (y - b)/h$

The equation for v_{ys} that was derived previously is:

$$v_{ys} = -2\frac{H}{L^2}xv_c \quad (\text{A12})$$

combining these two equations yields:

$$290 \quad \frac{(v_{yc} - (1-f)v_{yb})}{f} = -2\frac{H}{L^2}xv_c \quad (\text{A13})$$

which after reorganizing becomes:

$$v_{yc} = -2\frac{H}{L^2}xv_c f + (1-f)v_{yb} \quad (\text{A14})$$

reinserting the original expression for $f = (y - b)/h$ results in:

$$v_{yc} = -2 \frac{H}{L^2} x v_c (y - b)/h + (1 - (y - b)/h) v_{yb} \quad (\text{A15})$$

295 and inserting $b = \beta x$ and $h = (\alpha - \beta)x = \gamma x$ and $v_{yb} = \beta v_{xb} = \beta \frac{x}{L} v_c$ yields:

$$v_{yc} = \frac{-2Hxv_c}{L^2} \frac{y - \beta x}{\gamma x} + \frac{\alpha x - y}{\gamma x} \beta v_c x/L \quad (\text{A16})$$

with $H = (\alpha - \beta)L = \gamma L$:

$$v_y = \frac{-2v_c(y - \beta x)}{L} + \frac{(\alpha x - y)\beta v_c}{\gamma L} \quad (\text{A17})$$

which after rearranging yields an expression of the vertical particle velocity due to compression:

$$300 \quad v_{yc} = \frac{v_c}{L} \left(\left(-2 - \frac{\beta}{\alpha - \beta} \right) y + \left(2\beta + \frac{\alpha\beta}{\alpha - \beta} \right) x \right) \quad (\text{A18})$$

We simplify this equation by introducing two new terms for the geometry of the wedge:

$$\epsilon = \left(-2 - \frac{\beta}{\alpha - \beta} \right) \quad (\text{A19})$$

$$\zeta = \left(2\beta + \frac{\alpha\beta}{\alpha - \beta} \right) \quad (\text{A20})$$

and introducing the normalized compression velocity v_n :

$$305 \quad v_n = \frac{v_c}{L} \quad (\text{A21})$$

Inserting these three new terms into the equation yields:

$$v_{yc} = v_n (\epsilon y + \zeta x) \quad (\text{A22})$$

A3 Velocity due to compression, transport and accretion

The total velocity of rock particles can be found by combining the velocity due to compression (eqs. A4 and A22) and the
 310 velocity due to transport (eqs. A2 and A3). For the horizontal velocity this yields:

$$v_x = v_{xc} + v_{xt} = v_n x + v_{xt} \quad (\text{A23})$$

And for the vertical component of velocity this yields:

$$v_y = v_n(\epsilon y + \zeta x) + v_{yt} \quad (\text{A24})$$

Appendix B: Particle trajectories

315 B1 Trajectories due to compression

B1.1 Horizontal particle position

We integrate the equation for horizontal velocity due to compression of the wedge (eq. A4) to yield an expression for the horizontal particle position over time. The equation for horizontal velocity can be rewritten as:

$$\frac{\partial x}{\partial t} = v_n x \quad (\text{B1})$$

320 Integration of this equation with $x = x_0$ at $t = 0$ yields:

$$x = x_0 e^{v_n t} \quad (\text{B2})$$

B1.2 Vertical position

Taking the equation for vertical velocity due to compression (eq. A22) and replacing $v_{yc} = \frac{\partial y}{\partial t}$ results in:

$$\frac{\partial y}{\partial t} = v_n(\epsilon y + \zeta x) \quad (\text{B3})$$

325 This can be simplified as

$$\frac{\partial y}{\partial t} = C_1 y + C_2 x \quad (\text{B4})$$

where the new constants C_1 and C_2 are defined as:

$$C_1 = v_n \epsilon \quad (\text{B5})$$

and

$$330 \quad C_2 = v_n \zeta \quad (\text{B6})$$

Integration of this equation with boundary condition $y = y_0$ at $t = 0$, yields an expression for y :

$$y = \frac{\zeta v_n}{v_n - \epsilon v_n} x_0 e^{v_n t} + \left(y_0 - \frac{\zeta v_n}{v_n - \epsilon v_n} x_0 \right) e^{\epsilon v_n t} \quad (\text{B7})$$

which simplifies to:

$$y = \frac{\zeta}{1 - \epsilon} x_0 e^{v_n t} + \left(y_0 - \frac{\zeta}{1 - \epsilon} x_0 \right) e^{\epsilon v_n t} \quad (\text{B8})$$

335 The term $\frac{\zeta}{1 - \epsilon}$ equals β , which yields:

$$y = \beta x_0 e^{v_n t} + (y_0 - \beta x_0) e^{\epsilon v_n t} \quad (\text{B9})$$

and taking $y_0 = \alpha x_0$ results in:

$$y = \beta x_0 e^{v_n t} + (\alpha - \beta) x_0 e^{\epsilon v_n t} \quad (\text{B10})$$

