Abstract

The input sediments of the North Sumatra subduction zone margin, drilled during IODP Expedition 362, exhibit remarkable uniformity in composition and grain size over the entire thickness of the rapidly deposited Nicobar Fan succession (seafloor to 1500 mbsf), providing a unique opportunity to study the micromechanisms of compaction. Samples were prepared from dried core samples from sites (U1480 and U1481) by both Ar-ion cross-section polishing and broad-ion beam cutting and imaged with a field-emission Scanning Electron Microscope (SEM). The shallowest samples (seafloor to 28mbsf) display a sharp reduction in porosity from 80% to 52% due to collapse of large clay-domain/matrix pores associated with rotation and realignment of clay-platelets parallel to the bedding plane. The deeper succession (28mbsf to 1500mbsf) exhibits less rapid reduction in porosity from 52% to 30% by the progressive collapse of silt-adjacent larger pores through bending and subsequent sliding/fracturing of clay particles. In addition, there is a correlated loss of porosity in the pores too small to be resolved by SEM.

Clastic particles show no evidence of deformation or fracturing with increasing compaction. In the phyllosilicates, there is no evidence for pressure solution or recrystallization: thus, compaction proceeds by micromechanical processes. Increase in effective stress up to 18 MPa (~1500mbsf) causes the development of a weakly aligned phyllosilicate fabric mainly defined by illite clay particles and mica grains, while the roundness of interparticle pores decreases as the pores become more elongated. We propose that bending of the phyllosilicates by intra-particle slip may be the rate-controlling mechanism.

30 Pore size distributions show that all pores within the compactional force chain deform, irrespective of size, with
31 increasing compactional strain. This arises because the force chain driving pore collapse is localized primarily
32 within the volumetrically dominant and weaker clay-rich domains; pores associated with packing around isolated
33 silt particles enter into the force chain asynchronously and do not contribute preferentially to pore loss over the
34 depth range studied.

Introduction

36 Muds are fine-grained sediments (>50% of particles <63μm diameter) comprising platy detrital clay minerals and
37 equidimensional detrital grains such as quartz, feldspar, calcite, etc. (Nakano, 1967; Hesse, R., 1975; Sintubin,
38 1994). Understanding the mechanical, chemical, and microstructural properties of mud and mudstone is of great
39 interest for rock property prediction in basic earth science, in exploration, subsurface integrity studies and
40 geotechnical engineering (Yagiz, S., 2001; Aplin and Macquaker, 2011; Lazar et al., 2015). The chemical and
41 physical behavior of marine muds plays a critical role in defining the geometry of accretionary prisms, locating
42 the décollement for fault rupture (Vrolijk, 1990; Chester et al., 2013) and understanding subduction zone
43 earthquakes and tsunamis (Dean et al., 2010; Chester et al., 2013; Hüpers et al., 2017).

44 Marine mud is deposited with a highly porous isotropic fabric (Bowles, 1969; Bennett et al. 1981; 1991);
45 depositional porosity in mud is about twice as high as in sand (e.g., Velde, 1996, Lundegard, 1992). In contrast,
46 mudstones have low porosities, modal pore sizes measured in nm, and an absence of textural controls on porosity
47 (e.g. Aplin et al., 2006; Milliken et al., 2012; 2013). The processes in this dramatic evolution of porosity have
48 similarities to compaction of sand to sandstone, comprising a combination of compaction and cementation
49 (Milliken and Day-Stirrat, 2013), although the much smaller, elongated phyllosilicate grains increase the role of
50 clay-bound water in the process (Karaborni et al., 1996). Whereas a refined and somewhat predictive
51 understanding exists for porosity evolution in sand and sandstones (e.g., Lander and Walderhaug, 1999; Paxton et
52 al., 2002; Lander et al., 2008; Ajdukiewicz and Lander, 2010, Desbois et al., 2011), such a model is at best
53 preliminary for muds and mudstones (Pommer and Milliken, 2015; Milliken and Olson, 2017). It seems clear that
54 the composition of the grain assemblage importantly sets the stage for porosity evolution in muds (Milliken, 2014),
55 cementation being the greatest in muds with abundant biogenic debris. In contrast to sandstones, however,
56 cementation is far less common globally in mudstones (Milliken, 2019), leading to the notion that mechanical
57 compaction may be far more important in muds. In addition, depositional environment also strongly controls
58 porosity evolution, compaction and diagenesis in mudrocks (e.g. Burland, 1990; Baruch et al., 2015; Delle Piane
59 et al., 2015) as the initial clay and rigid grain compositions significantly affect both compaction (as this manuscript
60 shows) and subsequent diagenetic alteration due to variations in composition. Establishing the expected
61 compaction behavior for muds in a setting of well-constrained mud properties is an essential contribution that our
62 study hopes to serve.

