Abstract. In 2018 and 2019, the STIMTEC hydraulic stimulation experiment was conducted at 130 m depth in the Reiche Zeche underground research laboratory in Freiberg/Germany. The experiment was designed to investigate the rock damage resulting from hydraulic stimulation and to link seismic activity and enhancement of hydraulic properties in strongly foliated metamorphic gneiss. We present results from active and passive seismic monitoring prior to and during hydraulic stimulations. We characterise the structural anisotropy and heterogeneity of the reservoir rocks at the STIMTEC site and the induced, high-frequency (>1 kHz) acoustic emission (AE) activity, associated with brittle deformation at the cm to dm-scale. We derived the best velocity model per recording station from over 300 active ultrasonic transmission measurements for high accuracy AE event location. The average P-wave anisotropy is 12%, in agreement with values derived from laboratory tests on core material. We use a 16-station, seismic monitoring network comprising AE sensors, accelerometers, one broadband sensor and one AE-hydrophone. All instrumentation was removable, providing us with the flexibility to use existing boreholes for multiple purposes. This approach also allowed for optimising the (near) real-time passive monitoring system during the experiment. To locate AE events, we tested the effect of different velocity models and inferred their location accuracy. Based on the known active ultrasonic transmission measurement points, we obtained an average relocation error of 0.26 ± 0.06 m using a transverse isotropic velocity model per station. The uncertainty resulting from using a simplified velocity model increased to 0.5–2.6 m, depending on whether anisotropy was considered or not. Structural heterogeneity overprints anisotropy of the host rock and has a significant influence on velocity and attenuation, with up to 4% and up to 50% decrease on velocity and wave amplitude, respectively. Significant variations in seismic responses to stimulation were observed ranging from abundant AE events (several thousand per stimulated interval) to no activity with breakdown pressure values ranging between 6.4 and 15.6 MPa. Low-frequency seismic signals with varying amplitudes were observed for all stimulated intervals that are more correlated with the injection flow rate rather than the pressure curve. We discuss the observations from STIMTEC in context of similar experiments performed in underground research facilities to highlight the effect of small-scale rock, stress and structural heterogeneity and/or anisotropy observed at the decameter scale. The reservoir complexity at this scale supports our conclusion that field-scale experiments benefit from high-sensitivity, wide-bandwidth instrumentation, and flexible monitoring approaches to adapt to unexpected challenges during all stages of the experiment.

37 **1 Introduction**

38 Meso-scale, in-situ hydraulic stimulation experiments performed in well-instrumented underground research
39 laboratories (URL) offer a number of advantages over small-scale laboratory tests and reservoir-scale experiments. In
40 particular, URL experiments capture structural heterogeneity on a realistic length scale and are thus essential to transfer
41 results from laboratory tests on centimetre-scale rock samples to reservoir rocks at the kilometre-scale (Young et al.
42 2000; Gischig et al., 2019). Furthermore, URL experiments allow for validation of inferred results, e.g., through mine-
43 back drilling into stimulated rock volumes (e.g., Warren and Smith, 1985). Most importantly, intermediate-scale, in-
44 situ experiments, conducted in URLs, allow for a close to optimal placement of seismic sensor networks for monitoring
45 and characterisation of the target volume (Ohtsu, 1991; Zang et al. 2017; Amann et al., 2018; Kwiatek et al., 2018; De
46 Barros et al., 2019; Feng et al. 2019). Hydraulic stimulation was seismically monitored during in-situ experiments in
47 various settings (e.g. Ohtsu, 1991; Dahm et al. 1999). The monitoring systems need to be tuned to the seismic waves
48 associated with hydraulic stimulation in terms of sensitivity, frequency range and attenuation characteristics of the
49 rock, which limit the detection ranges of the seismic signals (e.g. Mendecki et al., 1999; Plenkers et al. 2010, 2011;
50 Manthei and Plenkers, 2018). Varying noise conditions on site often impact monitoring conditions (Plenkers et al.,
51 2010, 2013). Recently, monitoring of a hydraulic stimulation experiment at 410 m depth at the Äspö Hard Rock
52 Laboratory (AHRL) in southern Sweden in May/June 2015 (Zang et al., 2017; Kwiatek et al., 2018) showed that only
53 two of the multiple seismic monitoring systems in place were suitable to record the observed seismic processes. The
54 high-sensitivity acoustic emission (AE) network recorded high-frequency (>1 kHz) AE events from fracturing and
55 frictional sliding with rupture dimensions on the centimetre to decimetre scale. A five-station broadband network
56 recorded low-frequency signals of 0.004–0.008 Hz during the frac and refracs. Slow deformation processes have also
57 been monitored with tilt sensors during the "In-situ Stimulation and Circulation Experiment" performed at Grimsel
58 Test Site (GTS) in Switzerland. This experiment was conducted at a depth of 480 m below surface, within an
59 experimental volume of ca. 20 m × 20 m × 20 m of granitic rock between February and May 2017 (Gischig et al.,
60 2018). Dense 3-D coverage and the close proximity of seismic instrumentation to induced AE events both at the AHRL
61 and the GTS sites resulted in high-quality data sets resolving details of the hydro-mechanical processes on the
62 decimetre to metre scale (e.g., Dutler et al., 2019; Kwiatek et al., 2018; Villiger et al., 2020, Niemz et al., 2020). This
63 level of detail is necessary to advance our understanding of processes relevant for hydraulic stimulations such as (1)
64 hydro-mechanically coupled fluid flow and pore pressure propagation, (2) transient pressure-dependent and permanent
65 slip-dependent permeability changes, (3) fracture formation and interaction with pre-existing structures, (4) rock mass
66 deformation around the stimulated volume due to fault slip, failure processes and poroelastic effects, and (5) the
67 transition from aseismic to seismic slip (Amann et al., 2018). AE event distributions can provide detailed information
68 on the small-scale spatio-temporal- evolution of the deformation within the reservoir induced by hydraulic stimulation.
69 In particular, fracture dimensions, orientations, faulting style, and the orientation of the prevailing principal stress axes
70 may be inferred from the analysis of induced seismic events (Manthei et al 2001; van der Baan et al., 2013; Manthei
71 and Plenkers, 2018; Krietsch et al., 2019).

72
73 The STIMTEC experiment was designed to develop diagnostic criteria for successful hydraulic stimulations, and to
74 optimise monitoring and stimulation procedures. This experiment was conducted in strongly foliated and
75 heterogeneous metamorphic rock at shallow depth (~130 m). Complementary to the STIMTEC experiment, several

76 other meso-scale injection experiments in crystalline rock are currently underway. The "EGS Collab Experiment" is a
77 multi-institutional collaborative research project at a similar scale that aims to solve technological problems related to
78 reservoir creation and operation of enhanced geothermal systems (EGS) through different stimulation procedures under
79 realistic in situ stress conditions, and to provide a test bed for the validation of existing thermal-hydrological-
80 mechanical-chemical numerical modelling tools (Kneafsey et al., 2018). The second experimental phase is currently
81 planned at the Sanford Underground Research Facility (SURF) at 1.25 km below surface, located in the Homestake
82 mine, a former gold mine in South Dakota, USA (Kneafsey and the EGS Collab Team, 2020). The Bedretto experiment
83 aims at upscaling previous meso-scale experiments by a factor of ten (Gischig et al., 2019) and is located in the Bedretto
84 Underground Laboratory for Geoenergy research (BULG) in Southern Switzerland, about 10 km southeast of the GTS.
85 Current activities aim at stimulating the Rotondo granite at the Bedretto tunnel with an overburden about 1 km thick
86 in an estimated volume of ca. 300 m × 100 m × 50 m allowing to test different hydraulic stimulation as well as seismic
87 and deformation monitoring techniques.

88
89 Site complexity due to small-scale rock stress and structural heterogeneity and/or anisotropy of varying strength and
90 orientation is a major issue encountered by all meso-scale in situ experiments so far. To trace the spatio-temporal
91 evolution of AE events during hydraulic stimulations at high resolution, the accuracy of the applied seismic velocity
92 model for location in anisotropic and heterogeneous rock volumes is of fundamental importance. At the laboratory
93 scale, anisotropic velocity models are commonly applied (e.g., Stanchits et al., 2003) to monitor rock-deformation at
94 high resolution. At the mine scale, comprehensive and dense in-situ measurements, in particular active seismic surveys,
95 are performed to characterise heterogeneity and anisotropy of the investigated rock volume. These seismic surveys are
96 commonly performed prior to a stimulation to derive the velocity structure and repeatedly in material science and in-
97 situ experiments to monitor alteration of the rock volume e.g. by fracture generation. Repeated active measurements
98 throughout hydraulic stimulation experiment are still scarce. Their value for monitoring temporal changes resulting
99 from fluid pressure changes in the rock volume has only recently been recognized (Doetsch et al., 2018; Rivet et al.,
100 2016; Schopper et al., 2020). At the field scale, detailed site characterisation is often not possible because of associated
101 costs and limited placement of instrumentation (e.g. Zhu et al., 2017), resulting in velocity model ambiguity and lower
102 resolution of the seismic event distribution. Thus, in STIMTEC we performed resolution tests at the meso-scale to
103 place better constraints on model uncertainties and to provide estimates of the effect of simplifications and
104 approximations required at the field scale.

105
106 The seismic response to stimulation during recent URL experiments was highly variable. At the AHRL site seismic
107 response to stimulation likely depended on rock-type with granodiorite and granite stimulations showing seismicity in
108 contrast to diorite-gabbro host rocks. However, this interpretation is complicated by the fact that three different fluid-
109 injection schemes were applied to test their influence on injectivity and induced seismicity (Zang et al., 2013, Niemz
110 et al., 2020). At the GTS site, two shear zones (S1, S3) with different deformation histories in the Grimsel granodiorite
111 were stimulated. Hydrofrac experiments revealed remarkably different seismic responses north and south of the S3
112 shear zone in terms of injection pressure, amount of backflow, injectivity before jacking and final transmissivity (see
113 Fig. 4 and 5 of Dutler et al., 2019). Villiger et al. (2020) observed differences in the seismicity patterns observed during
114 hydroshear stimulation of the two shear zones. During stimulation of the S1 shear zones, the majority of AE events

115 occurred at the beginning of injection, when the total volume of injected fluid was low, whereas for the S3 shear zone
116 the number of AE events increased with the volume of injected fluid (Villiger et al., 2020). Hydroshear stimulations
117 of the ductile S1 shear zone showed less seismicity overall and larger transmissivity increases than S3 hydroshear
118 stimulations. The seismic responses to stimulation during the EGS Collab experiment were also complex (Schoenball
119 et al., 2020, Fu et al., 2021). Abundant seismicity accompanied the three hydraulic stimulations at 1.5 km depth at
120 SURF aiming to establish a connection between injection and production boreholes approximately 10 m apart
121 (Kneafsey et al., 2019). Seismicity delineated at least ten planar features with variable orientations that connected to
122 an open natural fracture, which formed a significant fluid pathway and controlled the stimulations (Schoenball et al.,
123 2020, Fu et al., 2021).

124

125 Here, we introduce the STIMTEC project, its monitoring concept and lessons learned from using a 16-station seismic
126 monitoring network for active and passive seismic monitoring during a decimetre-scale hydraulic stimulation
127 experiment in anisotropic and heterogeneous rock. We compare our monitoring experience with other previous and
128 ongoing research experiments in URLs. We review our seismic monitoring strategy, monitoring system adjustments
129 and discuss potential applications to the field scale. We address how anisotropy and heterogeneity are characterised
130 and provide estimates to place better constraints on the effect resulting from simplifications and approximations
131 commonly applied at the field scale.

132

133 **2 The STIMTEC project**

134 **2.1 Objectives, experimental framework, and monitoring strategy**

135 The STIMTEC experiment focuses on the development and optimisation of hydraulic stimulation (STIMulation
136 TEchnologies) and aims at establishing the link between damage patterns, hydraulic properties, and observed seismic
137 activity to provide diagnostic criteria for the success of a stimulation (Renner and STIMTEC team, 2021). Therefore,
138 seismic and hydraulic monitoring are key components of the experiment. In addition, validation through mine-back
139 drilling into stimulated volumes of complex rock, small-scale laboratory tests to characterise mechanical and physical
140 properties and numerical modelling are part of the integrated project approach.

141

142 The STIMTEC experiment comprised the following phases:

- 143 • a *pre-stimulation characterisation phase* (including site characterisation, borehole drilling and logging, core
144 analysis and hydraulic measurements for interval selection, as well as instrumentation);
- 145 • *the stimulation phase* (stimulation of ten selected intervals in the injection borehole during 16–18 July 2018);
- 146 • *the hydraulic testing phase* (testing of six intervals in the injection borehole during 8–10 August 2018);
- 147 • *the validation phase* (mine-back drilling of three validation boreholes, stress measurements in five intervals
148 of the vertical validation borehole on 21/22 August 2019); and
- 149 • *the final hydraulic testing phase* (testing of seven intervals in the injection borehole during 5–8 November
150 2019).

