## ABSTRACT

Improving the knowledge of seismogenic faults requires the integration of geological, seismological, and geophysical information. Among several analyses, the definition of earthquake focal mechanisms plays an essential role in providing information about the geometry of individual faults and the stress regime acting in a region. Fault plane solutions can be retrieved by several techniques operating in specific magnitude ranges, both in the time and frequency domain and using different data.

For earthquakes of low magnitude, the limited number of available data and their uncertainties can compromise the stability of fault plane solutions. In this work, we propose a useful methodology to evaluate how well a seismic network, used to monitor natural and/or induced micro-seismicity, estimates focal mechanisms as a function of magnitude, location, and kinematics of seismic source and consequently their reliability in defining seismotectonic models. To study the consistency of focal mechanism solutions, we use a Bayesian approach that jointly inverts the P/S long-period spectral-level ratios and the P polarities to infer the fault-plane solutions. We applied this methodology, by computing synthetic data, to the local seismic network operating in the Campania-Lucania Apennines (Southern Italy) aimed to monitor the complex normal fault system activated during the Ms 6.9, 1980 earthquake. We demonstrate that the method we propose is effective and can be adapted for other case studies with a double purpose. It can be a valid tool to design or to test the performance of local seismic networks and more generally it can be used to assign an absolute uncertainty to focal mechanism solutions fundamental for seismotectonic studies.

40

## 41 INTRODUCTION

42

43 Fault plane solutions represent primary information to describe earthquakes. The assessment of  
44 earthquake location, magnitude, and focal mechanism are the fundamental operations to characterize  
45 the earthquake source using a point source approximation. The focal mechanism describes the basic  
46 geometry and kinematics of a point source in terms of strike, dip, and rake of the fault plane along  
47 which the earthquake occurred. So, the focal mechanism is the most important marker of the geometry  
48 of the seismogenic faults and their style of faulting. Moreover, seismicity and focal mechanisms of events  
49 are often used to constrain seismotectonic models, individual seismogenic sources, the regional strain,  
50 and stress fields, also for small magnitudes. Consequently, an evaluation of their effective reliability  
51 becomes a fundamental issue in seismotectonic studies.

52 Nevertheless, focal mechanisms cannot be calculated and constrained every time an earthquake occurs.  
53 Although the calculation of focal mechanisms represents a routine analysis for seismological agencies,  
54 the solutions are calculated only for a specific range of magnitudes, usually greater than 4. In fact,  
55 constraining the solution for earthquakes with small magnitude is still a challenge, despite the  
56 advancement in the technological process and the use of increasingly performing seismic networks.  
57 This is due to several factors that we will analyse in detail. The techniques used to define the focal  
58 mechanism of large to moderate earthquakes are based on the inversion of the moment tensor, which  
59 corresponds to a stable and robust procedure, so much that it is the most common method for this  
60 type of analysis (Dreger, 2003; Delouis, 2014; Sokos and Zahradnik, 2013; Cesca et al., 2011). This  
61 technique requires accurate knowledge of the propagation medium in relation to the range of  
62 frequencies used for the modelling waveforms recorded during an earthquake. The smaller an  
63 earthquake, the higher the frequency range of the signal to be modelled, the more detailed the  
64 knowledge and scale of the Earth's interior must be. Several methods have been proposed to achieve  
65 a stable inversion of the moment tensor for earthquakes with a magnitude less than 3. Hybrid  
66 approaches that invert both amplitude and waveform moment tensor use the principal component

67 analysis of seismograms (Vavrycuk et al., 2017) or moment tensor refinement techniques (Kwiatek et  
68 al. 2016; Bentz et al., 2018) to facilitate a robust determination of the source type and its kinematics.  
69 In particular, the retrieved moment tensor is typically decomposed into volumetric and deviatoric  
70 components. Constraining the earthquake as a double-couple source can erroneously affect the  
71 retrieved fault plane solutions, especially in the case of induced seismicity where the volumetric or non-  
72 double couple component must be considered (Kwiatek et al. 2016).

73 Other analytical techniques are based on the recognition of the source radiation pattern. According to  
74 the position of seismic stations relative to the source, seismic waves on seismograms show different  
75 amplitudes and polarities. These features can constrain the geometry of the earthquake faulting through  
76 estimating the angular parameters strike, dip, and rake. The classical method (Raesenberg and  
77 Oppenheimer, 1985;) uses the P-wave polarities; more advanced approaches better constrain the focal  
78 mechanism of small earthquakes using P- or S- wave amplitudes or amplitude ratios together with first  
79 motions (Snoke, 2003). In fact, the use of polarities alone is inappropriate, especially if we consider  
80 micro-seismicity ( $M < 3$ ). The reasons could be the limited number of available data, their uncertainties,  
81 and the difficulty of measuring the P-polarity with a sufficient degree of precision. For these reasons,  
82 different techniques using different types of measurements such as P-wave amplitudes (Julian and  
83 Foulger, 1996; Tarantino et al., 2019), P/S or S/P amplitude ratios measured in the time or the  
84 frequency domain (Kisslinger et al., 1981; Rau et al., 1996; Hardebeck and Shearer, 2003; De Matteis  
85 et al., 2016), or S-wave polarizations (Zollo and Bernard, 1991) have been developed. The joint  
86 inversion of polarities and amplitude ratios led to more stable and robust solutions, allowing to account  
87 for geological site effects and to decrease the effects produced by the geometric and anelastic  
88 attenuations.