63 Investigations of mud and mudstone compaction are usually based on proxy data, such as velocity or density,
64 rather than direct measurements of porosity (e.g., references in Mondol et al., 2007). Direct measurement of
65 porosity is broadly classified into two categories: 1) experimental compaction in the laboratory; (e.g., Mitchell,
66 1956; Bennett et al. 1981; Griffiths and Joshi, 1989; 1990; Vasseur et al. 1995; Mondol et al. 2007; Fawad et al.

2010; Emmanuel and Day-Stirrat, 2012), and 2) studies on natural samples those are compacted in situ with depth (e.g., Meade, 1964; Ho et al., 1999; Aplin et al. 2003; 2006; Day-Stirrat et al., 2008; 2010; 2012; Milliken et al, 2012; 2013). A common shortcoming of the studies on the naturally compacted samples is the assumption that the bulk porosity is a direct measure of compaction although porosity loss has contributions of both compaction and cementation (Ehrenberg, 1989; Lundegard, 1992; Paxton et al., 2002), and this can only be accomplished by petrographic inspection (Milliken and Curtis, 2016). Experimental studies generally avoid this shortcoming as the sample sets generally do not undergo any chemical change during the investigation. Studies of shallowly buried units (like the present study) are the ones most likely to avoid the complication of cementation, especially if temperatures are low and bulk grain assemblages are siliciclastic (Milliken, 2008, 2014).

Previous studies report contrasting ideas about the mechanisms of mechanical compaction of mud. Some studies conclude that rotation is the dominant particle scale mechanism for mechanical compaction (Bowles et al., 1969; Oertel and Curtis, 1972; Vasseur et al., 1995), although other particle scale-deformation mechanisms were not investigated by these authors. A few studies state that burial compaction significantly increases the alignment of phyllosilicate (clay and mica) parallel to the bedding planes (Bowles et al., 1969; Oertel and Curtis, 1972; Vasseur et al., 1995) (a detailed review of the previous studies on mechanical compaction is given in Document S1 in Supplementary data). Other studies suggest that intense mechanical compaction (i.e. effective stress) has a limited impact on the development of phyllosilicate fabric in mud (Ho et al., 1999; Aplin et al., 2006; Day-Stirrat et al., 2008; 2011). In addition, earlier authors concluded that an increase in effective stress causes preferential loss of larger pores, and as a result, the mean porosity of the samples decreases (Delage and Lefebvre, 1984; Griffiths and Joshi, 1989; 1990; Emmanuel and Day-Stirrat, 2012). With increasing consolidation stress, a bimodal pore size distribution curve shifts toward smaller pore sizes as larger pores rapidly collapse (Griffiths and Joshi, 1989; 1990; 1991). These studies investigated the changes in particle alignment and reduction in porosity (Ho et al., 1999; Aplin et al., 2006; Day-Stirrat et al., 2008; 2011) but without imaging the evolution of pore morphology with increasing compactional strain. Moreover, in previous studies, the authors mainly performed laboratory consolidation experiments on lab produced particle packs, and used conventional techniques, such as mercury intrusion porosimetry and high-resolution X-Ray pole figure goniometry (HRXTG) to understand the evolution of pore size distribution with consolidation stress (Ho et al., 1999; Aplin et al., 2006). Studies on naturally compacted samples are less common.

We received 55 mud samples from drill cores collected during IODP Expedition 362 west of the North Sumatra subduction zone margin and investigated the evolution of petrographic microstructure and pore morphology as a function of compactional strain. Apart from general implications for global mudrocks, we hope this investigation will also contribute to studies that seek to predict rock properties in the deeper subsurface at the Sumatra subduction front.