151 High-resolution seismic monitoring accompanied all experimental phases, but with different foci. During the pre-
152 stimulation characterisation phase, active seismic monitoring aimed at identifying high-attenuation and deformation

153 zones to avoid sensor installation in these zones, to quantify detection ranges, and to obtain a velocity model. The
154 installed sensors were then used to characterise background noise levels and any natural seismicity at the site. During
155 the stimulation phase and subsequent validation phase, real-time passive monitoring aimed at optimised AE event
156 detection, localisation and magnitude estimation during stimulation of intervals in the injection and vertical validation
157 boreholes. Repetitive active seismic measurements were performed along the injection and validation boreholes to
158 investigate any elastic velocity changes resulting from the stimulation. During the final hydraulic testing phase, passive
159 seismic monitoring focused on verifying detection rates observed for some stimulated intervals with few AE event by
160 placing two sensors closer to these intervals.

161

162 **2.2 Site description and infrastructure**

163 The STIMTEC site is located on the second floor of the Reiche Zeche Mine, in the Eastern Ore Mountains beneath the
164 city of Freiberg, Germany at a depth of ca. 130 m below surface (Figure 1). The metamorphic gneiss complex, hosting
165 the mine, is referred to as the Freiburger gneiss anticline, and belongs to the Precambrian metamorphic basement of
166 the internal Mid-European Variscan orogen (Seifert and Sandmann, 2006). It hosts silver, lead and zinc ores, which
167 were mined for centuries (Bayer, 1999). Temperatures at the STIMTEC site are low (~10°C). The protolith of the Inner
168 Grey Gneiss at Freiberg likely was an S-type granite (Tichomirowa et al., 2001, and references therein), which was
169 metamorphosed at about 0.8 to 1.1 GPa and 600 to 700°C and has a Proterozoic age with minimum estimates of 548
170 to 534 Myrs (c.f. Fig. 11 of Tichomirowa et al., 2001). The fine-grained biotite gneiss has a granitic appearance and
171 often contains large potassium-feldspar porphyroblasts. The mineral composition of Freiberg gneiss is generally
172 characterised by biotite, potassium feldspar, plagioclase, and quartz (Tichomirowa et al., 2001). Freiberg gneiss is a
173 partly weathered, faulted and strongly foliated rock. Large, steeply-dipping mineralized fault zones strike through the
174 gneiss (Sebastian, 2013).

175

176 The monitored rock volume at the STIMTEC site has dimensions of 40 m × 50 m × 30 m and is situated between two
177 galleries: the straight driftway and the curved vein drift that tracks the mined ore lode “Wilhelm Stehender” (Figure
178 1), a major mineralized fault zone with a thickness of up to 2 m that strikes north and dips westward beneath the site.
179 Large ore lodes at Reiche Zeche are generally considered normal faults and trend predominantly north-south to
180 northeast-southwest. The galleries have a square cross section (width/height of ca. 2 m) and were excavated in 1903
181 (vein drift) and 1950 (driftway).

182

183 In total, seventeen boreholes with uniform radius (76 mm) were drilled in two phases. Eleven seismic monitoring
184 boreholes were completed with a range of orientations and lengths, extending horizontally or upwards from the
185 galleries (Figure 1). The 63 m-long injection borehole was drilled with a strike of N31°E and dip of 15° downwards,
186 to maximize the inclination angle between the sub-horizontal foliation and the injection borehole while fulfilling
187 seismic monitoring requirements (possible recording ranges to upwards directed boreholes, placed outside of damage
188 zones). A more steeply inclined (dipping 36°, striking N66°E) hydraulic monitoring borehole was drilled, extending
189 below the central part of the injection borehole with a minimum distance of 2.5 m between the borehole depth 18.4 m
190 in the hydraulic monitoring borehole and 33.9 m in the injection borehole. One cable borehole, connecting the two
191 galleries, was drilled for cable as well as seismic sensor installations. The validation phase comprised mine-back

192 drilling of two inclined validation boreholes of 19.3 m and 45.8 m length, running sub-parallel to the injection borehole
193 and targeting seismically active and inactive volumes, as well as a vertical borehole for evaluation of the stress field
194 (Figure 1). The short validation borehole dips $\sim 12^\circ$ and ends 3.5 m above injection interval 28.1 m in the injection
195 borehole, while the long inclined validation boreholes dips $\sim 15^\circ$, terminating 4.4 m sideways of injection interval 56.6
196 m. The 15.6m-long vertical validation borehole (dip angle of $\sim 89^\circ$) is located in the driftway and spans the same
197 absolute depth range as the injection borehole.

198
199 The STIMTEC site is located 180 m south of the GFZ underground laboratory (Giese and Jaksch, 2016), where
200 extensive site investigations and exploration monitoring in the 10–3000 Hz frequency range have been performed over
201 the last 20 years to characterise the rock mass. The excavation damage zone (EDZ) of the galleries at the GFZ lab may
202 extend up to 10 m into the rock volume with an estimated 7% reduction in P-wave velocity (Krauß et al., 2014). A
203 continuous east-west trending damage zone was seismically imaged showing a ca. 13% P-wave velocity reduction
204 compared to the surrounding rock mass (Krauß et al., 2014). Predominantly east-west trending structures are likely
205 relicts given their orientation with respect to the current regional stress field. The stress field was measured at 140 m
206 depth in the mine, a few hundred metres from the STIMTEC site using an overcoring technique (Table 1; Mjakischew,
207 1987), suggesting a strike-slip regime with maximum horizontal compressive stress orientation directed NNW-SSE,
208 which is typical for SE Germany.

209
210 **2.3 Structural analyses**
211 Geological structures within the STIMTEC rock volume were identified through mapping of the access galleries,
212 acoustic televiewer images of the injection, hydraulic monitoring and validation boreholes, and from inspection of the
213 recovered core material. This aimed at the detection of possibly continuous fracture systems or damage zones, which
214 could affect the recording of high-frequency acoustic emission events. The foliation was mapped at 34 positions and
215 determined to be sub-horizontal to shallowly dipping in a south-east-direction. At least two, east-west trending, steeply-
216 dipping deformation zones were identified in both galleries that occasionally serve as water conduits as indicated by
217 oxidation and Fe_2O_3 deposition in the otherwise intact rock mass. These are referred to as the northern and southern
218 deformation zone. A third zone, the ‘middle deformation zone’, was predominantly seen in the vein drift. Drilling and
219 coring of the injection and validation wells allowed us to check whether these deformation zones actually crossed the
220 entire STIMTEC volume (question marks in Figure 1). The density of open fractures identified from acoustic logs is
221 highest (with 20 fractures per meter) at the bottom of the injection and long inclined validation boreholes, compared
222 to typical values of five open fractures per metre elsewhere (Adero, 2020). Several prominent structures (at 60 and 62
223 m) with a range of orientations were identified in the logs from the injection borehole (Figure 2), where the core
224 becomes severely fractured and was not fully recovered. This zone is considered the continuation of the northern
225 deformation zone at depth within the rock volume. Its location and depth are consistent with the orientation of mapped
226 structures in both galleries (Figure 1).

227
228 A connection of the middle damage zone between the driftway and the vein drift is not well constrained. A prominent
229 single fracture is mapped at 32.5 m depth in the injection borehole, also seen at 17 m in the hydraulic monitoring
230 borehole and at 19.8 m in the long, inclined validation borehole (Figure 2). However, this notable structure was not

231 observed in the short, inclined validation borehole. Its interpreted orientation does not match the interpolated position
232 of the middle damage zone based on mapping in the galleries. Ultrasonic transmission measurements from the cable
233 borehole, connecting the two tunnels, indicate that the mapped deformation zone seen in vein drift extends several
234 meters into the rock volume but does not connect to the driftway.

235
236 Between 33–41 m depth in the injection borehole, the number of healed fractures identified from the core is largest.
237 Two prominent structures are seen at 46 and 47 m depth, located in a section of the injection borehole (42–50 m) that
238 contains more fractures on average (Figure 2). The same two structures are likely seen at 38–39 m depth in the long
239 validation borehole.

240
241 Based on the distribution of fractures obtained from core analyses and acoustic image logs as well as hydraulic pre-
242 characterisation results, ten stimulation intervals of 0.75 m length each were selected for stimulation in the injection
243 borehole. Intact intervals were located at borehole depths of 22.4, 24.6, 28.1, 33.9 and 37.6 m (depths reference to the
244 position of the middle of the double-packer probe), while intervals with pre-existing fractures were located at 40.6,
245 49.7, 51.6, 55.7 and 56.5 m depth (Table 2). Four intact sections and one test interval with a pre-existing fracture were
246 selected for stimulation in the vertical validation borehole, corresponding to 4.0, 6.7, 9.3, 11.7 and 13.2 m depth (Figure
247 1).

248

249 **2.4 Hydraulic injection scheme**

250 All selected intervals in the injection and vertical validation borehole were stimulated with a uniform fluid injection
251 scheme: First, a pulse test was performed in the packed-off interval. The test interval was pressurized to assess the
252 performance of the packers and to assess the presence or absence of pre-existing open, conductive fractures. Hydraulic
253 properties were obtained from the time that it takes the pressure to decay from the initial pressure to a certain level
254 (Bredehoeft and Papadopulos, 1980; Cooper et al., 1967). Secondly, fluid was injected into the packed-off interval,
255 maintaining a constant flow-rate and thereby raising the interval pressure until breakdown to create a hydraulic fracture.
256 Once the breakdown pressure was reached the injection was shut-in. Thirdly, three refrac tests were performed at the
257 same flow-rate as applied during the initial hydrofrac test to determine fracture re-opening pressures, to propagate the
258 fracture, and to monitor the evolution of shut-in pressures after each refrac. Subsequently, a step-rate test was
259 performed, comprising stepwise increases of the injected fluid to determine the jacking pressure, when the created
260 fractures changed their state from mechanically closed to mechanically opened. Optionally, a periodic pumping test
261 sequence was performed to derive hydraulic properties, consisting of phases of alternating flow-rates between two
262 levels, ranging from 0.6/1.5 l/min to 6.5/8.5 l/min, for periods varying between 20 s and 900 s (~15 minutes; Table 2).

263

264 **2.5 Seismic monitoring network and data acquisition**

265 The seismic monitoring network consisted of 16 sensors, installed in boreholes of 1.5 m to 20 m length to reach as far
266 as possible into or beyond the tunnel excavation damage zone. This sensor network was used for both active seismic
267 measurements and passive seismic monitoring. We used 12 *GMuG¹ MA BLw-7-70-75* AE side-view single-component

¹Gesellschaft für Materialprüfung und Geophysik (www.gmugmbh.de)

268 in-situ AE sensors that provided high sensitivity in the frequency range 1–100 kHz, allowing to detect AE events with
269 rupture plane dimensions in the cm- to dm-scale (cf. Kwiatek et al., 2011; 2018). The AE sensors were placed in
270 upwards pointing boreholes located above the injection well, reducing the risk of sensor failure due to water intrusion.
271 AE sensors were pneumatically clamped to the borehole wall using grease to improve coupling. Minimum sensor
272 distances to the stimulation intervals in the injection borehole were 5.3–19.7 m (Figure 1, c.f. Table 2 for average
273 distances). The spatial coverage of the sensors was optimised for event detection, determination of hypocentres and
274 focal mechanisms (cf. Plenkers et al., 2010; Kwiatek and Ben-Zion, 2016), based on results obtained from an active
275 seismic survey performed in the pre-stimulation characterisation phase. This survey showed a strong influence of
276 deformation zones on the amplitude and frequency content recorded by the AE sensors and placed constraints on
277 maximum recording distances. Given the limitations regarding the number of monitoring stations and expected strong
278 damping of elastic waves, we realised that not all parts of the injection borehole could be equally well monitored. We
279 therefore focussed the seismic monitoring on the intermediate-depth range (25–35 m depth) of the injection borehole.
280 However, we decided to drill two monitoring boreholes longer than required for the preferred network design to allow
281 for fine-tuning of sensor placement, if necessary. In addition, one channel of the datalogger was left available for
282 flexible use and testing onsite.