89 Two kinds of errors generally influence the goodness of the solution and retrieved model (Michele et  
90 al., 2016): the perturbation errors that are related to how the uncertainty on data affects the model,  
91 and the resolution errors that are referred to the capability to retrieve a correct model, given a dataset  
92 as input or how accurate could be the model that we can recover, even with error-free data. The sum

93 of perturbation and resolution errors corresponds to the final errors on the model obtained by solving  
94 an inverse problem, as the solution of focal mechanism. In particular, the resolution errors depend on  
95 the available data, and so on the initial condition of the inverse problem. In the case of focal mechanism,  
96 the number of seismic stations, as well as the seismic network geometry, and the velocity structure of  
97 the crust influence the resolution and the reliability of the retrieved model.

98 How will the geometry of a seismic network determine the accuracy of focal mechanism solutions? The  
99 answer to this question requires a deep knowledge of the geophysical and geological characteristics of  
100 the region, often unavailable. Moreover, the theoretical relationships that predict the focal mechanism  
101 solutions for an earthquake scenario could be very complicated if several factors, such as network  
102 configuration, noise level, source magnitude, or source kinematics are taken into account. A network  
103 configuration may be optimal for earthquake locations, but not for retrieving fault plane solutions (Hardt  
104 and Scherbaum, 1994). In fact, a given geometry may resolve some fault kinematics better than others.  
105 A seismic network layout is strictly associated with the goals of the network and the available funds;  
106 according to these features, a network operator decides how many stations are required and where  
107 they should be located (Havskov et al.; 2011). So, the number of seismic stations, the size, and geometry  
108 of the network are defined after a preliminary phase based on the evaluation of the specific  
109 seismological target (Trnkoczy et al., 2009; Hardt and Scherbaum 1994; Steinberg et al. 1995; Bartal  
110 et al. 2000). In the case of small earthquakes, the available recordings come from only a portion of the  
111 total network, while the distant stations show a seismic signal buried inside the noise. In order to detect  
112 and locate low-magnitude earthquakes, we must increase the number of seismic stations for area units  
113 by building a dense seismic network.

114 In this study, we propose a useful tool to evaluate both 1) the reliability of focal mechanism solutions  
115 inferred by the inversion of different seismological data and 2) the performance of the seismic network  
116 to assess focal mechanism solutions and their errors. We evaluate the network capability to solve focal  
117 mechanisms as a function of magnitude, location, and kinematics of seismic source. We consider three  
118 synthetic data set: P-wave polarities, P- S-wave amplitude spectral ratios and polarities and amplitude

119 ratios together. Moreover, different levels of noise are considered in order to simulate more realistic  
120 conditions.

121 We selected as target the Irpinia Seismic Network (ISNet), a local seismic network that monitors the  
122 Irpinia complex normal fault system (Southern Italy), activated during the Ms 6.9 earthquake of 23rd  
123 November 1980. Evaluating the specific performance of an existing network for a seismological goal is  
124 critical and can be used to decide how to improve its layout.

125

## 126 **METHODOLOGY**

127 With the main aim to define the reliability of focal mechanisms retrieved by specific seismic networks,  
128 we propose a methodology based on an empirical approach that consists of different steps.

129 ***Configuration and Parameter Tuning (Step 1).*** In a preliminary phase, we select for each earthquake  
130 simulation the: a) fault plane solution to test, b) seismic observables to be computed (i.e. P-wave  
131 polarities or P- S-wave amplitude spectral ratios), c) magnitude, d) the earthquake epicentre and depth;  
132 e) the network geometry; f) the noise level. The fault plane solution to test can be derived from  
133 instrumental seismicity as one of the strongest earthquakes occurred in the area or a median solution  
134 of the available ones or simply a fault plane solution representative of the regional seismotectonic.  
135 Once the network geometry and the hypocentre of the earthquake are defined, the seismic stations  
136 (number and type) for which the synthetic data are computed must be selected. The number of seismic  
137 stations that record an event depends on earthquake magnitude, source-stations distance, crustal  
138 medium properties, and the level of noise. We use an empirical approach, based on the statistical  
139 analysis of the local seismicity catalog, that allows us to define, for each magnitude range, a maximum  
140 (threshold) epicentral distance for which only the seismic stations within this distance are considered  
141 (See data analysis).

142 ***Synthetic Data Computation (Step 2).*** Using a crustal velocity model and the source-receiver relative  
143 position, the synthetic data are computed for the theoretical fault plane solution. The seismic

144 observables that can be reproduced are a) P-wave polarities, b) P/S spectral amplitude ratios, and c)  
 145 polarities and amplitude ratios together. For the P/S spectral level ratios, the Gaussian noise level is  
 146 added.