Geological background and drilling

The Sumatra subduction zone extends 5000km from the Andaman-Nicobar Islands in the northwest to the Java-Banda arc in the Southeast (Fig.1a and b) (Prawirodirdjo et al., 1997; Hippchen and Hyndman, 2008). The trench of the Sumatra subduction zone (Fig.1a) developed on the subducting Indo-Australian Plate at a convergence rate of 5.5 cm/yr in the north and 7.23 cm/yr in the South (Ghosal et al., 2014; Moeremans, and Singh, 2015).

On 26th December 2004, the west coast of Northern Sumatra recorded one of the largest earthquakes (Mw-9.3) in the 21st century, generating a devastating tsunami in the Indian Ocean (Ammon et al., 2005; Lay et al., 2005). Understanding the mechanism(s) behind this unprecedented event was the central idea behind IODP Expedition 362 (Fig.1). The main objective of the expedition was to collect core and log data from the incoming sedimentary succession of the Indo-Australian oceanic plate to understand the seismogenic process related to the margin (Dugan et al., 2017; McNeill et al., 2017a). During the expedition in 2016, drilling was performed on two sites: U1480 (Holes E, F, G and H) and U1481 (Hole A) located on the oceanic plate west of the North Sumatra subduction margin and east of the Ninety East Ridge (Fig.1a, b) (Dugan et al., 2017). The drilling sites recovered a complete, 1.5 km thick sedimentary section from late Cretaceous to Pleistocene down to the basement of basaltic crust (Dugan et al., 2017; McNeill et al., 2017a).

The input sedimentary section of the Sumatra subduction zone comprises the distal part of the trench wedge, Nicobar fan sequence, and pre-fan pelagic section on the basaltic crust at the bottom (Dugan et al., 2017; McNeill et al., 2017a). At Site U1480, the entire recovered section was categorized into six lithological entities, Units I to VI (Fig. 1c) (McNeill et al., 2017a). Unit I (0 to 26.72 mbsf) consist of unconsolidated calcareous clay, silty clay with alternating fine sand (McNeill et al., 2017a). Unit II from 26.72 to 1250 mbsf consists of three subunits (IIA, IIB and IIC) and mainly exhibits alternating fine-grained sand and silty clay to silt (McNeill et al., 2017a). Unit III (1250 ~ 1327 mbsf) is divided into two subunits: Unit IIIA and IIIB (McNeill et al., 2017a). Unit IIIA consist of thin to medium-bedded, gray-green or brown mudstone and intercalated siltstone, and Unit IIIB is composed of reddish-brown tuffaceous silty claystone with fragmented sponge spicules and radiolaria (McNeill et al., 2017a). The boundary between Units IIIA and IIIB (1310 mbsf) at this site marks the base of the Nicobar Fan and the beginning of the thin pre-fan succession (Pickering et al., 2020). Units IV, V, and VI include volcanoclastic rocks with tuffaceous sandstone, conglomerates, and basaltic oceanic crust, respectively. At Site U1481, the pre-fan succession was not encountered and a Unit III, a thicker equivalent of Subunit IIIA at Site U1480, represents the material of the lower Nicobar Fan (see Figure F15, in Site U1481 report; McNeil et al., 2017a). This study is restricted to the thin, distal trench wedge (Unit I) and Nicobar fan sequence (Units II and IIIA, which is equivalent to Unit-III at U1481).

X-ray diffraction (XRD) of bulk samples and clay fractions at Site U1480 show a clay mineral assemblage dominated by illite with lesser amounts of smectite and chlorite (Rosenberger et al., 2020) (Fig.2a, b, c, and d; Table S1 and Figure S1 in Supplementary data). Clay mineral data arise from three separate analyses: (1) bulk sample analyses of air-dried samples (random orientation) onboard ship used to define the proportion of all clay minerals in a sediment sample (McNeill et al., 2017a), (2) air-dried clay-sized samples (sedimented and oriented) analyzed in New Mexico that define the types and abundances of clay minerals (Rosenberger et al., 2020; note

that abundances limited to clay minerals used in the reference mixtures, which include discrete illite and discrete smectite), and (3) glycol-saturated clay-sized samples (sedimented and oriented) analyzed in New Mexico that determine the amount of illite in mixed-layer I/S, defined as smectite in #2 (Rosenberger et al., 2020). Note that the amount of illite in mixed-layer I/S is only accounted for in the expandability value and never in the discrete illite value.