283
284 Three AE sensors were co-located with uniaxial *Wilcoxon 736T* accelerometers with sensitivity between 0.05–25 kHz
285 for the in-situ calibration of the AE sensors (cf. Plenkers et al., 2010; Kwiatek et al., 2011, 2018). The accelerometers
286 were installed at the maximum possible depth of 1.5 m. They were screwed onto a brass coupling plate glued to the
287 polished borehole face. In addition, a six-component *ASIR² A-SiA-ULN-G4.5-GS-70* broadband sensor was installed
288 in a borehole to extend the range of recorded signals to low frequencies. It consists of a three-component 4.5 Hz
289 geophone and a three-component ultra-low noise optical accelerometer with sensitivity in the range 0.01–100 Hz. To
290 increase coupling of this sensor in the horizontal borehole we used a tile adhesive to fill the space between the sensor
291 and the borehole wall. This borehole sensor is noisier in the frequency band 0.01–10 Hz but less noisy for 10–100 Hz
292 compared to the Trillium Compact 120 s broadband sensors installed in the AHRL tunnels, which recorded low-
293 frequency signals associated with the hydrofrac and subsequent refracs (Zang et al., 2017). One component of the
294 sensor was simultaneously recorded on the high frequency AE system data logger (using the one channel available for
295 flexible use during pre-stimulation and stimulation phases) and by a low-frequency six-channel broadband system data
296 logger (during all experimental phases) for synchronous timing and data matching. The broadband sensor was first
297 installed in a 1.5 m long sub-horizontal borehole in the vein drift, but was then removed and modified for installation
298 in the 15 m- deep vertical validation borehole in the driftway. By placing the sensor closer and at a comparable absolute
299 depth to the deepest stimulation intervals in the injection borehole, we wanted to test if it recorded signals associated
300 with stimulation and hydraulic testing of these intervals.

301
302 A *GMuG HAE40k* sensor was installed in the down-going hydraulic monitoring borehole for the final hydraulic testing
303 phase, and connected to the available channel for flexible use. We refer to this sensor hereafter as an AE-hydrophone,
304 because of its qualitative characteristics somewhat similar to a hydrophone and suitability for in-water installation,

²Advanced Seismic Instrumentation and Research LLC (www.asirseismic.com)

305 This piezoelectric AE-sensor is sensitive to pressure changes in the frequency range 1–40 kHz and was added to the
306 network to provide a high-sensitivity sensor in close proximity (6–17 m) to the intermediate and deep stimulation
307 intervals.

308
309 Seismic waveforms were recorded with the *GMuG AE System* datalogger, a 16-channel, 16-bit acquisition system that
310 allowed recording both in trigger-mode with a sampling frequency of 1 MHz as well as in continuous mode with
311 sampling frequency of either 200 or 500 kHz. The acquisition system imposes an internal gain of 10 dB on recorded
312 signals, which is inverted by a -10 dB pre-amplifier for the accelerometers and augmented by an additional 30 dB pre-
313 amplifier for the AE sensors and the hydrophone. The accelerometers were operated with analogue 50 Hz high-pass
314 filters and a dynamic range of 1 V input, while all other sensors had 1 kHz high-pass filters and a dynamic range of 10
315 V input. The six-channel, high-gain Reftek130 data logger of the broadband system recorded continuously at 125 Hz
316 during the initial stimulation and hydraulic testing and 1000 Hz during the final hydraulic tests. By using a continuous
317 and a triggered seismic monitoring system simultaneously, data redundancy and different data accuracy was obtained.
318 The two seismic monitoring modes can be easily switched from one to the other, allowing for flexible use for active
319 (up to 32 channels, in triggered mode) and passive seismic monitoring (16 channels, both modes).

320

321 **2.6 Active seismic measurements**

322 For active measurements three different sources, capable of generating high-frequency signals in the kHz range, were
323 used. A survey, comprising sledge-hammer hits at 84 fixed positions in the vein drift recorded by four AE sensors
324 located in the driftway, was performed during the pre-stimulation characterisation phase. Each hit was also recorded
325 by a sensor fixed to the hammer, providing the origin time. These recordings were used to test the transmission of
326 elastic waves across the test volume and to obtain an estimate of the influence of deformation zones on the amplitude
327 and frequency content recorded by the AE sensors at varying recording distances. Together with the structural analysis
328 at the site, these measurements were used to determine final sensor placements of the seismic monitoring system,
329 omitting high-attenuation and deformation zones.

330

331 Similar active measurements were repeatedly performed at 24 fixed points in the vein drift and the driftway before,
332 during and after all other phases of the experiment (Figure 3) using sledge hammer and centre punch tools. To obtain
333 origin times for some of these hits, an additional accelerometer was installed next to the hitpoint. Centre punch tools
334 generate a more repeatable signal than the sledge hammer, with a defined impact force controlled by the internal
335 springs. We used three different centre punches with spring forces adjusted to 50 N, 130 N, and 250 N. The spectra of
336 the generated impulse signals partially overlap with the spectra of AE events, containing higher frequencies compared
337 to the hammer impulse (Supplement material Figure S1). The hits of the intermediate and largest centre punch as well
338 of the hammer were recorded by all AE sensors and all accelerometers, forming an extensive dataset for AE sensor
339 calibration, site attenuation and are a pre-requisite for estimating magnitudes of the AE events (Kwiatk et al., 2011).

340

341 Sledge hammer hits also served as a simple reference signal to mark critical monitoring periods during all phases of
342 the experiment: Three hammer hits before the start and three to six hits at the end of each hydraulic pumping operation
343 allowed to calibrate timing of the seismic and hydraulic observation systems, made different groups on site (located in

344 different galleries during the stimulation) aware of operations and helped to distinguish working noise from the target
345 AE signals.

346
347 In addition to the active surveys along the tunnel walls, >300 ultrasonic transmission (UT) measurements were
348 performed in the hydraulic monitoring, injection, validation, and cable boreholes for velocity model estimation. The
349 single ultrasonic transmitter (central frequency ~15 kHz) is charged slowly and then discharged rapidly, producing a
350 delta pulse. At each measurement point, a total of 1024 of these pulses were automatically stacked on each sensor
351 channel to improve the signal-to-noise ratio. The resulting signal generally contains more high frequency energy than
352 common AE signals (>30 kHz, Supplement material Figure S1). UT measurements in the injection borehole, with
353 sources placed every metre along most of its length, were performed for velocity measurements before and after the
354 stimulation. The side-view ultrasonic transmitter was pneumatically coupled to the borehole wall in three different
355 orientations before the stimulation and at one orientation after the stimulation. By using different orientations, the
356 maximum amplitude of the source radiation pattern was directed towards the AE sensor locations near driftway,
357 directly above the injection borehole and along vein drift, respectively. As the UT source signal was generally recorded
358 throughout the STIMTEC rock volume, only one orientation was adopted subsequently. The vertical validation
359 borehole was sounded before and after stimulation, while the remaining validation and cable boreholes were sounded
360 once at the end of the validation phase or the final hydraulic testing phase of the experiment, respectively (Figure 3).

361
362 **2.7 Passive seismic monitoring**
363 To monitor injection-induced fracture processes and associated small-scale brittle rock failure, we focussed passive
364 seismic monitoring on small magnitude ($M_w \leq 1.5$), high frequency ($f_c \geq 300$ Hz) AE events with expected fracture sizes
365 ranging from a few cm to the m-scale (Bohnhoff et al., 2010). Similar monitoring was previously successfully applied
366 (see review by Manthei and Plenkers, 2018; Kwiatak et al., 2018; Villiger et al., 2020).

367
368 Passive seismic (continuous and triggered) data were recorded during all injection operations. Triggering levels were
369 adjusted during hydraulic pumping operations and tuned for each stimulation interval to minimize false triggers that
370 lead to a dead time in the triggered recording system. Noisy channels were switched off to facilitate monitoring of
371 many partly overlapping AE events in real-time on site and to identify larger events. AE events detected in trigger
372 mode were automatically picked and located in near-real time on-site to obtain a preliminary catalogue and control the
373 experiment. Outside of stimulation campaigns, the continuous-mode system was operated between 29 June and 14
374 August 2018 (with some data gaps, see Supplementary Material Table S1) and 5 November to 4 December 2019 (no
375 gaps) to measure post-stimulation processes and to characterise potential background seismicity. We recorded >72 TB
376 of seismic data by the end of the field experiment.

377 **3 Methods**

378 **3.1 Data processing**

379 The different phases of the STIMTEC experiment were accompanied by varying in-situ noise conditions that affected
380 predominantly the high-sensitivity AE sensors. Passive seismic data often showed contamination with transient
381 electronic noise and noise generated by the hydraulic pumps during stimulation. To address this problem, we applied
382 filtering using the continuous wavelet transformation. We first identified the wavelet coefficients related to transient

383 noise signals by comparing continuous seismic data with and without noises. By removing the identified wavelet
 384 coefficients from the recorded wavelet spectrum, the unperturbed AE signal could be retrieved efficiently. This was
 385 possible because AE signal and noise overlapped only partially (Supplementary material Figure S2).

386
 387 For post-processing of the triggered AE event data, we apply the automatic phase identification algorithm by Wollin
 388 et al. (2018), which is based on the two-step approach by Küperkoch et al. (2010) to first determine a preliminary
 389 arrival time, which is then refined by suppressing noise and using a wider causal band-pass filter. The waveforms are
 390 first filtered using a third order Butterworth bandpass filter before a rolling higher-order-statistics kurtosis filter is
 391 applied to determine a preliminary onset time. Then, by systematically calculating suites of Akaike's information
 392 criterion (AIC)-functions on rolling and nested time windows of wavelet portions containing the phase onset, the
 393 variability of the global minima is used to estimate the final pick as well as an asymmetric pick uncertainty. Parameter
 394 settings are given in Table 4. The same procedure is applied for P- and S-arrivals. However, given the single-
 395 component data and the AE sensor's typical post-pulse oscillations, automatically picked S-arrivals are considered
 396 uncertain in this study. We observed that the amount of automatically picked S-arrivals is significantly larger than for
 397 a reference dataset of manually picked S-arrivals. The reference dataset, comprising 300 events with 2,286 manual P-
 398 and 1,021 S-picks, was used to tune the automatic picking algorithm.

399

400 **3.2 Velocity model**

401 We used the active seismic UT measurements to derive a velocity model. UT data were manually inspected and arrival
 402 times of the P- and S-waves, as well as the origin time of the UT source pulse, were identified. We distinguished
 403 between impulsive, high-signal to noise ratio P-wave arrivals and more emergent, low-signal to noise ratio P-onsets.
 404 Given the known origin time and location of each UT measurement point, travel times to the seismic sensors were
 405 calculated assuming straight ray paths (Figure 3 and Supplementary Material Figure S3). Uncertainties of the obtained
 406 velocities were assessed from repeated measurements from each point in the injection borehole.

407

408 The Freiberg gneiss displays a prominent sub-horizontal foliation and was expected to show transverse isotropic elastic
 409 properties as seen from core measurements (Adero, 2020) typically showing high P-wave velocities parallel to the
 410 foliation and low P-wave velocities perpendicular to it. To describe the observed anisotropy of the obtained velocity
 411 values, we applied the exact phase velocity equations for transverse isotropy (Thomsen, 1986, equations 10 a-d):

$$412 \quad v_p^2 = v_{p0}^2 [1 + \epsilon \sin^2 \theta + D^*(\theta)], \quad (1)$$

$$413 \quad v_{sv}^2 = v_{s0}^2 [1 + v_{p0}^2/v_{s0}^2 \epsilon \sin^2 \theta - v_{p0}^2/v_{s0}^2 D^*(\theta)], \quad (2)$$

$$414 \quad v_{sh}^2 = v_{s0}^2 [1 + 2\gamma \sin^2 \theta], \quad (3)$$

415 where ϵ and γ describe the strength of anisotropy for P-waves and for S-waves, respectively, v_{p0} or v_{s0} are velocities
 416 along the symmetry axis, and θ is the phase angle. The parameter D^* is defined as

$$417 \quad D^*(\theta) = 0.5 [1 - v_{s0}^2/v_{p0}^2] \{ [1 + 4 \delta^* \sin^2 \theta \cos^2 \theta / (1 - v_{s0}^2/v_{p0}^2)^2 + 4(1 - v_{s0}^2/v_{p0}^2 + \epsilon) \epsilon \sin^4 \theta / (1 - v_{s0}^2/v_{p0}^2)^2]^{0.5} - 1 \}, \quad (4)$$

418 with:

$$419 \quad \delta^* = (1 - v_{s0}^2/v_{p0}^2) (2\delta - \epsilon) \quad (5)$$

420 The angular dependence of the velocity is given by the shape factor δ .

421 Using the full description is significantly more complex than the weak anisotropy approximation:

422
$$v_P^2 = v_{P0}^2 [1 + \delta \sin^2\theta \cos^2\theta + \epsilon \sin^4\theta], \quad (6)$$

423
$$v_{SV}^2 = v_{S0}^2 [1 + (v_{P0}^2/v_{S0}^2) (\epsilon - \delta) \sin^2\theta \cos^2\theta], \quad (7)$$

424
$$v_{SH}^2 = v_{S0}^2 [1 + 2\gamma \sin^2\theta], \quad (8)$$

425 which was derived by Thomsen (1986) for weak-to moderate strength of anisotropy ($\epsilon, \gamma < 0.2$). This approximation is
 426 commonly applied and describes the actual transverse isotropy accurately along and perpendicular to the symmetry
 427 axis but not at intermediate angles.

