

1 results show that the pore spaces include residual intergranular pores, intergranular and
2 intragranular dissolution pores, and micro-fractures. The sandstones experienced a high
3 degree of mechanical compaction, and compaction is limited in well-sorted rocks or
4 abundant in rigid quartz grains. The most volumetrically important diagenetic minerals are
5 calcites. The framework grains experienced a varied degree of dissolution, and intergranular
6 and intragranular dissolution pores are formed. Special aims are paid on the dissolution
7 associated with the fracture planes. Most natural fractures are cemented by carbonate
8 cements, which limit fluid flow. In addition, presences of fracture enhance dissolution, and
9 the fracture planes are enlarged by dissolution. Cementation and dissolution can occur
10 simultaneously in fracture surfaces, and the enlarged fracture surfaces can be cemented by
11 late-stage cements. The in situ stress magnitudes are calculated using well logs. The
12 horizontal stress difference ($\Delta\sigma$) determines the degree of mechanical compaction, and rocks
13 associated with low $\Delta\sigma$ experienced a low degree of compaction, and there contain preserved
14 intergranular pores. Natural fractures are mainly related to the low $\Delta\sigma$ layers. The presences
15 of intergranular and intragranular dissolution pores are mainly associated with the fractured
16 zones. The high quality reservoirs with intergranular pores or fractures are related to low $\Delta\sigma$
17 layers. The structural diagenesis researches above help the prediction of reservoir quality in
18 ultra-deep sandstones, and reduce the uncertainty in deep natural gas exploration in Kuqa
19 depression.

22 ultra-deep sandstone

1 Introduction

2 The Kuqa depression is a foreland depression experienced multistage tectonic
3 evolutions during Mesozoic to Cenozoic periods, consequently many high and steep thrust
4 faults and fault-related folds were formed (Feng et al., 2018; Neng et al., 2018; Lai et al.,
5 2019). In addition, the dominant gas bearing Lower Cretaceous Bashijiqike Formation is
6 buried to an ultra-deep depth of 5500-8000m (Lai et al., 2019). The ultra-deep burial depths,
7 complex structure patterns and concentrated stress will result in complex diagenetic
8 modifications and pore evolution histories (Laubach et al., 2010; Wu et al., 2019; Del Sole et
9 al., 2020). Previous studies have individually unraveled the structural evolution, in situ stress,
10 fracture as well as diagenesis of Bashijiqike Formation in Kuqa depression (Jia and Li, 2008;
11 Lai et al., 2017a; Shen et al., 2017; Nian et al., 2018; Ju and Wang, 2018; Lai et al., 2019).
12 Despite the extensive researches on diagenesis and structure, few researches have been
13 conducted on the structural diagenesis by interacting structure with diagenesis.

14 Structural diagenesis, a cross-disciplinary approach investigating relationships between
15 structures (deformation, fractures, etc) and diagenesis (Laubach et al., 2010), helps to better
16 understand the changes in reservoir petrophysical properties and subsurface fluid flow
17 (Vandeginste et al., 2012; Matonti et al., 2017; Ferraro et al., 2019; Wu et al., 2019;
18 Rodrigues et al., 2021). Foreland fold-and-thrust belts are challenging for hydrocarbon
19 exploration due to their structural complexity and heterogeneous reservoir quality
20 distribution (Vandeginste et al., 2012). Actually the structural complexity highly impacts
21 fluid flow and diagenetic processes (Vandeginste et al., 2012). Therefore the comprehensive
22 structural diagenesis analysis in Kuqa depression is of great scientific and practical

1 significances.

2 This study is focused on linking diagenesis to structural complexity, and is organized as:

3 1) to describe the lithology and pore spaces; 2) to unravel the type and degree of diagenesis

4 and diagenetic minerals; 3) to characterize the fracture using core and image logs; 4) to

5 unravel the dissolution and cementation along the fracture surfaces; 5) to calculate the in situ

6 stress magnitudes; 6) to describe the in situ stress, compaction and preservation of

7 intergranular pores, as well as the fracture enhanced dissolution; 7) to unravel the diagenesis

8 (preservation of intergranular pores, formation of dissolution pores, and fracture) within the

9 structural complexity. Results of this study are hoped to better understand the structural and

10 diagenetic processes, and reduces the uncertainty for reservoir quality prediction of

11 ultra-deep sandstones in Kuqa depression.