Siliciclastic samples consist of 50-70% clay minerals (McNeill et al., 2017a). Smectite fraction, determined from the air-dried, clay-sized samples (as described in Underwood et al., 2020) is more abundant in Unit I than Unit II, where smectite abundance ranges from 5-30% with rare samples containing as much as 45% smectite. In Unit II, smectite fraction ranges from 10-30% with local discreet enrichments as great as 40-45%. Smectite again increases in Unit III, reaching a value as high as 68% in the samples attributed to the Nicobar Fan section. There is a weak increase in the expandability of mixed-layer I/S with depth (determined from glycol-saturated, clay-sized samples; Rosenberger et al., 2020; Underwood et al., 2020; Figure-S2 in Supplementary data), suggesting a shift in clay mieral provenance rather than smectite-illite diagenesis. Montmorillonite is interpreted as the smectite mineral (Rosenberger et al., 2020). Chlorite + kaolinite abundance is similar in Units I and II, ranging from 8 to 20% with rare occurrences as high as 24%; Unit III is almost devoid of chlorite + kaolinite. Heating experiments on select samples indicate that chlorite makes up 66-100% of this mineral category (Rosenberger et al., 2020). Illite comprises the remainder of the clay mineral assemblage, ranging from 50-79% in Unit II while Unit I is correspondingly less illite-rich (42-70%). In the Unit III Nicobar Fan section, illite makes up only 18-36% of the clay fraction. Again, it should be noted that, the shipboard methodology used for XRD analysis is semiquantitative and has limitations in identifying bulk mineralogy of the samples; the abundance of mixed-layer clays and the expandability of mixed-layer I/S is only inferred qualitatively (McNeil et al. 2017a; Underwood et al., 2020).

The Nicobar fan sequence exhibits almost compositionally homogeneous (silt/clay ratio; mostly 'silty-clay') subunits with uniform grain size (McNeill et al., 2017a), and a history of rapid deposition (125-290 m/my; Backman et al., 2019). The sedimentary sequence exhibits no evidence of uplift and currently occurs at maximum burial depth. The drilling sites are 255 km away from the deformation front; thus, the samples are undisturbed by tectonic faulting associated with subduction (Fig.1b). In addition, owing to the scarcity of biogenic grains and the low temperatures encountered (<68°C), cementation is only observed as highly localized concretions (Red colored symbols in Fig.2e, f, g, and h) (McNeil et al., 2017b; Torres et al., 2022). Such a homogeneous sedimentary succession extending across 1.5 km depth is rare in sedimentary basins. Hence, these samples provide us with a unique opportunity to study depth-wise variation in microstructure as a function of vertical effective stress with few complications from multiple causes of porosity loss.

Sampling and Methods

This study is based on two sample sets that were obtained from Sites 1480 (Holes E, F, G, and H) and 1481 (Hole A) independently and analyzed by slightly different methods. Samples have been prepared using Ar-ion cross-section polishing and analyzed using a scanning electron microscope equipped with a field emission gun (BIB-SE technique). The first sample set (33 mud samples; depth 1.24 to 1300 mbsf) was prepared and analyzed at RWTH Aachen University, Germany. The second sample set (22 samples; depths 6.25 to 1493.30 mbsf) was prepared and

Respective core

description of these 55 mud samples and their bulk mineralogy data are tabulated in Table-1.

BIB-SEM technique (First set of samples, Aachen University)

Sample preparation for BIB-SEM and imaging

After drilling, the samples were stored at Kochi drill core repository (IODP), Japan for four years (2016 ~ 2020) in refrigerated storage areas, maintaining a temperature of ca. 4°C and 80% humidity (http://www.kochi-core.jp/en/iodp-curation/curation-sop_2.html). We received a total of 33 freeze-dried mud samples (SN-1 to SN-33 in Table-1) for analysis at Aachen. The samples were collected using a tube inserted perpendicular to the cut face of the drill core in such a way that the notch of the tube identified the top of the sample so the orientation of bedding planes for each sample was known. In Fig. 1d, a tube sample received from the IODP repository is shown, where the red line on the top of the tube identifies the notch. Subsamples (10 x 5 x 2 mm^3) were cut from the individual freeze-dried samples using a razor blade. These subsamples were pre-polished using silicon carbide (SiC) paper to reduce the roughness of the surface down to 10 μm. Further, Broad Ion Beam (BIB) polishing was carried out using a JEOL SM-09010 cross-section polisher for 10 hours at 6 kV and 150 μA. BIB reduces surface damage by removing a 100 μm thick layer to generate a high-quality polished cross-section of 1-2 mm^2 with a topography less than 5 nm (Desbois et al., 2009).