428
 429 We determined Thomson's anisotropy parameters for P-waves (v_{P0}, ϵ, δ) for each seismic station assuming full
 430 transverse isotropy with a vertical symmetry axis. There was no angular asymmetry observed in the measured velocities
 431 that would indicate a tilt of the symmetry axis. We assume that the recorded wave velocities represent phase velocities
 432 rather than group velocities. We first calculated all wave velocities by systematically varying ϵ, δ in steps of 2% and
 433 v_{P0} in 100m/s steps. Then, the residual between computed and measured P-wave velocities were computed in a
 434 comprehensive grid search over the sampled parameter ranges. Due to the scarcity of S-wave observations in the UT
 435 data, the ratio of P-to-S wave velocities (v_{P0}/v_{S0}) along the vertical symmetry axis and the S-wave velocity anisotropy
 436 parameter γ were fixed to 1.77 and 18%, respectively. These estimates were based on Wadati (1933) plots for near-
 437 vertical ray paths and sonic logs from a 70 m-long, vertical borehole of the GFZ lab (Giese and Jaksch, 2016). This
 438 sonic log shows the average value at shallow and deep depths, but a large deviation for intermediate depths. The v_{P0}/v_{S0}
 439 value is slightly larger than the average value obtained from the sonic log in the (15°-inclined from horizontal) injection
 440 borehole. Both logs exhibit large scatter (± 0.15). To determine the set of best fitting Thomsen parameters per station
 441 (Table 5), we compared the parameter ranges for the best 10 and 100 models. This velocity model was referred to as
 442 the best transverse isotropic velocity model per station. It was compared to an isotropic velocity model ($v_P=5600$ m/s,
 443 $v_P/v_S=1.76$) and a single transverse isotropic velocity model for all stations ($v_{P0}=5300$ m/s, $\epsilon=11.3\%$, $\delta=0$,
 444 $v_{P0}/v_{S0}=1.76$).

445
 446 To clarify limits on the detection ranges as a function of distance, attenuation and anisotropy at the decameter scale,
 447 we investigate attenuation characteristics of the rock. Attenuation estimates of the elastic waves travelling in the fast
 448 anisotropy direction parallel to the foliation were obtained using hammer and centre punch hits.

449 We assume that the amplitude A of the wave decays with distance d from the active source according to

450
$$A(d) = GA_0 d^{-1} e^{-\gamma d}, \quad (9)$$

451 Where A_0 is the amplitude at the source, G is the gain factor of the recording sensor and γ is the anelastic attenuation
 452 coefficient. This neglects the effect of scattering. By multiplying the measured (assumed S-wave) amplitude by the
 453 distance, taking the natural logarithm and dividing by the distance, we see that γ can be obtained. We fit the data of
 454 the logarithm of the normalised amplitudes of sensors with the same gain against the distance from the source, with a
 455 regression line, where the slope m is proportional to the attenuation coefficient of the medium.

456 For each of the 10 hammer hits at each hitpoint along the galleries, an 8 ms time window starting at the P-arrival was
 457 chosen, from which the maximum amplitude value was extracted for each AE sensor. Then, the dominant frequency
 458 of the signal was determined for each AE sensor from the maximum amplitude in the frequency range containing 99%
 459 of the energy of the signal. The average of the dominant frequency from all sensors f_{dom} together with the slope of the

460 regression line m and the average S-wave velocity v_{S90} in the horizontal direction was used to estimate the quality
461 factor Q , according to:

$$462 \quad Q = |\pi f_{\text{dom}} / (m v_{S90})|. \quad (10)$$

463 Similarly, attenuation estimates were obtained by comparing waveforms of centre punch hits recorded by
464 accelerometers located in opposite galleries with one sensor next to the hitpoint. Spectral amplitude ratios were
465 analysed to obtain an estimate of the quality factor.

466

467 **3.3 Hypocenter locations and velocity model uncertainty**

468 During post-processing hypocenter locations were determined using the equal differential time (EDT) method by Zhou
469 (1994) combined with a downhill simplex optimization algorithm (Nelder and Mead, 1965) applying the developed
470 transverse isotropic velocity model derived for each station. The EDT method has the advantage that the inversion of
471 the hypocenter location is based on the relative arrival-times of pairs of P- and S wave arrivals at the same station or
472 pairs of P-arrivals at different stations. The origin time is not specifically inverted for, but obtained as a by-product.
473 Gischtig et al. (2018) demonstrated how the inversion for origin time, hypocenter location and station corrections are
474 affected by anisotropy. Applying the weak anisotropy approximation, these authors calculated the velocity-dependent
475 derivatives required for the inversion. We did not specifically account for anisotropy in the location procedure, because
476 the non-linear EDT method can handle 3-D heterogeneous velocity models. Instead, we used the anisotropic velocities
477 in the forward computation of the calculated travel-time grids, from which the EDT surfaces were determined. We
478 tested the method by relocating the known UT measurement points using the manually identified P-arrival times with
479 the derived velocity model per station.

480

481 To locate the AE events, we derived an initial hypocentre location based on P-wave arrivals only and a final location
482 including only those S-arrivals, consistent with the initially-derived hypocenter. To be included in the location
483 procedure, the root-mean-squared (rms) residual for an S-arrival needed to be less than 1.5 times the rms of the P-
484 arrivals for the initially derived hypocenter ensuring that inaccurately autopicked S-arrivals were discarded. The rms
485 is defined as

$$486 \quad \text{rms} = (\sum_i w_i (t_i^{\text{calc}} - t_i^{\text{obs}})^2 / \sum_i w_i)^{0.5}, \quad (11)$$

487 where t_i are calculated and observed travel times for i stations and w_i is the weight. Phase weighting for autopicked P-
488 arrivals was implemented, based on the signal-to-noise ratio (SNR), with $\text{SNR} \geq 6$ obtaining full weight, $6 > \text{SNR} \geq 3$ half
489 weight and $\text{SNR} < 3$ one tenth of the full weight. S-arrivals were weighted with two tenth of the full weight if included
490 in the hypocenter estimation. We consider only events with a minimum of five phase arrivals and display those
491 hypocenter locations with rms travel time-residuals below a selected limit of 2 ms. We also applied station residuals
492 obtained as average P-wave travel-time residuals per station.

493

494 To assess the influence of the applied velocity model on the hypocenter locations, we compared the median rms travel-
495 time residuals of all AE event hypocentres obtained using different velocity models as well as the location uncertainty
496 of the relocated UT measurement points. By comparing the relocation error from the isotropic velocity model with the
497 transverse isotropy model and the best transverse isotropic velocity model per station, we provide estimates for the
498 location uncertainty associated with inaccurate velocity models.

499 **4 Results**

500 **4.1 Constraints on velocity models and location uncertainty**

501 Using a transverse isotropic velocity model per station, we obtained more accurate locations (lower rms travel-time
502 residuals, Table 6) and reduced the uncertainties determined from re-locating the known UT measurement points (using
503 the manually identified arrival times and the derived v_P - and v_S -velocities, Figure 4) compared to using an isotropic
504 velocity model or a single transverse isotropic velocity model for all stations. The latter was determined from the
505 averaged Thomsen parameters of all stations (Table 5). The network geometry influences the direction, while the
506 velocity misfit determines the location uncertainty (length of the black bars in Figure 4a). The best velocity model per
507 station results in an average relocation error of 0.26 ± 0.06 m for the active seismic UT measurement points in the range
508 22–31 m borehole depth in the injection borehole (Figure 4b), along which the majority of AE events were observed,
509 compared to 2.6 ± 0.20 m for isotropic and 0.49 ± 0.12 m for the single transverse isotropic velocity model. Relocation
510 of the UT measurement points was based on using only P-arrival times. Adding the S-wave arrivals did not further
511 reduce the location errors. This is likely because there are only few S-picks (on average 3 per measurement point for
512 the injection borehole and 5 for the vertical validation borehole, compared to on average 12 and 13 P-picks,
513 respectively) identifiable in the UT data. Note that the S-wave velocity model is not well constrained, but the few S-
514 arrivals observed in the active UT dataset are consistent with the assumed S-anisotropy parameters (v_{S0}, γ).

515
516 The best transverse isotropic velocity model per station also provided the lowest relocation error on average along the
517 injection borehole outside the damage zone (borehole depths < 40 m), where the resolution accuracy is decreased by
518 70% for the isotropic model and 29% for the single transverse isotropic model (Table 6), respectively. We note that
519 the best velocity model per station is tuned to the injection borehole because its number of measurement points is
520 largest. This effectively provided a four times higher weight for measurement points along the injection borehole
521 (compared to double weight for the vertical validation borehole and single weight for all other boreholes) For
522 relocating the known UT measurement points in the vertical validation borehole, relocations obtained using the single
523 transverse isotropic model (average relocation error of 0.69 ± 0.53 m, Figure 4b) are more accurate than for the best
524 velocity model per station (average error 0.95 ± 0.46 m). For all other inclined boreholes the best velocity model per
525 station results in the lowest relocation uncertainties compared to the other velocity models (Figure 4b). The isotropic
526 velocity model performs best in relocating the known UT measurements in the wider deformation zones in the injection
527 and long inclined validation borehole based on the relocation error, compared to the anisotropic velocity models.
528 Within the deformation zones, all models show a systematic mislocation upwards above the injection borehole (Figure
529 4a and Supplementary Material Figure S4), reflecting predominantly the seismic network geometry.

530 531 **4.2 Structural heterogeneity, velocity and attenuation**

532 We investigated the influence of the various geological structures in the rock volume on the seismic wave propagation
533 and on the velocity model. The background anisotropy caused by the strong foliation of the host rock is overprinted
534 by structural heterogeneity on site. We observed significant velocity reductions of 1–4% per station over several UT
535 measurement points (Figure 8a) associated with a prominent fault, identified at 32.5 m in the injection well (Figure 2).
536 For most stations this v_P drop is larger than the velocity uncertainties obtained from 3–6 repeated measurements from

537 in total 48 points, predominantly in the injection borehole. The standard deviations for all stations range between 1 to
538 145 m/s with mean values of 35 m/s.

539 We also see significant misfit between the velocities predicted by the anisotropic velocity model and the observed
540 velocities for deformation zones at borehole depths >42 m in the injection borehole and >32 m in the long validation
541 borehole (Figure 4). At these depths the logged structures and elevated fracture densities likely affect seismic wave
542 propagation by strong attenuation and deviating ray paths. This suggests that the velocity models fitting the anisotropic
543 reservoir rocks are inadequate for prominent faults and surrounding damage zones.

544
545 Close to the prominent fault at 32.5 m depth, we observe an amplitude reduction of the stacked UT signal by up to
546 50% compared to the values of neighbouring measurement points. This value was determined as the difference between
547 the actual value and the value expected for these depths from linear regression of three neighbouring amplitude
548 measurements at shallower and deeper depth. Still, ambiguity prevails as other factors such as UT source coupling and
549 resonances at the receivers can also affect the recorded amplitudes. In general, we do not observe a systematic velocity
550 or amplitude reduction from UT measurements in the injection borehole after stimulation as compared to before.
551 Attenuation estimates of the elastic waves travelling in the fast anisotropy direction parallel to the foliation obtained
552 from hammer and centre punch hits result in $Q_p \sim 50$ near the galleries and $Q_p \sim 150$ in the centre of the rock mass.

553
554 We observed good SNR ratios for UT measurements in the records of the three accelerometers for distances ≤ 15 –18
555 m. For both accelerometers located off vein drift, we observed clipping of active centre punch hits generated at 10–15
556 m distance with incidence angles around 90° to the accelerometer axis. This likely reflects resonances and/or coupling
557 issues. UT measurements are not recorded beyond distance of 31 to 33 m by the AE sensors. The AE-hydrophone
558 recorded UT signals with good SNR for distances smaller than 17 m (c.f. Boese et al, 2021). This reduced recording
559 range compared to the AE sensors is likely related to the impedance contrast of the water-filled borehole and the rock.
560 For this reason, AE-hydrophones need to be placed as close as possible to stimulated intervals, or, alternatively,
561 installed permanently by cementation, which reduced the impedance and increases the sensitivity.