147 ***Focal Mechanism Inversion (Step 3)***. We estimated focal mechanism using BISTROP code (De Matteis  
 148 et al., 2016) that jointly inverts the ratio between the P- and S-wave long-period spectral levels and  
 149 the P-wave polarities according to a Bayesian approach. BISTROP has the advantage to use different  
 150 observables for the determination of fault plane solutions, such as the P/S long-period spectral level  
 151 ratios or P-wave polarities, individually or together. The benefits of the use of spectral level ratios are  
 152 multiples: 1) they can be measured for a broad range of magnitudes (also for  $M < 3$ ; De Matteis et al.,  
 153 2016); 2) they can be calculated by automatic procedures without visual inspection; 3) their estimates  
 154 do not require to identify the first arrival time accurately, but only a time window of signal containing  
 155 P- or S-phase is mandatory and 4) the spectral amplitude ratios, they can generally be used without  
 156 the exact knowledge of the geological soil conditions (site effects) and geometric/anelastic attenuation.  
 157 Moreover, the joint inversion of amplitude spectral ratios and polarities led to constraining fault plane  
 158 solutions reducing the error associated with the estimates of retrieved parameters. BISTROP solves an  
 159 inverse problem through a probabilistic formulation leading to a complete representation of uncertainty  
 160 and correlation of the inferred parameters.

161 For a double-couple seismic source, the radiation pattern depends on fault kinematics and relative  
 162 source-station position. In fact, it can be represented as a function of 1) strike, dip and rake angles ( $\varphi$ ,  
 163  $\delta$ ,  $\lambda$ ) and 2) take-off and azimuth angles ( $i_h$ ,  $\varphi_r$ ). We can define the ratio between P- and S-wave  
 164 radiation pattern coefficients as:

$$165 \quad \frac{\mathcal{R}^P(\phi, \delta, \lambda, i_h, \phi_R)}{\mathcal{R}^S(\phi, \delta, \lambda, i_h, \phi_R)} = \left( \frac{\alpha_s^2 \alpha_r}{\beta_s^2 \beta_r} \right) \frac{\Omega_0^P}{\Omega_0^S} \quad (1)$$

166 where  $\Omega_0^P$  and  $\Omega_0^S$  are the long-period spectral level of the P- and S-waves, respectively, and  $\alpha_s$ ,  $\alpha_r$ ,  
 167  $\beta_s$ ,  $\beta_r$ , are the P- and S-wave velocities at the source and at the receiver, respectively. Thus, using the  
 168 displacement spectra, assuming a given source and attenuation model (Boatwright, 1980), we can derive

169 from the signal recorded by a seismic station the ratio of radiation pattern coefficients for P- and S-  
 170 phases, as well as  $\alpha, \beta, i_h, \varphi_r$  are known from the earthquake location and the velocity model used. So,  
 171 from a theoretical point of view, the spectral amplitude ratios measured at several seismic stations can  
 172 be used to retrieve the ratio of radiation pattern coefficients  $\mathcal{R}_{\theta\varphi}^P/\mathcal{R}_{\theta\varphi}^S$  as a function of the source-  
 173 receiver azimuth and take-off angles.

174 BISTROP jointly inverts the spectral amplitude ratios with the observed P-wave polarities to infer the  
 175 parameters  $\varphi, \delta, \lambda$  of the focal mechanism in a Bayesian framework. A posterior probability density  
 176 function (PDF), for the vector of model parameter  $\mathbf{m}$  ( $\varphi, \delta, \lambda$ ) and the vector of observed data  $\mathbf{d}$ , is  
 177 defined as:

$$178 \quad q(\mathbf{m}|\mathbf{d}) = \frac{f(\mathbf{d}|\mathbf{m})p(\mathbf{m})}{\int_M f(\mathbf{d}|\mathbf{m}')p(\mathbf{m}') d\mathbf{m}'} \quad (2)$$

179  
 180 where  $f(\mathbf{d}|\mathbf{m})$  is the conditional probability function that represents the PDF given the data  $\mathbf{d}$  and for  
 181 parameter vector  $\mathbf{m}$  in the model parameter space  $M$ , and  $p(\mathbf{m})$  is the a priori PDF. If P-wave polarities  
 182 and P/S spectral level ratios are independent datasets, the conditional probability function may be  
 183 written as:

$$184 \quad f(\mathbf{d}|\mathbf{m}) = f(\mathbf{d}^L|\mathbf{m})f(\mathbf{d}^P|\mathbf{m}). \quad (3)$$

185  
 186  
 187 in which the pdf of the data vector  $\mathbf{d}^L$  of  $N^L$  measurements of spectral ratios is multiplied for the pdf  
 188 of data vector  $\mathbf{d}^P$  of  $N^P$  measurements of P-wave polarities given the model  $\mathbf{m}$ .

189 Assuming that the observables have the same finite variance, for the  $N^L$  observations of spectral level  
 190 ratios the conditional probability function may be defined as:

$$f(\mathbf{d}^L|\mathbf{m}) = \frac{1}{(\sqrt{2\pi}\sigma)^{N_L}} \exp\left(-\frac{\sum_{i=1}^{N_L}\{d_i - [G(\mathbf{m})]_i\}^2}{2\sigma^2}\right) \quad (4)$$

Where  $G(\mathbf{m})$  represents a functional relationship between model and data and corresponds to Equation 1 and  $\sigma$  represents the uncertainty on the spectral measure.