12

13 **2. Geological Settings**

14 The Kuqa depression is located in the North Tarim Basin, West China (Fig.1A, 1B).

15 The petroliferous Tarim Basin is located between the Tianshan and Kunlun Mountains, and

16 occupies an area of $56 \times 10^4 \text{ km}^2$ (Fig.1A) (Jin et al., 2008; Qiu et al., 2012; Gao et al., 2016;

17 Jiang et al., 2016; Fu, 2019). The Kuqa depression experienced a long and complex

18 evolutionary history during the Mesozoic to Cenozoic time, forming two sags and three

19 structural belts: Baicheng and Yangxia Sag, northern monocline, Kelasu and Qilitage

20 structural belts (Lai et al., 2015; Shen et al., 2017; Feng et al., 2018; Ju and Wang, 2018).

21 Large numbers of thrust faults and fault related folds, which act as structural traps in the

22 Kuqa depression (Fig.1C), were formed due to the multistage tectonic activity and strength

1 tectonic stress (Zhang and Huang, 2005; Zeng et al., 2010; Nian et al., 2016; Feng et al.,
2 2018; Zheng et al., 2020). Four wellblocks are recognized in the Kelasu structural belts, and
3 they include Bozi, Dabei, Keshen and Kela well blocks (Fig.1C).

4 The Mesozoic and Cenozoic strata are over 10, 000m thickness (Chen et al., 2000; Zou
5 et al., 2006). There contains a well-developed reservoir-cap rock assemblage in the Kuqa
6 depression (Jin et al., 2008). Among them, the Lower Cretaceous Kapushaliang Group (K_1kp)
7 and Bashijiqike Formation (K_1bs) are the dominant reservoir intervals, and many giant gas
8 fields including Kela 2, Awa, Bozi, Dina, Dabei, Keshen gas fields have been discovered in
9 this gas bearing formation (Fig.1C) (Jin et al., 2008; Shen et al., 2017; Nian et al., 2018).
10 The overlying Kumugeliemu group (E_{1-2km}) acts as the regional cap rocks in the Kuqa
11 depression due to the favorable cap property of the thick-layer gypsum salt rocks (Fig.1C).
12 Additionally, the underlying Triassic-Jurassic coal bearing formations (Jurassic Yangxia
13 formation (J_{1y}), Triassic Karamay (T_2k) and Huangshanjie (T_3h) formations) are the source
14 rocks in Kuqa depression (Zhao et al., 2005; Shen et al., 2017).

15 The Lower Cretaceous Bashijiqike Formation is divided into three members (K_1bs_3 ,
16 K_1bs_2 and K_1bs_1 member) from bottom to top. Depositional facies of the Bashijiqike
17 Formation are recognized as fan-braided deltaic environments (Jia and Li, 2008). The
18 lithologies include a wide range from siltstone, fine-medium grained sandstone, to
19 conglomerate and pebbly sandstones, and intergranular, intragranular pores as well as
20 fracture constitute the main reservoir pore spaces (Nian et al., 2018; Lai et al., 2019; Nian et
21 al., 2021). The depositional subfacies evolved from fan delta plain in K_1bs_3 to braided delta
22 front subfacies in K_1bs_2 and K_1bs_1 members, and the main depositional microfacies

1 recognized include distributary channel, mouth bar and distributary bay (Wang et al., 2013;
2 Lai et al., 2017a; Nian et al., 2018).

3

4 **3. Data and methods**

5 Cores were taken from 18 cored wells, and photos were taken for each species of core.
6 In addition, almost all the examined cores were slabbed 360° to better show the distinct
7 characteristics of core surfaces.