562

563 **4.3 Seismic monitoring and network sensitivity improvements**

564 The hydraulic stimulation campaign started in the deepest part of the 63 m-long injection borehole with an intended
565 progression of stimulation from deep to shallow intervals (Figure 1). No AE activity was observed during stimulation
566 of the two deep intervals at 56.5 m and 51.6 m borehole depth, closest to the highly fractured damage zone encountered
567 at the bottom of the borehole. These intervals locate furthest from the seismic monitoring network (HF1 and HF2;
568 Table 2). To test detection limits and the seismic monitoring equipment under the given noise conditions, we changed
569 the intended order of the stimulated intervals, so that two shallow intervals (at borehole depth smaller than 30 m: HF3
570 and HF4) were stimulated next, followed by two intermediate depth intervals (borehole depth between 30 m and 45
571 m: HF5 and HF6) before returning to the deep intervals (borehole depth greater than 45 m; HF7 and HF8). We observed
572 significant AE activity (several thousand events, Table 2, Figure 5 and Figure 6a) for the shallow stimulation intervals
573 (22.4 m, 24.6 m, and 28.1 m) and high breakdown pressures (11–13 MPa). Seismic activity was not identified before
574 the start of the stimulation and stopped shortly after shut-in. Few AE events were recorded during injection into
575 intermediate-depth intervals (33.9 m, 37.6 m and 40.6 m depth, Table 2). These events occurred diffusely throughout

576 the pumping sequence (Figure 6b). For the interval 33.9 m the second lowest breakdown pressure (6.4 MPa) of all tests
577 was observed, whereas the adjacent interval 37.6 m exhibited the highest observed value (15.8 MPa), pointing towards
578 significant spatial complexity. The breakdown pressure of interval 40.6 m (9.4 MPa) is comparable to those in the deep
579 intervals 49.7 m, 51.6 m, 55.7 m, 56.5 m, which show intermediate to low values (5.8–9.4 MPa, Table 2) and no AE
580 events, neither during the stimulation nor during subsequent hydraulic testing phases of the experiment.

581
582 For stimulations of the seismically active intervals in the injection borehole (HF3, HF4, HF10; Table 2) and in the
583 vertical validation borehole (HF12-15; Table 3, Figure 5), we observed a general correlation between seismicity, fluid-
584 injection cycles and volumes, when the injection pressure exceeded the fracture opening pressure. A small number of
585 AE events occurred during the frac and refrac sequences (5–70 AE per sequence), whereas significantly more events
586 were observed during subsequent step-rate tests (75–180 AE above jacking pressure) and during periodic pumping
587 tests (30–240 AE per cycle, Figure 6). We observed a progressive growth of the seismic clusters which extend about
588 5 m radially from the injection interval (Figure 5 and 6). The sub-horizontal foliation does not seem to noticeably
589 influence event propagation and seismic cloud growth. Note that the seismic clusters from the injection and vertical
590 validation borehole are spatially distinct (see also Supplementary Material Figure S5).

591
592 The highly variable seismic response to stimulation prompted us to relocate two of the 16 seismic monitoring sensors
593 (Figure 1) to test if the absence of AE activity results from limitations in network sensitivity or site characteristics. We
594 placed one AE-hydrophone at the bottom of the hydraulic monitoring borehole to verify AE detection levels for
595 intermediate-depth and deep stimulated intervals in the injection borehole. The AE-hydrophone recorded few AE
596 events during further hydraulic testing and accidental re-stimulation of the intervals 37.6 m and 40.6 m (at 6–8 m
597 hydrophone-interval distance), respectively, but no activity was observed for intervals 49.7 m and 56.5 m (at 10 m and
598 17 m distance), confirming previous observations of no AE activity in the deep stimulation intervals and recording
599 ranges for AE events of ~30 m for AE sensors at the STIMTEC site. The borehole broadband sensor was moved to the
600 bottom of the vertical validation borehole for the last phase of the experiment, so that it located at a comparable absolute
601 depth as the deepest stimulated intervals in the injection borehole. This was considered beneficial because of
602 indications that seismic wave attenuation perpendicular to the foliation may be larger than parallel to the foliation
603 (Adero, 2020). Overall, the broadband sensor recorded characteristic signals during hydraulic stimulations of all
604 intervals in the injection borehole on 16-18 July 2018 (Figure 7 and Supplementary Material Figure 3) that appear to
605 respond to the flow rate rather than the injection pressure (Supplementary material Table S2 and Figure S6). These
606 signals were not recorded by the only other nearby broadband sensor FBE (SX Net, distance 438 m SE of STIMTEC
607 site). The observed signals vary in amplitude and period and are best observed on bandpass filtered (0.001–1 Hz) daily
608 seismograms on the second horizontal component of the ASIR sensor, likely aligned parallel to vein drift
609 (perpendicular to the borehole). There are also spike signals observed that may indicate rapid tilting and recalibration
610 of the sensor (see also Supplementary material Figure S7), based on shake table calibration after the experiment. They
611 occur during operations at the site and their interpretation currently remains unclear.

612 **5 Discussion**

613 **5.1 Seismic monitoring network**

614 Using a seismic monitoring system consisting of AE-hydrophones, AE sensors, accelerometers and broadband sensors
615 bears several advantages. The AE-hydrophone can be attached on hydraulic tubing and therefore installed in
616 combination with hydraulic equipment. This places it much closer to the stimulated intervals and as a consequence,
617 AE-hydrophones can enlarge the 3-D density of sensors and their coverage in the volume of interest, thus improving
618 location accuracy and focal mechanism determination. AE-hydrophones do not require coupling to the rock mass and
619 are more easily installed than AE sensors. This comes at the cost of reduced recording ranges and frequency bandwidth
620 compared to common AE sensors (and reduced S-wave sensitivity cf. Boese et al., 2021).

621
622 All dedicated seismic monitoring boreholes were located above the stimulated volume to ensure that water entering
623 into the boreholes can drain during the experiment. This posed the general problem of increased location uncertainty
624 in the vertical direction. However, with this setup we achieved the desired monitoring quality without needing an extra
625 monitoring borehole placed close to the stimulation borehole. During the EGS Collab and GTS experiments, the
626 intersection of growing fractures with nearby monitoring boreholes caused immediate pressure release, inhibiting or
627 deflecting fracture growth (Schoenball et al., 2020, Fu et al., 2021). This illustrates the problem that monitoring
628 boreholes may impinge on the stimulation. Therefore, high sensitivity AE sensors placed at some distance (20–30 m,
629 considering the site characteristics of the STIMTEC experiment) to the stimulated intervals combined with AE-
630 hydrophones placed close to the stimulated interval in the stimulation borehole (above the double packer) likely offer
631 the best solution for high-resolution seismic monitoring during hydraulic stimulation in URLs. However, preservation
632 of the high-frequency content of seismic waves is site dependent and a prerequisite for the analysis of source properties
633 of AE events with expected fracture sizes at the dm-scale (e.g. Kwiatek et al., 2011). Empirical results of Plenkers et
634 al. (2010) provide upper bounds for detection limits of AE events in low-attenuating hard rocks at ~3 km depth. In the
635 more general case, we refer to the modelling of detection limits for high frequency energy of microseismic events by
636 Kwiatek and Ben-Zion (2016).

637
638 Adapting the stimulation on site by changing the stimulation order in the injection borehole allowed for testing the
639 sensitivity of the monitoring system and site conditions but also resulted in the stimulation of the most seismically
640 active intervals (HF3, HF4, HF10; Table 2, Figure 5) on three subsequent days. This adaption was possible because of
641 the near real-time processing and visualisation of AE events on site. It allowed us to separate the temporal distribution
642 of the AE events in the spatially overlapping seismicity clouds (Figure 5).

643 644 **5.2 Seismic response to stimulation**

645 We observed significantly different seismic and hydraulic responses of intervals separated by only a few meters in
646 heterogeneous, metamorphic rock (Figures 5 and 6). This generally agrees with observations from the AHRL, GTS
647 and EGS Collab experiments, which also highlighted the influence of the rock type, the pre-existing fracture zones,
648 and stress heterogeneity on seismic responses to hydraulic stimulation. Although it is not yet clear what causes the
649 large variability in deformation behaviour at the STIMTEC site, we verified that it is not primarily the result of
650 detection capabilities of the seismic monitoring network along the injection borehole. We posit that deformation in
651 response to stimulation in the deepest part of the injection borehole is predominantly aseismic (in the frequency band

652 1–40 kHz, corresponding to length scales in the cm to dm range). This observation is based on the absence of AE
653 events and a strong long-period signal recorded by the broadband sensor. We suspect the observed variability in seismic
654 response to stimulation is likely caused by rock-mass heterogeneity and the response of pre-existing fractures. In
655 addition, injection boreholes not aligned with one of the principal stress axes show complex fracture initiation
656 (Rummel, 1987; Haimson and Cornet, 2003), likely controlled by small-scale material heterogeneities at the borehole
657 wall, as also observed in lab experiments (Masuda et al., 1993). Reorientation of fractures with growth away from the
658 injection interval has been observed previously in boreholes misoriented with respect to the principal stress axes, for
659 example by mine-back in soft volcanic rock (Warren and Smith, 1985) and by AE event cluster orientations in
660 crystalline rocks (Gischig et al., 2018; Schoenball et al., 2020) and salt rock (Manthei et al. 2001). Re-orientation of
661 AE event clouds has not yet been identified during the STIMTEC experiment. We note, however, that unexpected
662 (based on stress modelling), strong, local variations of the stress magnitudes in the experimental volume were observed
663 from stress measurements in the injection and vertical validation boreholes (Adero, 2020). The variability of shut-in
664 pressures (with the largest deviations from the average values observed in the adjacent stimulation intervals at 33.9 m
665 and 37.6 m depth in the injection borehole) and orientations of induced fractures suggest overall small-scale stress
666 heterogeneity at the STIMTEC site (Adero, 2020).

667
668 The observed low-frequency broadband recordings are similar to the broadband records observed by Zang et al. (2017,
669 their Figure 11) at the AHRL. In particular, we obtained strong signals from stimulations that did not yield high
670 frequency AE events. We also observed transient low-frequency signals recorded shortly before the start of the
671 stimulation (Supplementary Material Figure S6). In particular, they correlate with the flow record associated with the
672 installation of the hydraulic equipment, and we assume that these signals result from packer setting and flushing,
673 causing transient low-frequency amplitude signals. These observations require further investigation to determine what
674 causes the low-frequency broadband signals. Nevertheless, our observations suggest that borehole sensors sensitive in
675 the frequency range 0.01–100 Hz positioned at distances of 19.6–26.6 m are adequate to monitor low-frequency
676 deformation signal associated with hydraulic stimulations.

677

678 **5.3 The role of anisotropy and heterogeneity for mine- and lab-scale experiments**

679 Laboratory and active seismic measurements from the STIMTEC experiment show moderate to strong elastic wave
680 anisotropy controlled by the pronounced foliation of the gneiss. We compare the here obtained Thomsen parameters
681 to those values determined in a range of laboratory tests on cylindrical Freiburger gneiss samples at different confining
682 pressures (≤ 30 MPa) and orientations at room temperature (Adero, 2020). P-wave velocity measurements on samples
683 in the laboratory exhibit similar mean values and ranges for wave propagation in different orientations with respect to
684 the foliation as observed in field measurements. In laboratory tests, P-wave velocities for ray paths parallel to the
685 foliation are slightly larger, about 20% higher compared to a direction normal to the foliation (Figure 8). This is
686 irrespective of the significant differences in frequency bands of UT sources in the laboratory (500 to 800 kHz) and in
687 the mine (5 to 60 kHz). Uncertainties of the obtained velocities in the field range between 1 to 145 m/s with mean
688 values of 35 m/s for all stations, corresponding to 0.1–4.2%.

689 At the STIMTEC site, P-wave velocities for ray paths parallel to the foliation are on average 12% higher than
690 perpendicular to the foliation for UT data. A large amount of active UT field measurements was needed to cover the

691 range of incidence angles necessary to determine the degree of P-wave velocity anisotropy and the symmetry axis of
692 the metamorphic rock (Figure 3, and Supplementary Material Figure S8). Near-vertical ray-paths (parallel to and at
693 acute angles to the symmetry axis) were difficult to obtain due to geometrical constraints limiting sensor positioning.
694 In general, we observed a trade-off between the obtained P-wave velocity along the symmetry axis v_{p0} and the P-wave
695 anisotropy parameter ε for the UT data (Supplementary material Figure S9). This likely is an effect of missing
696 constraints near the symmetry axis because of few near-vertical ray paths for the majority of stations. The two stations
697 located furthest above the injection borehole with the highest number of near-vertical incidence angles, display
698 intermediate ε values of 8–12% and v_{p0} =5200–5400 m/s. The average velocities of v_{p0} =5275 m/s and v_{s0} =2980 m/s
699 from a sonic log for comparable depths in the vertical borehole of the nearby GFZ lab is consistent with the obtained
700 velocity models. The average horizontal velocities of v_{p90} =5650 m/s and v_{s90} =3260 m/s from sonic logs in the injection
701 borehole at the STIMTEC site are lower than the average velocities obtained for near-horizontal wave propagation
702 from the UT data (Figure 8). These sonic log velocities are more consistent with P-wave velocities derived for foliation-
703 parallel wave propagation at the GFZ lab. We interpret the lower values to reflect the effect of dispersion, given the
704 frequency content of the measurement (4–30 kHz for sonic log, 0.15–3 kHz for tomography at the GFZ lab, versus 5–
705 60 kHz for active UT at the STIMTEC site).