For the  $N^P$  observations of P-wave polarities, the conditional probability function is (Brillinger et al., 1980):

$$f(\mathbf{d}^P|\mathbf{m}) = \prod_{i=1}^{N_P} \frac{1}{2} [1 + \psi(\mathcal{R}_i^P, \gamma_i, \rho_0) Y_i \text{sign}(\mathcal{R}_i^P)] \quad (5)$$

in which:

$$\psi(\mathcal{R}_i^P, \gamma_i, \rho_0) = (1 - 2\gamma_i) \text{erf}(|\rho_0 \mathcal{R}_i^P(\mathbf{m})|) \quad (6)$$

The quantity reported in square brackets in Equation 5 represents the probability that the observed  $i_{th}$  polarity  $\gamma_i$  is consistent with the theoretical one computed from the model  $\mathbf{m}$ , whose theoretical P-wave amplitude is  $\mathcal{R}_i^P$  and  $\text{sign}(\mathcal{R}_i^P)$  is its polarity at  $i_{th}$  station for a given fault plane solution. The parameters  $\rho_s$  and  $\gamma_0$ , referring to the errors in ray tracing due to velocity model ambiguity and to the uncertainty on polarity reading, regulating the shape of the PDF. For more details about the mathematical formulation, see De Matteis et al. (2016).

***Evaluation of the Results (Step 4).*** Once the best solution is estimated, the focal mechanism uncertainties and its misfit, respect to the theoretical solution as Kagan angle, are computed. The focal mechanism parameter (strike, dip and rake) misfit and their uncertainties are also calculated.

212

## 213 IRPINIA SEISMIC NETWORK

214 As testing case of our methodology, we choose the area of the M 6.9, 1980 Irpinia earthquake  
215 (Southern Italy). Since 2005, ISNet, a local, dense seismic network monitors the seismicity along the  
216 Campania-Lucania Apennines covering an area of about  $100 \times 70 \text{ km}^2$  (Figure 1; Weber et al., 2007).  
217 The seismic stations are deployed within an elliptic area whose major axis, parallel to the Apennine  
218 chain, has a NW-SE trend with an average inter-stations distance of 15 km that reaches 10 km in the  
219 inner central zone. Each seismic station ensures a high dynamic range and it is equipped with a strong-  
220 motion accelerometer, Guralp CMG-5T or Kinematics Episensor, and a short period three-component  
221 seismometer, Geotech S13-J with a natural period of 1 sec. In 6 cases, broadband seismometers are  
222 installed such as the Nanometrics Trillium with a flat response in the range 0.025–50 Hz. ISNet is  
223 operating by INFO (Irpinia Near Fault Observatory) and it provides real-time data at local control centres  
224 for earthquake early warning systems or real-time seismic monitoring (Satriano et al., 2011). Seismic  
225 events are automatically identified and located from continuous recordings by automatic Earth-worm  
226 Binder and data are then manually revised by operators (Festa et al., 2020).

227 The 1980, M 6.9, Irpinia earthquake was one of the most destructive, instrumental earthquakes of the  
228 Southern Apennines, causing about 3000 fatalities and severe damages in the Campania and Basilicata  
229 regions. It activated a NW-SE trending normal fault system with a complex rupture process involving  
230 multiple fault segments according to (at least) three different nucleation episodes delayed each other  
231 of 20 s (Bernard and Zollo, 1989; Pantosti and Valensise; 1993; Amoruso et al.; 2005). No large  
232 earthquakes occurred in the Irpinia region since 1980. A Mw 4.9 earthquake took place in 1996  
233 originating a seismic sequence inside the epicentral area of the 1980 earthquake (Figure 1; Cocco et  
234 al., 1999). Recent instrumental seismicity occurs mainly in the first 15 km of the crust showing fault  
235 plane solutions with normal and normal-strike slip kinematics, indicating a dominant SW-NE extensional  
236 regime (Pasquale et al., 2009; De Matteis et al., 2012; Bello et al., 2021). Low-magnitude seismicity  
237 ( $M_L < 3.6$ ) is spread into a large volume related to the activity of major fault segments of the 1980

238 Irpinia earthquake (Figure 1; Adinolfi et al., 2019; Adinolfi et al., 2020). Seismic sequences or swarms  
239 often occurred in the area, extremely clustered in time (from several hours to a few days) and space  
240 and seem to be controlled by high pore fluid pressure of saturated Apulian carbonates bounded by  
241 normal seismogenic faults (Stabile et al., 2012; Amoroso et al., 2014).

242

## 243 DATA ANALYSIS

244 We applied the method we proposed and evaluated the capability of the ISNet local network to resolve  
245 fault plane solutions using different observables as input data: a) P-wave polarities, b) P/S spectral  
246 amplitude ratios and c) polarities and amplitude ratios together. The analysis is carried out by evaluating  
247 the effect of 1) earthquake magnitude, 2) epicentral location, 3) earthquake depth, 4) signal-to-noise  
248 ratio, and 5) fault kinematics on retrieved focal solutions as previously described.