8 Approximately 200 thin sections were polished to approximately 0.03 mm and
9 impregnated with blue resin to highlight porosity. Thin sections were also stained with
10 mixed Alizarin Red S and potassium ferricyanide solution for differentiating various types of
11 carbonate minerals (calcite, dolomite and their ferroan equivalents).

12 Thin sections were firstly examined by optical transmitted light and subsequently
13 Cathode Luminescence (CL) microscopy. The CL observations were made using a
14 ORTHOPLAN cold cathode device.

15 SEM (scanning electron microscope) (secondary electron image) coupled with an
16 energy dispersive x-ray analyzer was used to detect the various types of clay minerals and
17 recognize the micropores within clay minerals.

18 Conventional well logs include three lithology logs as calipers (CAL), Gamma ray
19 (GR), Spontaneous Potential (SP); three porosity logs as sonic transic time (AC) and
20 compensated neutron log (CNL), and bulk density (DEN); deep and shallow lateral
21 resistivity logs (LLD, LLS).

22 Schlumberger's FMI (Fullbore Formation MicroImager) image logs were used to

1 obtain the high resolution (5mm) borehole images. A series of data processes including
2 speed correction, eccentering correction, and normalization were used to generate the static
3 and dynamic images. Beddings, natural and induced fractures are manually picked out on
4 the image logs by fitting sinusoidal waves (Lai et al., 2018; Nian et al., 2021).

5

6 **4. Results**

7 **4.1. Lithology and pore systems**

8 The lithologies of the Cretaceous Bashijiqike Formation in Kuqa depression include a
9 wide ranges from conglomerate (Fig.2A), pebbly sandstone (Fig.2B), fine-medium grained
10 sandstone (Fig.2C-2D), siltstone (Fig.2E-2F), and mudstone (Fig.2G-2H), indicating a
11 fan-braided deltaic environment (Jia and Li, 2008; Wang et al., 2013; Lai et al., 2018).

12 The pore spaces include residual intergranular pores with irregular morphology (Fig.3A,
13 3B), intergranular and intragranular dissolution pores (Fig.3C, 3D) due to dissolved feldspar
14 and rock fragment grains. In some cases, the coexistence of intergranular pores and
15 intragranular dissolution pores is common (Fig.3A-3D). Micro-fractures can also constitute
16 an important pore space (Fig.3E, 3F). Micro-fracture can occur in sandstones with evident
17 intergranular pore spaces (Fig.3E), and they also can be detected in carbonate cemented
18 sandstones (Fig.3F).

19

20 **4.2. Diagenesis type and degree**

21 The degree of mechanical compaction varied significantly for the Bashijiqike
22 sandstones in Kuqa depression (Lai et al., 2017a). The sandstones are buried to a great depth

1 from 5500-8000m, and compaction is extensive due to the overburden rocks. The rocks are
2 very heavily compacted especially the very fine-grained or poor sorted rocks (Fig.4A-4B).
3 However, some of the rocks which are well –sorted or abundant in rigid grains can preserve
4 large amounts of intergranular pores (Fig.3A-3B). In addition, the pore-line grain contacts
5 also suggest a limited degree of compaction (Fig.4C).

6 Diagenetic minerals are mainly carbonates, and they are the most volumetrically
7 important (Fig.4D). Carbonate cements, which are in the form of calcites (Fig.4D) and
8 dolomites (Fig.4E), significantly reduce pore spaces. There are even no evident pore spaces
9 in rocks which are extensively cemented by carbonates (Fig.4D, 4E). The CL images prove
10 the extensive carbonate cements in the intergranular pore spaces, and they can even replace
11 framework grains (Fig.4F). There are also minor amount of quartz cements and clay minerals
12 in the Bashijiqike sandstones of Kuqa depression (Lai et al., 2017a).

13 Dissolution occurred along the framework grain boundary and the intragranular pore
14 spaces, forming intergranular and intragranular dissolution pore spaces (Fig.4G, 4H). The
15 dissolution degree is also varied greatly, and significant dissolution is mainly associated with
16 the fine-medium grained rocks (Fig.4G, 4H). The secondary dissolution pores are developed
17 due to framework grains (feldspar and rock fragments) dissolution (Fig.4G, 4H).