706
707 Anisotropy complicates the analysis of all measurements in the STIMTEC test volume, especially regarding velocity
708 model calibration and AE event location. In retrospect, we estimate that approximately one third of all active UT
709 measurements in combination with the lab measurements, sonic logging and other available information (Krauß et al.,
710 2010) would have been sufficient to characterise the single transverse isotropic velocity model, which captures the
711 general features of the background anisotropy on site. This implies that the effect of dispersion is insignificant.
712 However, to resolve the best-possible velocity model for each station and to obtain high-accuracy AE event locations
713 required a transverse isotropic velocity model per station, derived from a large amount of active in-situ velocity
714 measurements covering a range of incidence angles. The best velocity model per station allowed for a significant
715 location improvement of AE events from the injection and vertical validation borehole as shown by comparing the rms
716 travel-time residuals for different velocity models as well as the relocation error of known active UT measurement
717 points along the boreholes (Table 6). Neglecting anisotropy would lead to significant and systematic location bias by
718 up to 2.6 m (Figure 4b). The average P-wave anisotropy for the STIMTEC site is larger than observed for the granite
719 and granodiorite host rocks at the GTS (~7%) and AHRL but comparable to the phyllites at SURF (Gao et al., 2020).
720 Gischig et al. (2018) showed that at the GTS similar but slightly more scattered AE event clouds could be obtained
721 using the joint hypocenter determination method with an isotropic velocity model and station corrections for AE event
722 locations compared to using the anisotropic velocity model. Their approach is based on the weak anisotropy
723 approximation, but it suggests that the effect of anisotropy can be mitigated this way. However, 32 seismic stations
724 were installed at the GTS and structural heterogeneity is not as pronounced there as at the STIMTEC site, because the
725 shear zones are similar in orientation compared to the foliation causing anisotropy in the rock volume. Our work
726 demonstrates that high-resolution AE event locations (average rms=0.00015 s) can be obtained in heterogeneous rocks
727 with pronounced anisotropy, if an accurate velocity model can be derived. This requires numerous UT calibration
728 measurements from various angles, which is achievable for URL experiments, some computational effort to derive the
729 velocity model and a smart event location procedure. This demonstrates that hydraulic stimulation in complex rock

730 such as anisotropic and heterogeneous metamorphic gneiss is possible and can be monitored (with additional effort),
731 so future in-situ experiments do not need to consider homogeneous rocks only.

732
733 Lab experiments also documented a strong influence of the foliation on the mechanical strength and therefore on
734 fracture propagation and length (c.f. Adero 2020, Vervoort et al., 2014). The shallow depth of the STIMTEC site
735 results in low absolute stress magnitudes (1–6 MPa) and lower differential stress conditions compared to URL sites
736 elsewhere. To limit the effect of the foliation on the stimulation, the injection borehole was drilled at a 15°-angle to
737 the foliation. Despite the low absolute stress magnitudes, neither impression packer marks nor AE cluster orientations
738 indicated that the foliation determined fracture propagation in the injection borehole. This was also found at SURF,
739 where hydro-fractures did not follow the strong foliation but the inclined maximum principal stress over tens of meters
740 in the injection borehole (Oldenburg et al., 2016).

741
742 We observed significant velocity reductions (1–4%) associated with prominent pre-existing structures, in particular in
743 the deformation zones crossing the injection and long inclined validation boreholes (Figure 8). In general, we do not
744 observe a systematic velocity or amplitude reduction from UT measurements in the injection borehole after stimulation
745 as compared to before. We conclude that only prominent pre-existing structures identified in logs have a significant
746 effect (velocity drop larger than the average measurement uncertainty) on velocity and attenuation. Whether transient
747 fluid pressure variations during the stimulation have a measurable effect on velocity (Doetsch et al., 2018) and/ or
748 attenuation at the STIMTEC site remains the subject of further investigations, which will be attempted using relative
749 travel times from centre punch measurements as opposed to absolute travel times from UT measurements. P-wave
750 attenuation factors determined here for the fast anisotropy direction are generally consistent with the values obtained
751 for the GFZ lab (Krauß et al., 2010). Laboratory measurements revealed that attenuation perpendicular to the foliation
752 is stronger than parallel to the foliation (Adero, 2020), but this has not yet been investigated from the obtained field
753 data.

754

755 **5.4 Implications for monitoring field-scale hydraulic stimulation experiments**

756 In field-scale projects, sensor placement is significantly more limited and constrained than in mine-scale settings,
757 where due to the 3D placement of sensors in close vicinity of the injection a close to ideal situation for monitoring of
758 a hydraulic stimulation experiment is achieved (similar to the laboratory scale). By avoiding permanent installations
759 and temporarily removing seismic sensors, we could use the existing boreholes for different purposes throughout the
760 STIMTEC experiment (e.g. for hydraulic monitoring, for passive seismic monitoring using different sensors, for stress
761 measurements, repeating measurements to verify impression packer marks and for repeated active seismic
762 measurements). Accessible boreholes provided us with more flexibility, especially as more boreholes became available
763 during the course of the experiment. Adapting the monitoring (by implementing, testing, and assessing a new AE
764 hydrophone and a broadband borehole sensor) and modifying the order of stimulations proved successful to achieve
765 the monitoring goals of STIMTEC. During a recent geothermal stimulation in Finland adapting the stimulation
766 procedure in response to high-quality real-time monitoring observations was critical for controlling fluid-induced
767 seismicity (Kwiatek et al., 2019). Maintaining flexibility during experiments at the mine and field scale, which have
768 less controlled conditions as compared to lab experiments, is a key element to address surprises and unexpected

769 challenges, which seem inevitable given the higher degree of reservoir complexity observed at these scales. Flexibility
770 requires good on-site communication between the various groups involved in the experiment, time and budget to allow
771 for changes, as well as practical and integrated approaches to manage, exchange, visualise and interpret large 3-D data
772 sets of different formats during the experiment.

773
774 Another observation of fundamental importance was that approximately half of the stimulated intervals were not
775 accompanied by any AE activity, despite appropriate monitoring in-place. Villiger et al. (2020) estimated the amount
776 of aseismic deformation during hydroshear experiments at the GTS and compared this to the amount of seismic
777 deformation, showing that aseismic deformation was dominant for both brittle and brittle-ductile structures. This
778 estimation was based on the total moment, calculated from borehole dislocations of mapped fractures, compared to
779 cumulative seismic moment of AE events and observed cloud extents. Guglielmi et al. (2015), De Barros et al. (2019)
780 and Cornet (2016, and references therein) also showed that deformation is mainly aseismic during stimulations in softer
781 rocks (shales, limestone) at the intermediate scale and sedimentary rocks at the field scale. To simultaneously capture
782 fast and slow deformation processes, which are currently often categorised as either seismic or aseismic due to the
783 limitations of current monitoring systems, requires better high-sensitivity instrumentation with a wider bandwidth.
784 Alternatively, the combination of sensors with different sensitivity and frequency ranges (e. g. AE sensors, broadband,
785 tilt, fibre-optic based strain sensors) is necessary, but requires time synchronisation and amplitude calibration, which
786 can pose sophisticated technical problems (c.f. Zang et al., 2017). To address these, marker signals and regular active
787 seismic measurements proved valuable during the STIMTEC experiment. The mine scale has the advantage that new
788 tools and/or different configurations (numerous sensor arrays) can be more easily tested, and maybe regular high-
789 resolution laser-scan tunnel mapping (Grehl et al., 2015) can be applied as an equivalent tool to InSAR, which was
790 successful in monitoring larger-scale slow- deformation processes at the reservoir scale.

791 **6 Summary and conclusions**

792 Meso-scale experiments currently provide the most-detailed in-situ information to further understanding of hydro-
793 mechanical processes associated with hydraulic stimulation and allow for validation of inferred results. In the here
794 presented STIMTEC experiment, conducted in the Reiche Zeche mine URL at 130 m depth, we used a high-resolution
795 seismic monitoring network comprising twelve in-situ AE sensors (for high-sensitivity monitoring of induced
796 seismicity and the recording of active source signals), three accelerometers (for sensor cross-calibration purposes), one
797 broadband sensor (to extend monitoring to the low frequency range) and an AE-hydrophone (to improve the network
798 sensitivity in the deeper rock volume of the experiment). We relocated two monitoring stations and tested new sensors
799 during the course of the experiment to optimise passive and active seismic monitoring. In contrast to other similar
800 experiments, we stimulated strongly foliated rock with pronounced anisotropy during STIMTEC. We acquired a large
801 quantity of active UT measurements for characterising the anisotropy and heterogeneity of the host rock. We monitored
802 in near-real-time small-scale rock failure and friction processes associated with hydraulic stimulation and tracked the
803 spatio-temporal distribution of AE events.

804 The key observations from the experiment are: (1) We demonstrated that high-frequency (up to 100 kHz) seismic
805 monitoring in complex rock volumes with pronounced anisotropy is possible, if measures are taken to accurately
806 quantify the 3-D anisotropic velocity structure. (2) We applied Thomsen's exact phase velocity equations to deduce a

807 transverse isotropic velocity model per station that accurately locates known active ultrasonic measurement points in
808 the stimulated boreholes. Estimates of the uncertainties related to simplifications of the velocity structure and
809 neglecting anisotropy significantly affect resolution and range between 0.5 and 2.6 m in our experiment. (3) We
810 obtained average Thomsen parameters (P-wave anisotropy of 12%) in agreement with those derived from laboratory
811 and sonic logging data. (4) We observed that rock mass heterogeneity as seen in high-fracture density zones overprints
812 the anisotropy of the host rock and has a significant influence on velocity and attenuation. (5) We observed seismic
813 responses to hydraulic stimulation in ten intervals in the injection borehole, performed with similar injection protocols,
814 ranged from abundant AE activity to no AE activity and are unrelated to monitoring limitations. We attribute the
815 observed variability in deformation to the small-scale rock mass and stress field heterogeneity observed in the injection
816 borehole.

817
818 Our observations indicate that stimulation of strongly foliated and fractured rock mass, such as the Freiberg gneiss,
819 results in activation of a complex fracture network. We infer that most of the induced deformation of the reservoir
820 remains aseismic given the high number of stimulated intervals with little or without AE activity and the observed
821 low-frequency signals recorded by the borehole broadband sensor. Aseismic deformation may be related to injection
822 into open pre-existing fractures in the injection interval; yet, borehole logs do not systematically show pre-existing
823 fractures present in ‘quiet’ stimulated borehole intervals.

824

825 **Data availability**

826 All active UT transmission data used in this study, sensor coordinates, measurement recording times and positions as
827 well as manually identified phase arrivals are available from the GFZ data server ([https://dataservices.gfz-](https://dataservices.gfz-potsdam.de/panmetaworks/review/fe97aa96c11b9aebca07a838bcb37a99e659ab2280e4045905484df76ae959c1/)
828 [potsdam.de/panmetaworks/review/fe97aa96c11b9aebca07a838bcb37a99e659ab2280e4045905484df76ae959c1/](https://dataservices.gfz-potsdam.de/panmetaworks/review/fe97aa96c11b9aebca07a838bcb37a99e659ab2280e4045905484df76ae959c1/))

829

830 **Author contributions:**

831 GD conceptualised the experiment and acquired funding for it, GD, GK and KP planned the experiment and its
832 instrumentation, CB, TF, KP, FB and CJ conducted fieldwork, JS and FB helped CB with data curation. CB
833 administered the project, formally analysed the data and lead the investigations. CB wrote the manuscript with
834 feedback and reviewing by GD, GK and KP.

835

836 **Competing interests:**

837 The authors (except TF, KP and FB) state that they are currently employed at the same institution as the
838 journal’s chief executive editor Charlotte Krawczyk.

839

840 **Acknowledgements**

841 This project was funded by the BMBF, project number 03G0874C. We thank LfLUG for providing fault surface data
842 created on a small scale, a mine layout of the Reiche Zeche mine complex and surrounding mines and a digital elevation
843 model. Staff from GMuG, Bad Nauheim, and Mesy SolExperts, Bochum, are thanked for their field measurement
844 contributions to this project. Support by Frank Reuter and his team of miners at Reiche Zeche is gratefully
845 acknowledged. Discussions with Joerg Renner and Marco Bohnhoff substantially improved this manuscript. We thank
846 Chet Hopp and an anonymous reviewer for their detailed reviews.