249 *Step 1.* In order to select focal mechanisms (FMs) to be used for our resolution study (Figure 2a), we  
250 carried out statistical analysis to define the most frequent fault plane solutions of instrumental  
251 seismicity. We classified, according to the plunge of P- and T-axes, the fault plane solutions reported  
252 in De Matteis et al. (2012) choosing only the FMs occurring within the Irpinia area since 2005 to 2011.  
253 As shown in Figure 2b, splitting the range of the data into equal-sized bins, we selected the focal  
254 mechanism corresponding to the median value of the most populated class. We report it in Figure 2a  
255 as FM2. This corresponds to a normal-strike-slip fault plane solution with strike, dip, and rake equal to  
256  $292^\circ$ ,  $53^\circ$ , and  $-133^\circ$ , respectively. Then, we decided to test the focal mechanism solution of the 1980  
257 Irpinia earthquake, a pure normal fault (strike, dip, rake:  $317^\circ$ ,  $59^\circ$ ,  $-85^\circ$ ; Westaway and Jackson, 1987;  
258 Fig. 2a) here and after FM1. This solution is very similar to the focal mechanism corresponding to: 1)  
259 the regional stress field (see Supplementary Material); 2) the  $M_L$  2.9, Laviano earthquake, one of the  
260 most energetic earthquakes of the last years (Stabile et al., 2012), and 3) those of the 2<sup>nd</sup>, 3<sup>rd</sup>, 4<sup>th</sup> most  
261 populated bins. Finally, we selected the solution corresponding to the 5<sup>th</sup> bin reported as FM3 in Figure

262 2a. This focal mechanism is quite different from the others due to a predominant component along the  
263 fault strike (strike, dip, rake:  $274^\circ$ ,  $71^\circ$ ,  $-128^\circ$ )

264 **Step 2.** For each of the three selected fault plane kinematics, we calculated synthetic data (P-wave  
265 polarities or P- and S-wave spectral amplitudes) at seismic stations varying the earthquake location and  
266 by using a local velocity model (Matrullo et al., 2013). We discretize the study area with a square grid  
267 ( $100 \times 100 \text{ km}^2$ ), centred on the barycentre of ISNet, with 441 nodes and a sampling step of 5 km.  
268 Each node corresponds to a possible earthquake epicentre (Figure 3).

269 For each grid node and according to the earthquake magnitude to be tested, we have to select the  
270 ISNet stations for simulations. The number of seismic stations that record an event depends on  
271 earthquake magnitude, source-stations distance, crustal medium properties, and the noise level.  
272 Theoretical relationships that link the seismic source to the signal recorded at every single station are  
273 quite complicated (Kwiatek et al., 2016; 2020) and are based on the accurate knowledge of crustal  
274 volumes in which the seismic waves propagated, such as the three-dimensional wave velocity structure,  
275 anelastic attenuation or/and site conditions of a single receiver. To overcome this limitation, we used  
276 an empirical approach to define the number and the distance of the seismic stations that record a  
277 seismic signal as a function of magnitude, once its epicentral location (grid node) and depth are fixed.  
278 Using the bulletin data retrieved by INFO at ISNet during the last two years (January 2019-March 2021;  
279 <http://isnet-bulletin.fisica.unina.it/cgi-bin/isnet-events/isnet.cgi>), we selected two earthquake catalog  
280 datasets with depths equal to 5 (+- 2) km and 10 (+- 2) km, respectively, and local magnitude ranging  
281 between 1.0 and 2.5. These choices are motivated by the characteristics of the Irpinia micro-seismicity  
282 recorded by ISNet. Then, we divided each dataset into bins of 0.5 magnitudes and for each bin, we  
283 retrieved the median number of P-wave polarity readings and the median epicentral distance of the  
284 farthest station that recorded the earthquake (Table 1). The bulletin data are manually revised by  
285 operators, and we selected only seismic records that provide P- and/or S- wave arrival times. The  
286 median value of the distance of the farthest station is then used to select the seismic stations for which  
287 synthetic data are calculated. Therefore, for each earthquake simulation of specific magnitude and

288 depth, only the seismic stations with a distance, from the grid node under examination (epicentre), equal  
289 or lower than the maximum distance, reported in Table 1, are considered. We run simulations only for  
290 earthquakes recorded at least by 6 seismic stations. The synthetic P-wave polarities are simulated only  
291 at a number of stations corresponding to the median value previously defined. (Table 1). We pointed  
292 out that the number of P-wave polarities empirically assigned is related to the available earthquake  
293 catalogue data of the Irpinia region where the seismicity can occur in different portions of the area  
294 covered by the network, not always with optimal azimuthal coverage.