18

19 **4.3. Compaction, cementation and porosity reduction**

20 Compaction and pore filling cements will reduce porosity in sandstones (Houseknecht
21 et al., 1987; Lima and DeRos, 2002; Mansurbeg et al., 2008; Lai et al., 2015; Haile et al.,
22 2018).

1 The compactional porosity loss (COPL) is commonly estimated by Eq.(1):

$$2 \quad COPL = OP - \frac{(100 \times IGV) - (OP \times IGV)}{(100 - IGV)} \quad (1)$$

3 Where OP is the original porosity (the OP values were estimated as 40% for
4 fine-medium grained, well sorted sandstone), and IGV is the sum of present intergranular
5 porosity and total cement content (intergranular porosity before cementation but after
6 compaction) (Houseknecht et al., 1987; Ozkan et al., 2011; Lai et al., 2015).

7 The cementational porosity loss (CEPL) can be calculated as Eq.(2) (Houseknecht et al.,
8 1987; Zhang et al., 2008; Ozkan et al., 2011):

$$9 \quad CEPL = (OP - COPL) \times \frac{CEM}{IGV} \quad (2)$$

10 Where OP is the original porosity, COPL is compactional porosity loss, and CEM is the
11 total cement volume percentages of rock volume.

12 The calculated results show that COPL range from 11.8% to 39.6% with an average of
13 32.0%, while CEPL is in the range from 0 to 27.2%, and averaged as 5.2% (Fig.5). Porosity
14 reduction by mechanical compaction was more significant than by cementation (Fig.5).
15 However, COPL shows no evident relationship with burial depth, and can reach as high as
16 40% even are shallower buried, and even in depths deeper than 7500m, the COPL can be
17 lower than 20% (Fig.5).

18

19 **4.4. Fracture and image log characterization**

20 Natural fractures are important subsurface fluid flow conduits and they play important
21 roles in hydrocarbon accumulation and production (Khoshbakht et al., 2009; Zeng, 2010;
22 Lyu et al., 2016; Lyu et al., 2017; Laubach et al., 2019). In terms of fracture attributes (dip

1 angles), natural fractures can be divided into vertical fractures and high dip angle fractures
2 ($>60^\circ$), medium dip angle fractures (30° - 60°), and low angle fracture ($<30^\circ$) and horizontal
3 fracture from the aspect of image log interpretation. Additionally, fracture can be classified
4 into open, partly open or closed fractures in terms of fracture status. Natural fractures can be
5 easily picked out from the image logs as dark sinusoidal waves in case the drilling muds are
6 conductive (water based drilling muds) (Fig.6) (Ameen et al., 2012; Khoshbakht et al., 2009;
7 Lai et al., 2019). The continuity of the sinusoidal waves depend on the filling degree of
8 fracture surfaces, i.e., the partly to fully closed fractures (sealed by resistive calcite cements)
9 may show discontinuous to continuous bright sinusoidal waves on the image logs.

10 Dip direction of fracture can be derived from the lowest point of the sinusoidal waves,
11 while dip angles can be determined by the sine wave amplitudes (Fig.6) (Nie et al., 2013;
12 Keeton, et al., 2015). Therefore the bedding planes, natural open and closed fractures can be
13 picked out for the entire log intervals. Then rose diagrams of bedding planes, open and
14 closed fractures can be drawn (Lai et al., 2021) (Fig.7). In addition, four fracture parameters
15 including fracture aperture (FVAH), fracture density (FVDC), fracture porosity (FVPA) and
16 fracture length (FVTL) can be calculated from the image logs (Table.1) (Ameen and
17 Hailwood, 2008; Khoshbakht et al., 2012; Lai et al., 2019; Lai et al., 2021).