1052

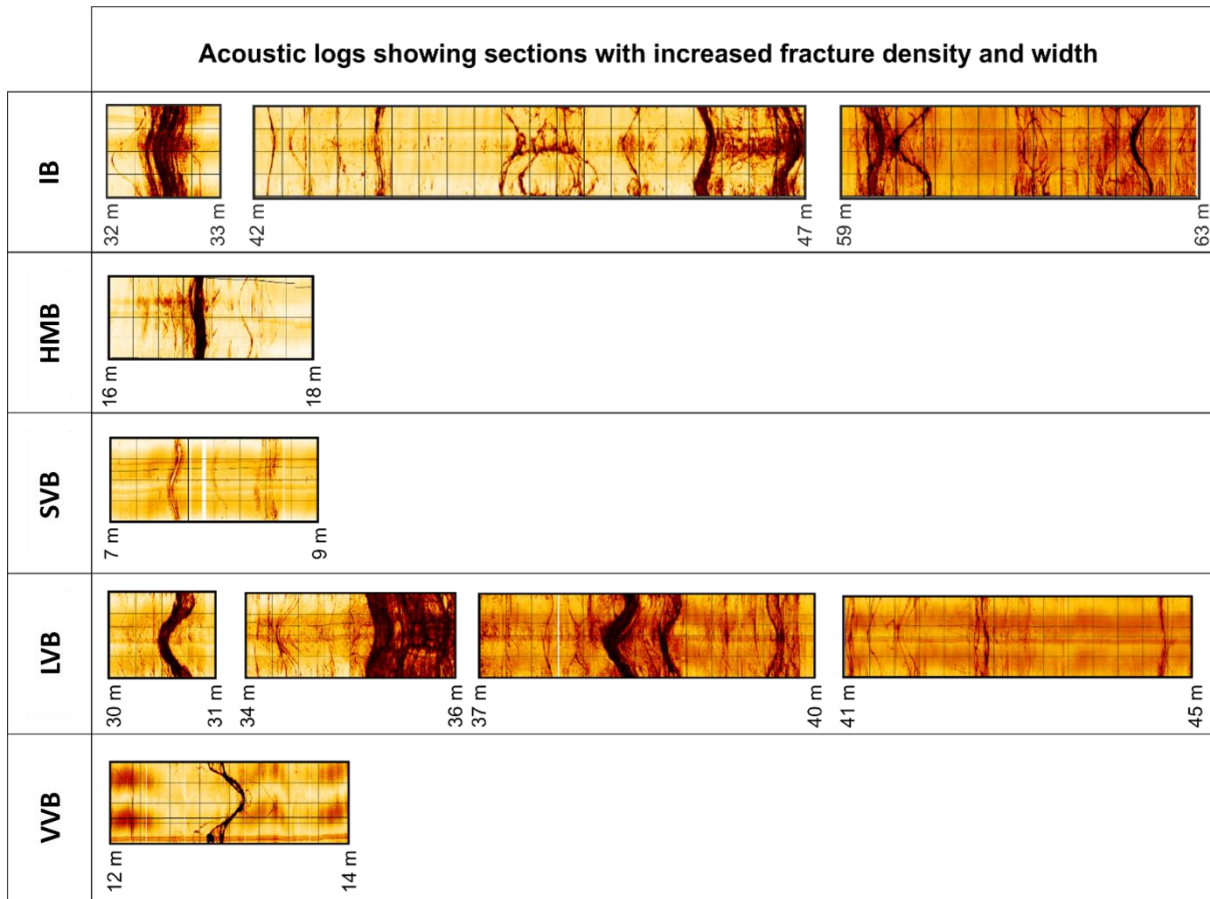

1053

1054 **Figure 1: Overview of the borehole network and mapped structures along the galleries at the STIMTEC site in the Reiche**
1055 **Zeche mine. Eastern gallery is the curved vein drift, the western gallery is the straight driftway, which is oriented almost**
1056 **north–south. Deformation zones (brown zones) are marked along the galleries and assumed to belong to connected systems**
1057 **between the galleries based on the orientations of mapped structures identified in the pre-characterisation phase of the**
1058 **experiment. The monitoring system comprises twelve acoustic emission piezo-sensors (purple) located in horizontal or**
1059 **upward going seismic monitoring boreholes (yellow). Three accelerometers (light green) are collocated with AE sensors. A**
1060 **broadband sensor was moved from a short horizontal borehole off the vein drift to the vertical validation borehole (red) in**
1061 **driftway during the course of the experiment. An AE-hydrophone was placed at the bottom of the hydraulic monitoring**
1062 **borehole (green) for the last hydraulic testing phase of the experiment. Stimulation intervals (dark blue) in the injection**
1063 **borehole (cyan) and the vertical validation borehole (red) are shown together with hydraulically tested intervals (light blue).**
1064 **Inset shows the regional setting of the mine in Freiberg, Germany.**

1065

1066

1067

1068

1069 **Figure 2: Acoustic borehole televiewer logs indicating sections along the boreholes with increased fracture density and width,**
 1070 **intercepted by the injection borehole (IB), hydraulic monitoring borehole (HMB), short inclined (SVB), long inclined (LVB)**
 1071 **and vertical (VVB) validation boreholes. Modified from Adero (2020).**

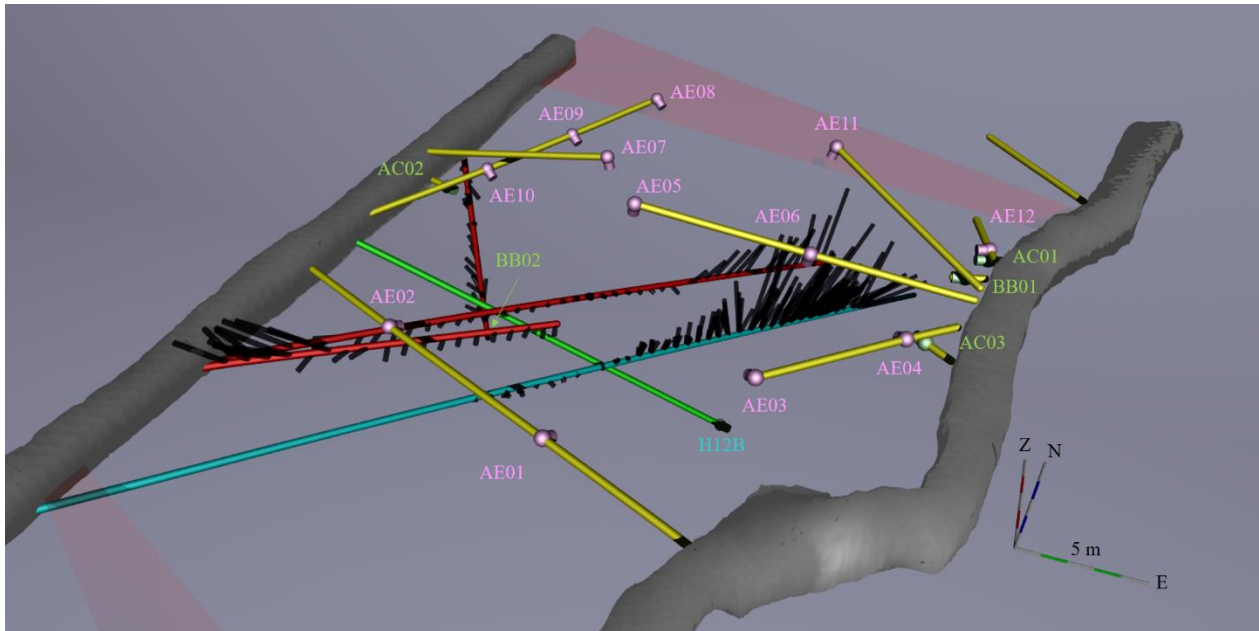

1072

1073

1074 **Figure 3: Overview of active seismic measurements within the STIMTEC volume: Ray paths show coverage achieved using**
 1075 **UT measurements from boreholes to sensors. See Supplementary Material Figure 3 for different 3-D views. Hit points (black**
 1076 **stars) along the galleries mark positions of repeated active hammer and centre punch measurements.**

1077

1078

1079

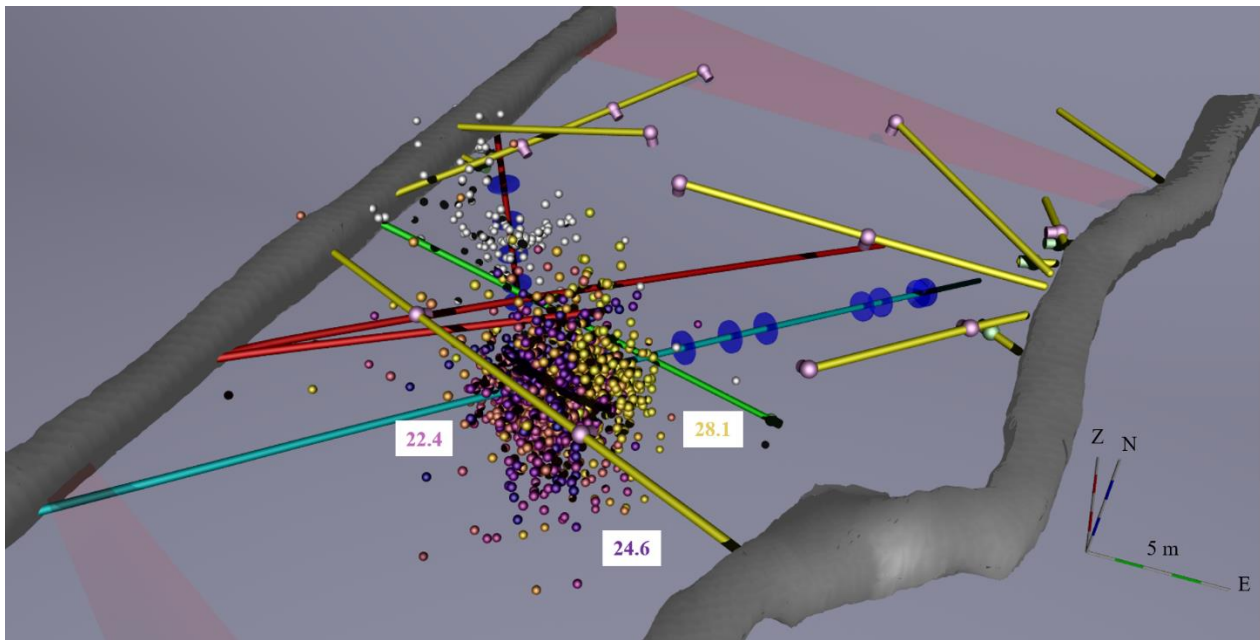

1080

1081 **Figure 4: a) Overview of location uncertainty estimates (black lines) along the injection, vertical and horizontal validation**
 1082 **boreholes as estimated from locating known UT measurement positions (see Figure 3) with the derived best transverse**
 1083 **isotropic velocity model per seismic sensor. Note that the location error becomes larger than 1 m, where the injection (cyan)**
 1084 **and long inclined validation borehole (red) show higher numbers of fractures and more prominent ones (c.f. Figure 2). As**
 1085 **shown in more detail in Supplementary Material Figure 4, the estimated location uncertainty is systematically directed**
 1086 **upwards, likely a result of the station distribution. Labels refer to AE sensors (pink), accelerometers or broadband sensor**
 1087 **(green, with the broadband sensor being moved to a new position during the experiment) and AE hydrophone (blue).**
 1088 **Deformation zones (pink zones) that transverse the rock volume between the galleries are also shown.**

1089 **b) Comparison of location error of known active UT measurement points in the injection, vertical and horizontal validation**
 1090 **boreholes as well as the hydraulic monitoring borehole for different velocity models. Relocation errors in black are obtained**
 1091 **using the best transverse isotropic velocity model per station, in red from the single transverse isotropy velocity model and**
 1092 **in blue from the isotropic velocity model. Coloured horizontal lines represent averages relocation errors for the given depth**
 1093 **range. Note that the anisotropic velocity model per station minimizes the location uncertainties over most depth ranges in**
 1094 **all boreholes, except for the vertical validation borehole, where the single transverse isotropy model performs slightly better.**
 1095 **The isotropic velocity model performs better at larger borehole depths (where no AE events were observed) and in the wider**

1096 fracture zones of the injection and long validation boreholes (as indicated by the vertical grey bars, which correspond to the
 1097 sections shown in Figure 2).