295 Additionally, we simulated the uncertainty on the measure of spectral level ratios or the effect of seismic  
296 noise adding a zero mean, Gaussian noise to the synthetic data with a standard deviation equal to two  
297 different percentage levels, as 5% and 30%. With this configuration, we simulated:

- 298 • Three datasets of seismic observables: P-wave polarities (D1), P/S spectral level ratios (D2) and  
299 polarities and P/S spectral level ratios together (D3)
- 300 • Two hypocentre depths: 5 km and 10 km
- 301 • Three magnitude bins:  $M_L$  1.0 - 1.5 (M1),  $M_L$  1.5 - 2.0 (M2) and  $M_L$  2.0 - 2.5 (M3)
- 302 • Three focal mechanism solutions: FM1 ( $317^\circ$ ,  $59^\circ$ ,  $-85^\circ$ ), FM2 ( $292^\circ$ ,  $53^\circ$ ,  $-133^\circ$ ) and FM3  
303 ( $274^\circ$ ,  $71^\circ$ ,  $-128^\circ$ )

304 Two level of Gaussian noise: 5% and 30%. When D2 is simulated, in order to solve the verse ambiguity  
305 of the slip vector, a P-wave polarity is added to the earthquake data to be inverted for the focal  
306 mechanism.

307 **Step 3.** For each earthquake simulation the focal mechanism was estimated by inverting the synthetic  
308 data with BISTROP (De Matteis et al.; 2016).

309 **Step 4.** In order to analyse the results, we defined five kinds of map to study how the focal mechanism  
310 (FM) resolution and error spatially change in the area where ISNet is installed (Table 2):

311

- 312 • Kagan angle misfit map (KAM)
- 313 • Map of the focal mechanism parameter misfit (FMM)

- 314 • Strike, Dip and Rake error map (FME)
- 315 • Kagan angle average map (KAA)
- 316 • Kagan angle standard deviation map (KAS)

317

318 The Kagan Angle (KA) measures the difference between the orientations of two seismic moment tensors  
319 or two double couples. It is the smallest angle needed to rotate the principal axes of one moment tensor  
320 to the corresponding principal axes of the other (Kagan et al.; 1991; Tape and Tape; 2012). The smaller  
321 the KA between two focal mechanisms, more similar they are. In KAM map, for each node the value of  
322 KA between the theoretical and retrieved solution is reported, while in FMM map, the absolute value of  
323 the misfit between the strike, dip, and rake angles of the retrieved and theoretical solution is indicated.  
324 FME is defined as the error map of strike, dip, and rake in which the uncertainties (standard deviations)  
325 are calculated considering all the solutions with probability larger than the 90% (S90) of the maximum  
326 probability, corresponding to the best solution retrieved. Additionally, these solutions are used to study  
327 how constrained is the FM solution. The KA is calculated between each FM of S90 solutions and the  
328 retrieved best solution. The mean and the standard deviation of the resulting KA distribution are plotted  
329 in KAA and KAS maps, respectively. The smaller KA mean and std, the more constrained is the obtained  
330 fault plane solution (Table 2).

331

## 332 **DISCUSSION**

333 We consider the FM1, i.e. the focal mechanism of the 1980 Irpinia earthquake located at 10 km depth,  
334 first. Looking at Figures 4 and 5, we see the effect of using the three different datasets. Considering  
335 D1, we can calculate the FM only for earthquakes with magnitude 2.0-2.5 for which at least 6 polarities  
336 are available. As shown by KAM map in Figure 4a, the retrieved solutions are characterized by high KA  
337 ( $> 50^\circ$ ) with limited areas or single nodes with values in the range  $40^\circ$ - $50^\circ$ . Therefore, D1 cannot  
338 retrieve with acceptable accuracy the FMs for earthquakes with magnitude 2.0-2.5. The same result is  
339 obtained for FM2 and FM3 (Figure 4b-c). Comparing the results of the simulations using D2 and D3

340 (Figure 5), the accuracy of the retrieved solution is improved when P-wave polarities data are added to  
341 spectral level ratios. The areas in KAM map with high value of KA ( $KA \geq 18^\circ$ ; red or green areas)  
342 disappear or are strongly reduced. Nevertheless, even with D2 dataset, the FMs are well retrieved for  
343 all magnitudes with the KA misfit mostly lesser than  $10^\circ$ , except in some small areas. The spatial  
344 resolution of the network is strongly influenced by the earthquake magnitude. In fact, for both M1 and  
345 M2, there are nodes (white areas where we assume the  $KA = -1$  as an indeterminate value) for which  
346 the FMs cannot be calculated because less than 6 stations (the minimum number) are available (Table  
347 1). At the same time, the areas better resolved correspond to the region inside the network. With D2  
348 and D3 acceptable solutions are calculated for M1 and M2 earthquakes also outside the network,  
349 (Figure 5).

350 Looking at Figure 6, using the D3 dataset, the dip angle is the best resolved compared with strike and  
351 rake angles. For the M2 and M3 focal mechanisms, the misfit of dip is very low ( $< 8^\circ$ ), followed, in  
352 ascending order, by rake and strike that show higher values ( $10^\circ < \text{misfit} < 22^\circ$ ). For M1 (Figure 6a-  
353 d-g), rake and strike misfits are larger than  $50^\circ$ , with rake worse resolved than strike. The unresolved  
354 areas correspond to the regions outside the seismic network.