18

Table 1. Image log derived fracture parameters for Well Dabei 1101 in Kuqa depression

Strata	Depth intervals with fractures (m)	Open fractures		Closed fractures		Number of fracture	FVDC (1/m)		FVTL (m)		FVAH (mm)		FVPA (%)

1 **4.5. Dissolution and cementation along the fracture surface**

2 Cementation and dissolution within fractures impact fracture patterns and properties
3 (Laubach et al., 2019). Core observation (including the scanning image of core surfaces)
4 show that the fractures in Bashijiqike sandstones are highly cemented, and the presences of
5 fractures improve subsurface fluid flow (Matonti et al., 2017), and therefore the active fluids
6 rich in Ca^{2+} will be cemented along the fracture surfaces (Fig.8A-8C). No matter high angle,
7 low angle or even horizontal fractures are highly cemented (Fig.8A-8C). Cemented
8 subsurface fractures limit the fluid flow (Laubach et al., 2004; Matonti et al., 2017). In
9 addition, the presence of fracture enhances dissolution, and the fracture surfaces can be
10 observed to be enlarged by dissolution (Fig.8D). In some cases, the cementation and
11 dissolution can occur simultaneously in a fracture surface, and the enlarged fracture surfaces
12 can be fully cemented by the late-stage cements (Fig.8E). Also, in some cases the mudstones
13 can fill the fracture spaces (Fig.8F). Dissolution occurring along the fracture surfaces can
14 even form vugs (Fig.8G-8H), indicating a high degree of dissolved framework grains.
15 However, the dissolved fracture surfaces can in some cases be filled by late-stage carbonate
16 cements (Fig.8G-8H).

17 Thin section observations also show that the fractures play important roles in enhancing
18 dissolution and cementation (Fig.9A-9C). Calcite cements are commonly detected to occur
19 along the fracture planes, and they can partly to fully fill the fracture spaces (Fig.9A). Also
20 fractures are important channels for fluid flow, and consequently the acids-rich fluids will
21 enhance framework grain dissolution. Therefore, the fracture surfaces are commonly
22 observed to be dissolved (Fig.9B). In some cases, both dissolution and cementation can

1 simultaneously occur along the fracture planes (Fig.9C). The calcite cementation fills the
2 fracture spaces, and reduces fracture effectiveness, while dissolution improves the fracture
3 connectivity (Fig.8; Fig.9). Actually, most opening-mode subsurface fractures contain some
4 amount of cement (Laubach et al., 2018; Bruna et al., 2020).

5 Vuggy fractures, which were formed due to dissolution along the fracture planes, can
6 also be observed on the image logs, and the fracture surfaces are evidently enlarged (Fig.10).
7 These fractures occur as continuous or discontinuous, conductive, resistive, or mixed (partly
8 resistive and partly conductive) sinusoidal waves on the image logs (Fig.10) (Lai et al.,
9 2018).

10

11 **4.6. In situ stress direction and magnitudes**

12 **4.6.1. In situ stress direction**

13 Determination of the in situ stress direction is important for stress-related geo-hazards
14 and reservoir-related issues (Nian et al., 2016). In situ stress direction can be determined
15 from the induced fractures and borehole breakouts picked out from image logs (Rajabi et al.,
16 2010; Ameen et al., 2012; Nian et al., 2016; Lai et al., 2018). Drilling induced fractures
17 formed as a result of the local stress field around the borehole, and they are parallel to
18 SHmax (present-day maximum horizontal compressive stress) (Wilson et al., 2015).
19 Borehole breakouts are wellbore enlargements induced by in situ stress concentrations, and
20 indicates the orientations of the minimum ($S_{h_{min}}$) horizontal stress directions (Bell and
21 Gough, 1979; Zeng and Li, 2009; Massiot et al., 2015; Nian et al., 2016). The trend of the
22 drilling induced fractures is approximately NW-SE direction (Fig.11).

1

2 4.6.2. In situ stress magnitudes

3 The calculation of in situ stress magnitude supports petroleum engineers' decisions
4 about well design, wellbore stability and fracture stimulation (Zoback et al., 2003; Ju and
5 Wang, 2018; Iqbal et al., 2018; Lai et al., 2019). The three mutually orthogonal principal
6 stresses include (1) vertical (overburden) stress (S_v), (2) maximum horizontal stress
7 (SHmax), and (3) minimum horizontal stress (Shmin) (Zoback et al., 2003; Verweij et al.,
8 2016; Dixit et al., 2017; Lai et al., 2019).