After polishing, the BIB cross-sections were coated with tungsten and imaged with a Zeiss Supra 55 SEM with SE2, BSE, and EDX detector (Figure S3 in Supplementary data). SE2 images were used to image porosity and BSE images are combined with an EDX map as well as EDX point analysis for identifying mineral phases. For each cross-section, we made mosaics of hundreds of SE2 and BSE images at a magnification of 20,000x (~14.3 nm pixel value) and 10,000x respectively, with an overlap of 20% to 30%, (Klaver et al., 2012; 2015; 2016; Hemes et al., 2013; 2015; 2016; Laurich et al., 2014). The mosaics are stitched together using Aztec software preserving the original pixel resolution. Finally, these stitched images are used for the segmentation of pore spaces, minerals, and other respective analyses.

Image segmentation and pore analysis

For quantifying porosity and pore morphology, individual SE2 image mosaics were segmented using a 'seed and grow' algorithm (Adams and Bischof, 1994) implemented with a MatLab code (Jiang et al., 2015; Schmatz et al., 2017) (Figure S3 in Supplementary data). The 'seed and grow' algorithm works based on the difference in intensity of greyscale value in an image (bright = minerals, dark= pores). After automatic segmentation, individual pores in SE2 images are manually corrected if required.

Similarly, using ImageJ software (threshold toolbox and machine learning algorithm), segmentation of the individual mineral phases was carried out combining BSE images and EDX elemental maps. While quartz, calcite, pyrite, mica minerals are efficiently segmented using these tools, feldspars are found difficult to segment because of similar composition as clay (Figure S4, S5 and S6 in Supplementary data). Finally, corrected pore segmented

209   SE2 mosaics are overlaid on the phase maps using the 'georeference' tool of QGIS (http://qgis.osgeo.org), (Figure

210   S4, S5 and S6 in Supplementary data).

Pore detection resolution (PPR) and representative area analysis (REA)

212   'Practical pore detection resolution' (PPR) indicates the pore sizes above which one can assume to detect 100% of

213   the pores present in the SE2 mosaic (Klaver et al., 2012). In agreement with earlier results using this instrument

214   (Klaver et al., 2012; 2015; 2016; Hemes et al., 2013; 2015; 2016; Laurich et al., 2014), we found PPR of ~2000

215   nm^2 and ~8500 nm^2 for the magnification of 20,000x and 10,000x images, respectively, corresponding to 10 pixels.

216   After segmenting all minerals, representative elementary area analysis (REA) was performed using the box

217   counting technique on mineralogical phase maps (Kameda et al., 2006; Klaver et al., 2012). Similar steps are also

218   followed for determining a representative elementary area for SE2 images. The estimated REA values using SE2

219   and BSE mosaics for the analyzed 33 mudstone samples are documented in Table S2 in Supplementary data.

220   Porosity, pore morphology, pore size, and the statistical distribution of pores were obtained using image analysis

221   techniques on 2D images collected using BIB-SEM technique. Because pores are non-spherical 3D objects that

222   are cut perpendicular to the bedding plane to acquire a 2D image dataset, there may be random and systematic

223   errors when comparing 2D and 3D results. We plotted shipboard measured MAD (moisture and density) porosity

224   vs depth (Fig.2e) and also BIB-SEM porosity vs depth for the analyzed samples (Fig.3a), where MAD porosity

225   documents bulk porosity for the sample, and BIB-SEM porosity represents 2D cuts of the non-spherical 3D

226   pores/porosity. As there is a first-order correspondence between the two porosity measurements, we deduce that

227   porosity and pore size distributions obtained from 2D image analysis reflect the bulk rock porosity and 3D pore

228   size distribution of the samples. In addition, the estimated REA appears appropriate for minimizing systematic

229   errors in the bulk pore characteristics of the sample.