1098

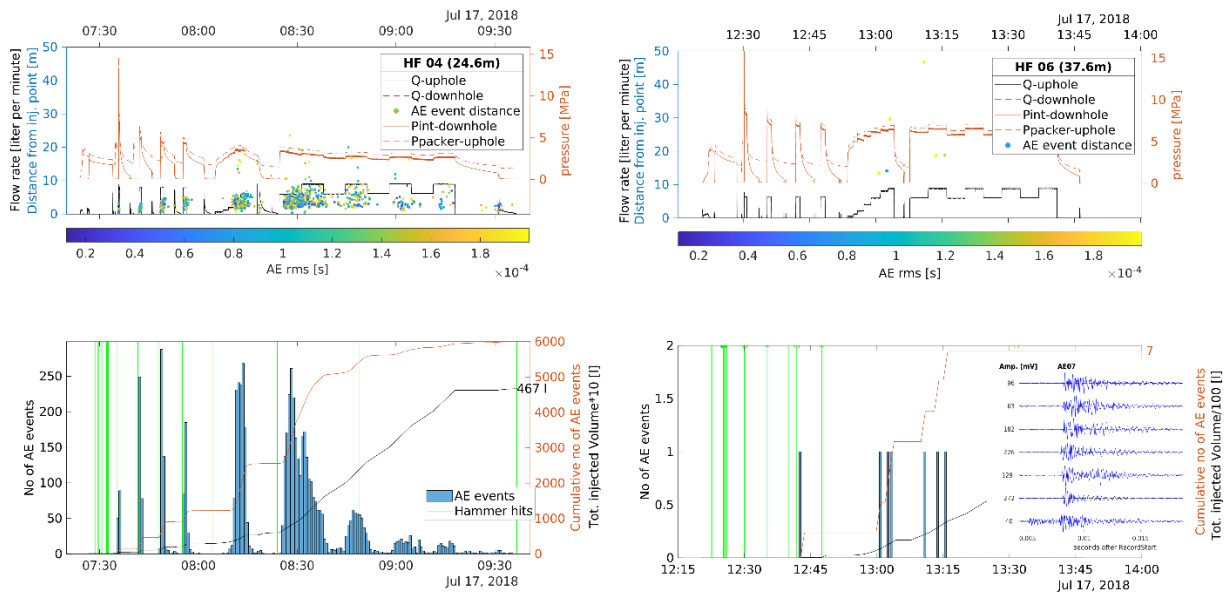

1099

1100 **Figure 5: Acoustic emission (AE) locations obtained for stimulations in the injection borehole (coloured dots according to**
 1101 **stimulated interval as marked) and the vertical validation borehole (white dots). See Supplementary material Figure S5 for**
 1102 **different 3-D views. Note that the intermediate-depth and deep stimulated intervals in the injection borehole produced little**
 1103 **to no AE activity**

1104

1105

1106

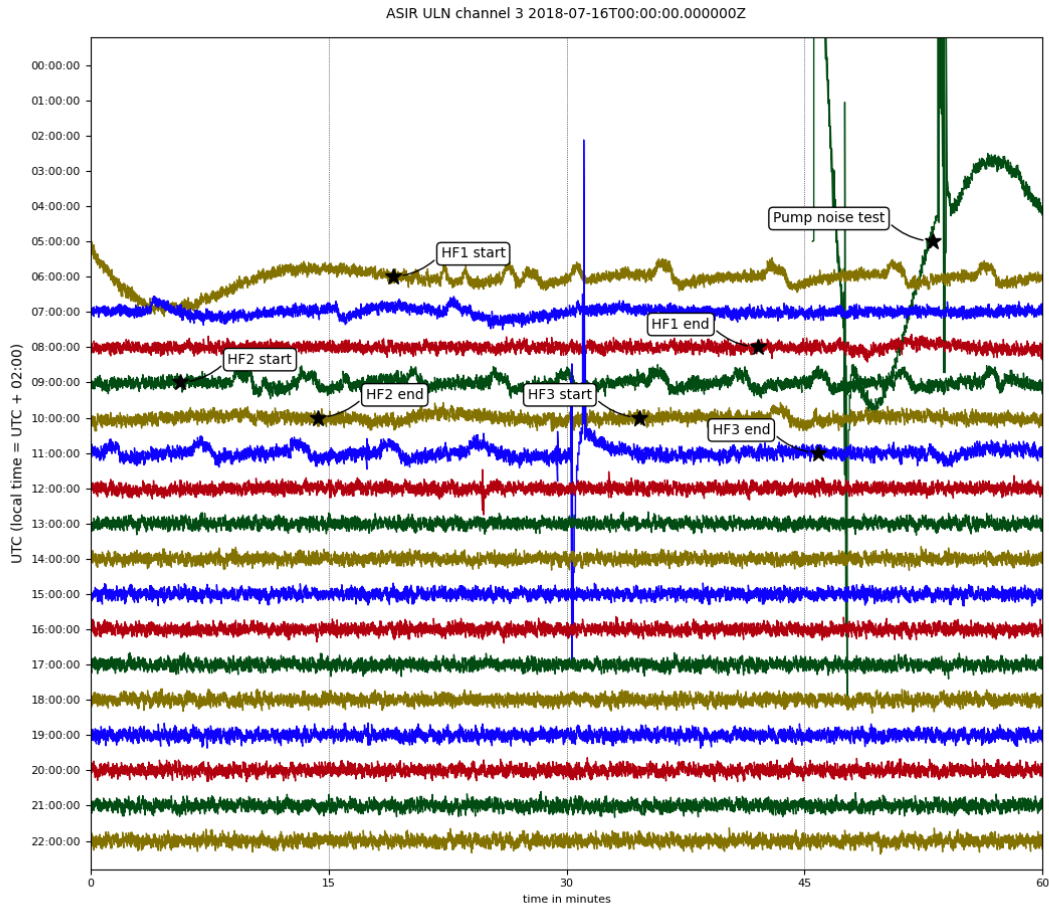

1107

1108 **Figure 6: Stimulation sequence consisting of a frac, three refracs, step-rate pump test and periodic pumping test for the**
 1109 **intervals at 24.6 m and 37.6 m borehole depth in the injection borehole. Top panel shows flow rate (black) and pressure**

1110 records (orange) measured in the intact intervals downhole and at the wellhead uphole as well as the acoustic emission (AE)
1111 activity plotted with distance from the center of the injection interval (coloured dots). Bottom panel shows an AE event
1112 histogram (blue), the cumulative number (orange) of located AE events and the cumulative injected volume (black). Active
1113 hammer hits (green lines) were used as marker signals throughout the injection sequence. An example of all the AE events
1114 observed during stimulation of interval 37.6 m as recorded by sensor AE07 is shown as an inset.

1115

1116

1117

1118

1119

1120 **Figure 7: Daily records of the horizontal channel of the ASIR and vertical channel FBE broadband sensor located at Reiche**
 1121 **Zeche mine for the first day of stimulation on 16 July 2018. The distance between both sensors is ca. 440 m. Hydrofrac start**
 1122 **and end times are marked (by stars) as listed in Table 2. Note that long period swings in the records result from bandpass**
 1123 **filtering (0.001–1 Hz) in combination with data gaps as seen for the beginning of the records for the ASIR sensor and**
 1124 **throughout the day for FBE. Some local quarry blasts are seen on both sensors, whereas stimulation related signals are only**
 1125 **visible on the ASIR broadband sensor deployed at the STIMTEC site. Note that the two largest drops seen for the ASIR**
 1126 **sensor are likely associated with sensor self-centering as determined on a shake table at GFZ lab after the experiment. See**
 1127 **Supplementary Material Figure 7 for the other stimulation intervals during the following two days of stimulation.**

1128

1129 **Figure 8: Apparent velocities obtained from the source-receiver distance divided by the travel-time from ultrasonic**
 1130 **transmission (UT) measurements used for calibration of the transverse isotropic P-wave velocity model. (a) Average**
 1131 **apparent velocities with uncertainty estimate (<145 m/s) against measurement depth in the borehole and (b) velocity against**
 1132 **angle relative to the vertical symmetry axis. The red line shows the theoretical P-wave velocities with incidence angle as**
 1133 **determined using the Thomsen parameters derived from the laboratory measurements on Freiberg gneiss samples ($\alpha=5300$**
 1134 **m/s, $\delta=0.12$, $\epsilon=-0.05$). Measurement ranges obtained from sonic logs (cyan) from the vertical borehole in the GFZ lab and**
 1135 **from the 15°-inclined STIMTEC injection borehole are shown, as well as from P-wave tomography parallel to the foliation**
 1136 **direction in the GFZ-lab (blue). Velocity estimates obtained in the deformation zone in the injection borehole as shown in**
 1137 **Fig. 2 are marked by grey bars in (a) and black points in (b). See also Supplementary Material Figure S8 for the other**
 1138 **inclined boreholes.**

1139

1140

1141

1142

1143

1144 **Table 1: Results of stress measurements through overcoring by Mjakischew (1987) at 140 m depth in the Reiche Zeche Mine**

1145

Principal stress	Magnitudes [MPa]	Orientation/Plunge [°/°]	
σ_1	4.5	347/0	NNW/Horizontal
σ_2	3.6	0/90	-/Vertical
σ_3	3.0	77/0	ENE/Horizontal

1146

1147 **Table 2: Overview of stimulation details for the ten stimulated intervals of the injection borehole. The total injected volume and number of AE events are given for the whole stimulation sequence as shown in Figure 4. The stimulation intervals were chosen to contain as little pre-existing structures as possible based on cores and acoustic logs. The interval condition was reassessed based on the stimulation results as either intact where hydrofracs were created or pre-fractured, meaning that hydroshearing occurred.**

Table 4: Parameter setting for automatic picking routine.

parameter	initial pick	final pick
3rd order band-pass filter	[8, 50] kHz	[0.5, 120] kHz
AIC window width	0.0015 s	same
boundaries for uncertainty limits	[-0.0012, 0.0088] s	same
window boundaries for mean energy	[-0.001, 0.009] s	-
min SNR (amplitude/standard dev.)	(3,2)	-

1160 **Table 5: Thomsen parameters (ϵ , δ , and γ) characterising elastic anisotropy of the rock mass derived from fitting all active seismic UT measurements per seismic station. The last two columns give the numbers of measurement points for v_p and v_s , from which the parameters were derived.**

Station	ϵ	δ	v_{p0}	v_{s0}	γ (fixed)	Number v_p	Number v_s
AE01	0.02	-0.10	5.8	2.9545	0.18	70	58
AE02	0.02	-0.18	5.7	3.2386	0.18	72	36
AE03	0.02	0.14	5.5	2.5568	0.18	63	25
AE04	0.02	0.20	5.9	2.5568	0.18	66	1
AE05	0.08	-0.01	5.4	3.0682	0.18	73	12
AE06	0.16	0.38	5.8	2.6705	0.18	73	6
AE07	0.12	0.14	5.2	2.9545	0.18	73	22
AE08	0.28	0.84	4.6	2.5568	0.18	73	11
AE09	0.14	0.04	5.2	2.8977	0.18	73	49
AE10	0.1	-0.16	5.5	2.6136	0.18	73	32
AE11	0.10	0.26	5.2	2.8977	0.18	73	3
AE12	0.02	-0.22	5.9	2.7841	0.18	71	1

1170 **Table 6: Comparison of root-mean-square residual and number of obtained event locations in the injection (IB) and vertical validation borehole (VVB) obtained using different velocity models. For location accuracy assessment, the average relocation error of the known UT measurement points outside of identified damage zones is provided which represents an average of all values shown in Figure 4b.**

Velocity model	RMS IB $\cdot 10^{-4}$ s (number AE events located with P and S)	RMS VVBH $\cdot 10^{-4}$ s (number AE events located with P and S)	Average relocation error outside damage zones (m) (located with P only)
Isotropic model ($v_P=5.6$ km/s, $v_P/v_S=1.76$)	2.8 \pm 1.2 (2842)	1.6 \pm 1.3 (401)	1.7 \pm 0.80
Transverse isotr. model ($v_{P0}=5.3$ km/s, $v_{P0}/v_{S0}=1.76$, $\epsilon =$ 11.3%)	2.9 \pm 1.3 (3080)	1.3 \pm 1.3 (402)	1.1 \pm 0.78
Transverse isotr. model with SNR weighting	1.9 \pm 1.3 (4634)	1.3 \pm 1.3 (405)	0.9 \pm 0.65
Trans. isotr. model per station ($v_{P0}=5.25$ km/s, $v_{P0}/v_{S0}=1.76$, $\epsilon =$ 12%)	1.6 \pm 1.2 (4613)	1.0 \pm 1.3 (395)	0.8 \pm 0.73
Trans. isotr. model per station with SNR weighting	1.5 \pm 1.3 (5531)	0.9 \pm 1.3 (392)	0.8 \pm 0.70