B2 Trajectories due to transport, compression and accretion

340 Horizontal position

Using the equation for the horizontal velocity of rock particles (eq. A23) and recasting the velocity term as the derivative of position over time results in:

$$\frac{\partial x}{\partial t} = v_n x + v_{xt} \quad (\text{B11})$$

Integration of this equation yields:

$$345 \quad x = K e^{v_n t} - \frac{v_{xt}}{v_n} \quad (\text{B12})$$

Where K is a constant. Taking $x = x_0$ at $t = 0$ gives a solution for the horizontal particle position over time:

$$x = \left(x_0 + \frac{v_{xt}}{v_n} \right) e^{v_n t} - \frac{v_{xt}}{v_n} \quad (\text{B13})$$

B2.1 Simplified solution for vertical position

The first solution for the vertical position is a simplified solution, where we take the depth below the surface for compression
 350 and for transport and add these two to get an expression for depth over time. For deformation due to compression the vertical
 position of rock particles over time is given by equation B10. If we define depth due to compression as

$$d_c = y_0 - y_c = \alpha x_0 - y_c \quad (\text{B14})$$

we can combine this with eq. B10 to yield:

$$d_c = \alpha x_0 - \beta x_0 e^{v_n t} - (\alpha - \beta) x_0 e^{\epsilon v_n t} \quad (\text{B15})$$

355 which can be rearranged as:

$$d_c = (\alpha - \beta) x_0 (e^{v_n t} - e^{\epsilon v_n t}) \quad (\text{B16})$$

The equation for depth over time due to the transport of rock particles in the wedge follows:

$$\frac{\partial y_t}{\partial t} = v_{yt} \quad (\text{B17})$$

Integration of this equation yields:

$$360 \quad y_d = y_0 + v_{yt} t \quad (\text{B18})$$

rewriting the equation in terms of depth due to transport (d_t) gives:

$$d_t = -v_{yt} t \quad (\text{B19})$$

Combining the depth due to transport and due to compression results in an approximate solution for the depth of rock
 particles (d) over time:

$$365 \quad d = -v_{yt} t + (\alpha - \beta) x_0 (e^{v_n t} - e^{\epsilon v_n t}) \quad (\text{B20})$$

B2.2 Full solution for vertical position

Inserting the expression for x derived earlier (eq. B13) into the solution for the vertical velocity (eq. A24) yields:

$$v_y = C_1 y + C_2 \left(\left(x_0 + \frac{v_{xt}}{v_n} \right) e^{v_n t} - \frac{v_{xt}}{v_n} \right) + v_{yt} \quad (\text{B21})$$

which can be shortened to

$$370 \quad \frac{\partial y}{\partial t} = C_1 y + C_3 e^{v_n t} + C_4 \quad (\text{B22})$$

where

$$C_3 = C_2 \left(x_0 + \frac{v_{xt}}{v_n} \right) \quad (\text{B23})$$

and

$$C_4 = v_{yt} - C_2 \frac{v_{xt}}{v_n} \quad (\text{B24})$$

375 which can be recast as:

$$C_4 = v_{yt} - \zeta v_{xt} \quad (\text{B25})$$

The solution of this integral yields:

$$y = (K + \lambda(t)) e^{C_1 t} \quad (\text{B26})$$

where K is a constant and $\lambda(t)$ is:

$$380 \quad \lambda(t) = \frac{C_3}{v_n - C_1} e^{(v_n - C_1)t} - \frac{C_4}{C_1} e^{-C_1 t} \quad (\text{B27})$$

For the boundary condition $y = y_0$ at $t = 0$ this yields:

$$y = (y_0 - \lambda(t_0) + \lambda(t)) e^{C_1 t} \quad (\text{B28})$$

with

$$\lambda(t_0) = \frac{C_3}{v_n - C_1} - \frac{C_4}{C_1} \quad (\text{B29})$$

385 Reinserting the expressions for the constants C_1 , C_2 , C_3 and C_4 yields the following equation:

$$y = \left(\alpha x_0 + \beta \left(x_0 + \frac{v_{xt}}{v_n} \right) \left(e^{v_n(1-\epsilon)t} - 1 \right) - \frac{v_{yt} - \zeta v_{xt}}{v_n \epsilon} \left(e^{-v_n \epsilon t} - 1 \right) \right) e^{v_n \epsilon t} \quad (\text{B30})$$

Author contributions. EL conceived the idea after JK showed that straight lines often fit thermochronometer age profiles in orogens relatively well. EL and LB derived the equations. EL led the model experiments and the writing. CvH and SL drafted figure 1 and 2. All authors contributed to the discussion of the results and writing the manuscript