230

Ion polishing and SEM technique (second set of samples; BEG, UT Austin).

232   22 Samples (SN-34 to SN-55 in Table 1) were taken shipboard from the sample half of the still-wet core in small

233   plastic tubes (similar to the ones used for the sample set at Aachen) inserted into the core by manual pressure. The

234   tubes were removed from the core and sealed in plastic bags. In the laboratory at the BEG, sample bags were

235   opened, and the muds were allowed to dry slowly in the tubes over several weeks. No discernible shrinkage was

236   observed as the dried core pieces still fully filled the tubes. The tubes were carefully removed, and a small cube

237   (approximately 0.5 to 1 cm^3) was cut using a sharp knife and small hand saws; an orientation mark was placed on

238   the cube to indicate the bedding direction. Bed-perpendicular surfaces were prepared by Ar-ion cross-section

239   polishing, using the Leica EM TIC020 triple ion beam miller and coated with Ir for imaging. Manual placement

240   of the cut cubes into the ion mill is not precise so the ion-polished surfaces have slight variation from perpendicular

241   to bedding. Pore imaging was performed on the FEI Nova NanoSEM 430 using the in-lens SE detector, a 30 μm

242   aperture, 15 KeV accelerating current, a working distance of around 5–6 mm, and an intermediate-range sample

243   current (spot size = 3nm, mid-range for the instrument). Randomly selected views (typically 3-6) of all samples

244 were collected at 6000x machine magnification; additional views illustrating pore types and pore/grain
245 relationships were made at 10,000x to 30,000x (machine magnification).

246

Results

Compaction strain derived from MAD-porosity data

249 During Expedition 362, mass and volume of mud samples were measured in both wet and dry states using a high
250 precision electronic mass balance and helium pycnometer (http://www-odp.tamu.edu/publications/tnotes/tn37/
251 tn37_8.htm). Using the obtained mass and volume dataset for wet and dry conditions, bulk MAD (moisture and
252 density) porosities were calculated. Porosity values reported by McNeill et al. (2017b) and downloaded from IODP
253 databases serve as the basis for strain calculations.

254 Shipboard MAD porosity for mud samples exhibits a sharp reduction from 80% to 52% from the seafloor to 28
255 mbsf (Fig.2e). Deeper samples display a comparatively smaller reduction in porosity of approximately from 52%
256 to 30% over a depth range of 28 to 1500 mbsf (Fig.2e and f).

257 We calculated compaction strain following a method proposed by Nollet et al. (2005) and subsequently used by
258 Neagu et al. (2010) (Fig.2g and h), assuming 1D consolidation and no change in solid volume. The compaction
259 strain (ε_c) is then computed as:

260 $$\varepsilon_c = \frac{1-\phi_0}{1-\phi_1}$$ (Eqn-1)

261 Here ϕ_0 = initial porosity, and ϕ_1 = final porosity. Samples from sites U1480 and U1481 show no evidence of
262 tectonic faults (McNeill et al., 2017a), supporting an assumption of 1D strain. We considered the initial porosity
263 ϕ_0 as the MAD porosity at 0.6 mbsf depth (ϕ_0 = 80%). Compaction strain following Eqn-1 (Table S2 in
264 Supplementary data), is plotted against depth in Fig.2g and h. Compaction strain increases from 1 to 2.05 from the
265 seafloor to 28 mbsf (i.e. Unit I), and from 2.00 to 3.05 from 28mbsf to 1500 mbsf (Fig. 2g and h).

266 Another common measure of compaction is the intergranular volume (IGV; Paxton et al., 2002), which
267 corresponds to the sum of intergranular porosity and intergranular cement. In some mudstones, it may be necessary
268 to calculate IGV differently because of the presence of abundant primary intragranular pores and pore-filling
269 bitumen (Milliken and Olson, 2017). In our sample set, cement is absent, and IGV is taken to equal the bulk
270 porosity from shipboard MAD measurements.