9 The magnitudes of SHmax, Shmin and S_v can be determined by constructing 1-D
10 MEMs (one-dimensional mechanical Earth models) (Fig.12) (Zoback et al., 2003; Tingay et
11 al., 2009; Ju et al., 2017; Lai et al., 2019). The vertical stress is caused by the gravity of
12 overburden rocks (Hassani et al., 2017; Lai et al., 2019). The magnitude of S_v at a certain
13 depth equals to the weight of overburden rocks, and it can be calculated by Eq.(3) (Verweij
14 et al., 2016; Lai et al., 2019).

$$15 \quad S_v = \int_0^H \rho g dz \quad (3)$$

16 where H is the burial depth, m, ρ is the bulk density, kg/m^3 , g is 9.8 m/s^2 (Verweij et al.,
17 2016; Zhang and Zhang, 2017; Ju and Wang, 2018).

18 Pore pressure (P_p), also is known as formation pressure at a certain depth (Dixit et al.,
19 2017), can be calculated from sonic well logs using Eaton's method (Eaton, 1969; Tingay et
20 al., 2009).

$$21 \quad P_p = P_0 - (P_0 - P_w)(\Delta t_n / \Delta t)^c \quad (4)$$

22 where, P_p is the pore pressure (MPa), P_0 (S_v) is the overburden pressure (MPa), P_w is

1 hydrostatic pressure (commonly taken as 9.8 MPa/km), Δt_n is sonic interval transit time at
2 normal pressure, Δt is sonic transit time and c is the coefficient of compaction (Zhang, 2011;
3 Ju et al., 2017).

4 The determination of the Sh_{min} and SH_{max} magnitudes via well logs can be calculated
5 based on vertical stress, Poisson's ratio, and pore pressure (Eq.(5), Eq.(6)) (Eaton, 1969;
6 Zhang, 2011; Maleki et al., 2014; Lai et al., 2019; Zhang et al., 2019). The Sh_{min} will be
7 equal to the SH_{max} in isotropic stratigraphy (Maleki et al., 2014), however, SH_{max} is not
8 equal to Sh_{min} in true formation, and the SH_{max} and Sh_{min} difference ($\Delta\sigma=SH_{max}-Sh_{min}$)
9 will vary greatly due to presences of major faults and active tectonics (Fig.12) (Maleki et al.,
10 2014; Yeltsov et al., 2014; Ju and Wang, 2018; Lai et al., 2019).

$$11 \quad SH_{max} = \frac{\nu}{1-\nu} Sv + \frac{1-2\nu}{1-\nu} \alpha P_p + \frac{E}{1-\nu^2} \varepsilon_H + \frac{E\nu}{1-\nu^2} \varepsilon_h \quad (5)$$

$$12 \quad Sh_{min} = \frac{\nu}{1-\nu} Sv + \frac{1-2\nu}{1-\nu} \alpha P_p + \frac{E}{1-\nu^2} \varepsilon_h + \frac{E\nu}{1-\nu^2} \varepsilon_H \quad (6)$$

13 where Sv is vertical stress, P_p is pore pressure. E (GPa) is Young's modulus and ν is the
14 Poisson's ratio. α is the Biot's coefficient, which can be obtained on empirical equation. The
15 ε_H and ε_h are the coefficients related to the maximum and minimum horizontal stress
16 magnitudes (Zhang et al., 2019).

17

18 **5. Discussion**

19 **5.1. Stress and compaction**

20 The horizontal stress difference ($\Delta\sigma$) plays an important role in reservoir quality and
21 fractures (Lai et al., 2019). The thin section at about depth of 6356m has abundant
22 intergranular pore spaces, indicating a limited mechanical compaction the rocks experienced.