355 The KAA and KAS maps (Figures 7 and 8) show how the network constrains the fault plane solution as  
356 a function of the epicentral location. Moreover, Figures 7d-e-f and 8d-e-f indicate that the areas with  
357 KA mean and standard deviation greater than  $30^\circ$  and  $20^\circ$ , respectively, are reduced when P-wave  
358 polarities and spectral level ratios data are used. On the contrary, only for M1 focal mechanisms, there  
359 is no improvement because the number of P-wave polarities is the same for both D2 and D3 datasets  
360 (Table 1). The worst constrained regions correspond to a belt surrounding the seismic network, with  
361  $KA \text{ mean} < 30^\circ$  and  $KA \text{ std} < 20^\circ$  for M2 and M3 solutions. For M1, areas with high uncertainty remain  
362 outside and inside the network, specifically in the central and eastern sectors.

363 Looking at the uncertainties of FM parameters, obtained by using the D3 dataset, Figure 9 shows that  
364 the dip is the better-constrained parameter with an error  $< 10^\circ$ , also for M1 solutions. The rake angle  
365 shows an uncertainty lower than  $20^\circ$  for M2 and M3, while it higher than  $50^\circ$  for M1. The strike angle  
366 has the highest uncertainty, with values greater than  $50^\circ$  in the eastern and southern sectors of the

367 map for any analysed magnitudes (M1, M2, and M3). Accuracy improves moving from M1 to M3  
368 earthquakes.

369 The accuracy of fault plane solutions evaluated using the KA misfit and D3 dataset is similar for FM1,  
370 FM2, and FM3, mostly with values lesser than  $8^\circ$  for all the magnitudes (Figure 10). FM2 and FM3  
371 show a slightly higher precision than FM1 in the area inside the seismic network (see FMM, FME, KAA,  
372 and KAS maps for FM2 and FM3 in Supplementary Material). In the regions outside the network, where  
373 the azimuthal gap increases, the FMs better constrained in descending order are: FM3, FM2, and FM1.  
374 This effect should be due to the geometric relationship between the spatial distribution of the seismic  
375 stations and the orientation of the principal axes (P, T, B) that characterize the FMs.

376 Considering the effect of hypocentre depth, the results achieved for earthquakes at 5 km depth, by  
377 using the D3 dataset, are overall unchanged (Figure 11). We note that the fault plane solutions are  
378 slightly worse resolved due to a smaller number of P-wave polarities available for M2 and M3. The KA  
379 misfit generally is lesser than  $10^\circ$ , even though the number and the dimension of areas with misfits >  
380  $20^\circ$  are greater than those obtained considering earthquakes at 10 km depth. Moreover, the dip angle  
381 shows a misfit lower than strike and rake angles for M1, M2, and M3; the accuracy of the retrieved FMs  
382 parameters is mainly lesser than  $8^\circ$ , as shown in Figure 11.

383 Previous analyses are carried out considering data affected by 5% Gaussian error. In the last test, we  
384 simulated synthetic data adding a 30% Gaussian error. As illustrated in Figure 12, FM solutions show  
385 an overall larger misfit, in particular, the KA inside the seismic network is less than  $20^\circ$ . The area best  
386 resolved ( $KA < 8^\circ$ ) is reduced to the central portion of the network. This result indicates that the  
387 accuracy of the spectral level ratio estimates is crucial: noisy waveforms with a low signal-to-noise ratio  
388 can critically affect the result of the focal mechanism inversion. So, seismic noise as well as the number  
389 of available stations, variable due to the operational conditions, strongly influence the capability of the  
390 seismic network to retrieve a fault plane solution. Using the results of our simulations, we classified the  
391 focal mechanism provided by De Matteis et al. (2016) according to a quality code based on the  
392 resolution of fault kinematics (Table 3). In fact, we assigned to focal mechanisms of the Irpinia  
393 instrumental seismicity a qualities A, B and C for the solutions that fall into the bins relative to FM3,

394 FM2 and FM1 kinematics, respectively. The quality A, B and C correspond to the average value of KA  
395 misfit (FM3=2.4°, FM2=3.1°, FM1=4.5°) calculated for M1, M2 and M3 magnitudes using D3 dataset  
396 and considering earthquakes at 10 km depth with 5% Gaussian errors.

397 As last analysis, we carried out a test in a more general framework, without a fixed network  
398 configuration. We explored the reliability of focal mechanism estimation as a function of the uniformity  
399 of the focal sphere coverage, defined by the number of recording seismic stations and azimuthal gap.  
400 We simulated 10400 earthquakes fixing the fault plane solution and varying: 1) the number of seismic  
401 stations (6-30), 2) the take-off angle and 3) the azimuth of each single station. For each possible  
402 number of seismic stations, we run about 400 simulations, and we randomly sampled the focal sphere  
403 varying the azimuth and take-off of the stations, thus changing the geometrical configuration of our  
404 virtual network of each simulation. We computed the KA between the theoretical and retrieved focal  
405 mechanism (best) solutions using only P-polarities for each simulation. We show the results in Figures  
406 13 and S7, as 3-D histograms and 3-D scatter plot, respectively. In Figures 13a, as expected, the  
407 number of stations increases while the KA and its range of variation decrease. If the number of stations  
408 is less than nine, only few solutions have  $KA < 40^\circ$ . Figure 13b shows that most value of KA less than  
409  $30^\circ$  are obtained for azimuthal gap less than about  $80^\circ$ . In Figure S7, the relation among the KA,  
410 azimuthal gap and number of stations is clarified by the three-dimensional spatial point patterns as well  
411 by the projections of the data on the three coordinate planes.