271 Compactional porosity loss (COPL), referenced against the original sediment volume, is calculated from the initial
272 primary intergranular porosity (Pi; 80% in this case) and the IGV as follows (Ehrenberg, 1989, Lundegard, 1992;):

273 COPL= Pi-(((100-Pi) x IGV)/(100-IGV)) (Eqn-2)

8

274 At an IGV of 50%, COPL is 60%; in the deepest samples in the Nicobar fan (IGV of around 30%) COPL is 70%

275 (Table S2 in Supplementary data).

Description of grain microstructure and pore morphology

277 To have consistency in the data set, we prepared SE2 mosaics for all samples from the Aachen sample set at

278 20,000x magnification covering an average 100×100 μm^2 area. In addition, to examine the effect of magnification

279 on BIB-SEM porosity and representative area analysis (REA), three samples (i.e. SN-7, SN-15, and SN-29) were

280 also imaged each at 5,000x and 10,000x magnification, respectively. A decrease in magnification and resolution

281 reduces visible BIB-SEM porosity.

282 We observed consistent results for the REA analysis. For SE2 mosaics, REA varies between 45×45 μm^2 to 85×85

283 μm^2 at 20,000x magnification, and for segmented phase maps, REA varies between 90×90 μm^2 to 130×130 μm^2

284 at 10,000x magnification. In the UT sample set, the standard images taken at 6000x with machine magnification

285 are 49.7x45.7 μm^2, so these images are also within the estimated REA range.

286 Based on EDX elemental map or point analysis, six mineral phases occur in significant amounts in the Sumatra

287 samples: quartz, feldspar (K-feldspar, Na-feldspar), calcite, pyrite, micas (muscovite, biotite, and chlorite), and

288 clay. Based on XRD analyses (Rosenberger et al., 2020), the clay size fraction is dominated by illite. Clay + mica

289 percentage in these mudstone samples varies between 65% to 75%. Samples SN-1 (77%) and SN-4 (76%) have

290 more clay + mica, whereas SN-7, SN-9, SN-17, SN-28, SN-29, and SN-31 contain less clay + mica (<65%) (Table

291 S2 in Supplementary data). It should be noted that, using EDX analysis, we are able to differentiate Na-feldspar,

292 and K-feldspar considering the concentration of Na and K elements in the grains. However, the XRD dataset

293 provides only information about the overall percentage of plagioclase feldspar present in these samples (Table 1),

294 perhaps an artifact of different detection limits for EDX and XRD analyses.

295 Using BIB-SEM and automatic pore segmentation techniques, an average of >30,000 pores have been detected

296 for each individual sample in the Aachen sample set at 20,000x magnification. Correlating with the MAD data set,

297 the estimated BIB-SEM porosity reduces from 32% to 19% over a depth range of seafloor to 28 mbsf, while the

298 deeper samples display a smaller reduction from 19% to 10% over a depth range of 28 to 1500 mbsf respectively

299 (Fig.3a). Consistent with numerous previous studies, the results document a mismatch between bulk measured

300 porosity (MAD) and imaging porosity (BIB-SEM) (e.g., Hemes et al., 2013; Houben et al., 2014; Nole et al., 2016;

301 Oelker et al., 2019) (Table S2 in Supplementary data). We plotted BIB-SEM porosity vs MAD porosity and found

302 an approximately linear correlation with coefficient of determination ($R^2 = 0.8621$) (Fig. 3b). It should also be

303 noted that, although there is a correlation, there is a large difference in the porosity values which increases with

304 increasing porosity.

Type of pores

306 Intergranular pores contribute >99% of the total visible porosity. Intragranular pores (see below) are rare. The size

307 and shape of intergranular pores change during compaction (Table S3 in Supplementary data).

308 Intergranular pores are classified (Fig.4) based on the size of surrounding particles (irrespective of mineralogy):
309 1) Clay domain (matrix) pores, and 2) silt-adjacent pores. Based on the variation in size, clay domain pores are
310 divided further into: 1) Large clay domain pores (pore size $>5x10^5$ nm^2) and the pore boundary is defined by more
311 than three clay particles; and 2) small clay domain pores (pore size $<5x10^5$ nm^2) that occur between 2-3 clay
312 particles (see further details below). Large and small clay domain pores are classified by geometry as: 1) Elongate
313 pores (aspect ratio >3:1) and 2) equant-shaped pores (aspect ratio <3:1). Elongate pores consist of 1) Linear-
314 elongated pores, and 2) crescent-shaped elongated pores. Examples of different clay-domain pore types are shown
315 in Fig. 5, 6, and 7.