1 The calculated $\Delta\sigma$ is less than 40 MPa, which is much less than the surrounding rocks
2 (Fig.13). The thin section at about 6420m depth also indicates a limited mechanical
3 compaction and evident intergranular pores can be observed. The calculated $\Delta\sigma$ is only about
4 36-39MPa, indicating a low in-situ stress magnitude. Conversely, the rocks at about 6369m
5 depth, have experienced an extensive in-situ stress concentration, and the $\Delta\sigma$ can reach as
6 high as 45MPa (Fig.13). The thin section observation reveals that the rocks have
7 experienced a high degree of compaction, and no evident intergranular pore spaces are
8 observed, and the grains are tightly compacted (Fig.13).

9 Consequently, horizontal stress difference is a good indicator for the compaction degree
10 (Fig.13) (Lai et al., 2019). High values of horizontal stress difference will result in a high
11 degree of compaction, and the intergranular pore spaces will be low, and the rocks are easily
12 to be tightly compacted (Fig.13). Conversely, rocks associated with low horizontal stress
13 difference will experience a low degree of compaction, and the intergranular pore spaces can
14 be preserved (Fig.13). High quality reservoirs are commonly associated with the layers with
15 low horizontal stress differences (Fig.13).

16 Natural fractures are also mainly associated with the layers where $\Delta\sigma$ is low (Fig.14)
17 (Lai et al., 2019). There are 6 numbers of fractures picked out by image logs in Layer A of
18 Fig.14, and the related $\Delta\sigma$ value is only 40-42MPa. Additionally, the Layer C in Fig.14 also
19 has 6 fractures, and the calculated $\Delta\sigma$ value is only 40MPa. Conversely, the high $\Delta\sigma$ layers
20 commonly relate to the non-fracture (tight matrix rock) intervals (Layer B in Fig.14).

21

22 5.2. Fracture and dissolution

1 Coupling observation of thin sections and image logs shows that fractures are easily to
2 be dissolved along the fracture surfaces (Fig.15). In addition, microscopic observation of
3 thin section reveals that dissolution pores are also commonly associated with the fractured
4 layers (Fig.15). In some cases, the dissolution enlarged pores can be detected, indicating a
5 high degree of dissolution. Additionally, microfractures are observed to be coexisted with
6 the intergranular and intragranular dissolution pores (Fig.15). The presences of fractures
7 enhance fluid flow, and will improve grain dissolution in sandstones (Fig.16). In fractured
8 intervals, the thin section confirms the presence of intergranular and intragranular
9 dissolution pores, and the dissolution pores are commonly coexisting with intergranular
10 pores (Fig.15; Fig.16).

11 Dissolution pores are mainly associated with natural fractures, and vuggy fracture
12 surfaces can be observed (Fig.17). Conversely no evident dissolution pores are observed in
13 layer without fractures (Fig.17). Therefore the presences of natural fractures greatly improve
14 fluid flow and will enhance framework grain dissolution, forming intergranular and
15 intragranular dissolution pores.

16

17 **5.3. Structure patterns and diagenesis**

18 In foreland fold-and-thrust belts in Kuqa depression, the stress is concentrated (Ju and
19 Wang, 2018; Feng et al., 2018), and large amounts of fractures are formed (Fig.18).
20 However, the natural fractures show no evident relationships with burial depth as picked out
21 by image logs, and they can form well connected fluid flow channels (Fig.18). The deep and
22 shallow lateral logs (M2Rx, M2R3) show evident separation characteristics in fractured

1 zones, which implies a good flow property (Fig.18).

2 The Well Bozi 102, which was drilled in an anticline, also shows high density of natural
3 fractures (Fig.19). However, there is also no increasing or decreasing trend of fracture
4 density with burial depth. The fractured zones also show evident shallow and deep resistivity
5 deviations, indicating a favorable fluid capacity (Fig.19). When combining thin section
6 observation with image logs, it is found that the fractured zones enhance framework grain
7 dissolution (Fig.19). The presences of intergranular and intragranular dissolution pores are
8 mainly associated with the fractured zones (Fig.19). Additionally, the fracture surfaces can
9 themselves be dissolved as interpreted from the image logs, and the dissolution pores will be
10 formed since the fractures improve fluid flow and enhance grain dissolution (Fig.19).
11 Conversely, the layers with no evident dissolution pores mainly related to the non-fracture
12 zones (Fig.19).