412

## 413 CONCLUSIONS

414 We studied the focal mechanism reliability retrieved by the inversion of data recorded by ISNet, a local  
415 dense seismic network that monitors the Irpinia Fault System in Southern Italy. Three different datasets  
416 of seismological observables are used as input data for focal mechanism determination: a) P-wave  
417 polarities, b) P/S long-period spectral amplitude ratios, and c) joint polarities and amplitude ratios.  
418 Starting from empirical observations, we computed synthetic data for a regular grid of epicentre  
419 locations at two depths (5 and 10 km), for earthquake magnitude in the range 1.0-2.5, and for three

420 focal mechanism solutions. Two different levels of Gaussian error (5% and 30%) are added to the  
421 data.

422 Our results show that:

- 423 • The joint inversion of P-wave polarities and P/S spectral amplitude ratios allows retrieving  
424 accurate FM (KA misfit  $< 8^\circ$ ) also for earthquakes with magnitude ranging between 1.0 and 2.5,  
425 at depths of 5 km and 10 km. Due to the low-energy magnitude, the number of P-wave polarities  
426 cannot constrain fault plane solutions.
- 427 • The spatial resolution analysis of ISNet shows that the most accurate FM solutions are obtained  
428 for earthquakes located inside the network with strike, dip and rake misfit  $< 8^\circ$ . Nevertheless,  
429 outside the network or at its borders, acceptable solutions can be calculated even if the  
430 azimuthal coverage is inadequate (especially for M2 and M3 events). This is due to the  
431 geometrical relationship between the seismic stations and the orientation of the principal axes  
432 (P, T, B).
- 433 • The geometry of the network allows to resolve well fault plane solutions varying between normal  
434 and normal-strike focal mechanism with strike, dip and rake misfit generally less than  $10^\circ$  and  
435 for the magnitude range 1.5-2.5. The network resolves slightly better normal-strike fault plane  
436 solution than pure normal focal mechanism.
- 437 • Among the FM parameters, the dip angle shows the lowest uncertainty. Strike and rake angles  
438 have higher errors especially for M 1-1.5 earthquakes in the region outside the seismic network.
- 439 • Adding a 30% Gaussian error worsens the accuracy of the retrieved FMs. Despite the higher  
440 uncertainty fault plane solutions (KA misfit  $< 20^\circ$ ) are still resolved in the central part of the  
441 network, especially for M2 and M3.

442 The methodology described in this work can be a valid tool to design and test the performance of local  
443 seismic networks, aimed at monitoring natural or induced seismicity. Moreover, given a network  
444 configuration, it can be used to evaluate the reliability of FMs or to classify fault plane solutions that  
445 represent a fundamental information in seismotectonic studies. Although it is a theoretical study, many

446 earthquake scenarios with several magnitude, locations and noise conditions can be simulated to mimic  
447 the real seismicity.

**Table 3.** Fault plane solutions of instrumental seismicity occurred in Irpinia region in 2005-2008 and calculated by De Matteis et al., (2012). The solutions are classified according to a quality code based on the resolution of fault plane kinematics as derived in this study. The result of our simulations suggests a quality as follows: FM1=C, FM2=B, FM3=A.

**Figure 1.** Epicentral map of the earthquakes (green circles) recorded by Irpinia Seismic Network (ISNet, red triangles) from 2008 to 2020 (<http://isnet-bulletin.fisica.unina.it/cgi-bin/isnet-events/isnet.cgi>). The yellow and orange stars refer to the epicentral location of the 1980, M 6.9, and of the 1996, M 4.9 earthquakes, respectively. Historical seismicity is shown with black squares ( $IO \geq 6-7$  MCS). Seismogenic sources related to the Irpinia fault system are indicated by orange rectangles; potential sources for earthquakes larger than M 5.5 in surrounding areas are indicated in grey (Database of Individual Seismogenic Sources, DISS, Version 3.2.1)

**Figure 2.** Fault plane solutions used for earthquake simulations. a) From left to right: 1) Ms 6.9, 23rd November 1980 (FM1; Westaway ) 2) and 3) Median focal mechanism found from solutions of the 1<sup>st</sup> (FM2) and 5<sup>th</sup> (FM3) most populated bin of histogram of panel b. b) Fault plane solutions (black dots) are classified according to the plunge of P- and T-axes with the specific tectonic regimes (Legend: NF, normal fault; NS, normal-strike; SS, strike-slip; TF, thrust ; TS, thrust-strike; UF, unknown fault). The number of earthquakes (colour bar) is counted in bins of 15° × 15°.