13 The Well KS8, which was also drilled at the core part of an anticline, also shows high
14 degree of fracture development (Fig.20). Also the fractures are not controlled by burial depth.
15 In the vertical geophysical cross section, there is an overall increase of $\Delta\sigma$ with burial depths
16 (Fig.20). The fractured zones are mainly associated with the low $\Delta\sigma$ layers, in addition, the
17 rocks with evident intergranular pores also are characterized by low $\Delta\sigma$ values (Fig.20).
18 Consequently, high quality reservoirs with intergranular pores or fractures are associated
19 with the low $\Delta\sigma$ layers (Fig.20). The presences of intergranular pores have no evident
20 relationships with fractures, and they can be elsewhere providing the $\Delta\sigma$ values are low
21 (Fig.20). However, the layers with evident dissolution pores or microfractures are mainly
22 corresponding with the fractured zones, and these fractured zones are also characterized by a

1 low $\Delta\sigma$ value (Fig.20). Consequently, the in situ stress magnitude is related to the structure
2 pattern, and low $\Delta\sigma$ values are favorable for the preservation of intergranular pores. The
3 fractured zones will also result in a low $\Delta\sigma$ stress. Dissolution pores are controlled by the
4 presences of fractures (Fig.20).

5 To conclude, there are complicated compaction, multiple fracturing, and cementation
6 and dissolution along the fractured zones, and a comprehensive structural diagenesis
7 analysis will provide insights into the distribution of intergranular pores, dissolution pores
8 as well as fracture developments. The comprehensive structural diagenesis analysis helps
9 better understand the structural and diagenetic processes, and reduces the uncertainty in
10 reservoir quality prediction of ultra-deep sandstones.

11

12 **6. Conclusions**

13 Relationships between thrust faults and fault-related folds and diagenesis in Kuqa
14 depress are investigated, and the following conclusions can be drawn:

15 The pore spaces in Lower Cretaceous Bashijiqike Formation consist of residual
16 intergranular pores, intergranular and intragranular dissolution pores. The sandstones
17 experienced a high degree of mechanical compaction, and the compaction is limited in well
18 –sorted rocks or rocks abundant in rigid grains. The most volumetrically important
19 diagenetic minerals are carbonates (in the form of calcites and dolomites). Dissolution
20 degree is varied, and intergranular and intragranular pore spaces are formed.

21 Natural fracture attitude and status are characterized by image logs, and fracture
22 parameters including fracture porosity, fracture density, fracture length and fracture aperture

1 are calculated. Special aims are paid on the dissolution along the fracture planes. There are
2 abundant natural fractures cemented by carbonate cements. No matter high angle, low angle
3 or even horizontal fractures are highly cemented. Cementation along the fracture surfaces
4 limits fluid flow. In addition, core and image log observation reveal that fracture enhances
5 dissolution, and the fracture planes are enlarged by dissolution. The cementation and
6 dissolution can occur simultaneously in a fracture surface in some cases, and the enlarged
7 fracture surfaces can be fully cemented by late-stage cements.

8 The magnitudes of vertical stress S_v , maximum horizontal stress (SH_{max}), and
9 minimum horizontal stress (SH_{min}) are calculated by constructing one-dimensional
10 mechanical Earth models. The horizontal stress difference ($\Delta\sigma$) determines the compaction
11 degree, and rocks associated with low horizontal stress difference experienced a low degree
12 of compaction, and the intergranular pore spaces can be preserved. Additionally, natural
13 fractures are also mainly associated with the low $\Delta\sigma$ layers.

14 Dissolution pores are mainly associated with fractured zones since the presences of
15 fractures enhance fluid flow. The presences of intergranular and intragranular dissolution
16 pores are mainly associated with the fractured zones. The high quality reservoirs with
17 intergranular pores or fractures are associated with low $\Delta\sigma$ layers. Structural diagenesis
18 which integrates diagenesis with fracture, in situ stress and structure patterns provides new
19 insights into the reservoir quality evaluation of ultra-deep sandstones in Kuqa depression.