316 Silt-adjacent pores are categorized by two types: 1) large silt-adjacent pores are $>5x10^5$ nm^2, and pore boundaries
317 are defined by more than three particles; and 2) small silt-adjacent pores include pore sizes $<5x10^5$ nm^2, and pore
318 boundaries are defined by two/three particles (see further detail on the modal sizes of these pore types below).
319 Large and small silt-adjacent pores are either: 1) Equant shaped (aspect ratio <3:1) or 2) elongated (aspect ratio
320 >3:1). Further, elongated silt-adjacent pores consist of 1) linear-shaped elongated pores and 2) crescent-shaped
321 elongated pores. These pore types are highlighted in Fig. 5, 6, and 7.

Change in inter-particle pore morphology with depth

Seafloor to 28mbsf (Unit I)

324 The shallow mud samples in Unit I are unconsolidated and porous (Fig. 5a). We analyzed a total of 10 samples (6
325 samples at Aachen and 4 samples at UT Austin) from this depth range. Among them, two samples have been
326 analysed both in Aachen as well as in Austin, respectively. Sample SN-1 (1.24 mbsf) has a maximum MAD
327 porosity of 80%. We observe three types of clay particle contacts in the microstructure of SN-1; edge to edge (EE),
328 edge to face (EF), and face to face (FF) contacts (Table S4 in Supplementary data). Among them, EF and FF
329 contacts are abundant and EE contacts are rare. The sample exhibits abundant large clay domain pores and large
330 silt-adjacent pores that are equant with smooth edges and a rounded pore perimeter. The sample also contains
331 abundant linear-elongated and equant-shaped small clay-domain pores. Crescent-shaped small clay domain pores
332 are rare in the microstructure of this sample. Equant-shaped, small silt-adjacent pores are abundant. In addition,
333 linear elongated and crescent-shaped small, silt-adjacent pores are also common (Fig.5a; Table S3 in
334 Supplementary data).

335 With increasing compaction strain ($\varepsilon_c = 1.119$) and depth (5.1 mbsf; Figure S7 in Supplementary data), porosity
336 (MAD) reduces to 75% and corresponding COPL=19% (sample SN-2; Fig. 5b, Table S2 in Supplementary data).
337 The microstructures of SN-2 display are similar characteristics to those observed in sample SN-1, although there
338 are fewer large clay domain pores in SN-2 than SN-1. Linear elongated and equant-shaped small clay domain
339 pores are common Table S3 in Supplementary data), but crescent-shaped small clay domain pores are rare. The
340 microstructures of SN-2 exhibit abundant equant-shaped large and small silt-adjacent pores.

341 With an increase in compaction strain to ε_c ~2.00 (28 mbsf), the sample microstructure is dominated by FF contacts
342 (Fig. 5e), and EE and EF contacts are rare (Table S4 in Supplementary data). Additionally, large clay-domain
343 pores become infrequent in the microstructure (Fig.5e and Fig. 8). Crescent-shaped, small clay domain pores in

the microstructure are rare, whereas equant-shaped small clay domain pores are common. Both small and large silt-adjacent pores exhibit equant shapes (Fig.5e and Fig. 8d, e, f). The sample analyzed at the base of Unit I (SN-6; 28 mbsf) contains rare large clay-domain pores and abundant FF contacts (Fig. 5c; MAD porosity = 54% and COPL = 55%).

28 mbsf to 1500 mbsf (Units II and III)

Mud samples from the Nicobar fan section are more compacted than shallower samples (Fig. 6, 7 and Figure S8 in Supplementary data). We analyzed a total of 29 samples using at Aachen and 18 samples at UT Austin from this section. An increase in compactional strain from 2.00 to 3.15 over a depth range of 28 to 1500 mbsf causes a porosity reduction (MAD) of 54% to 28%, and the corresponding change in average COPL is 55% to 72%. The microstructure of these samples is dominated by FF contacts among clay particles; EF and EE contacts are rare (Table S4 in Supplementary data; Fig. 6 and 7 b, c). All samples exhibit abundant small linear-elongated clay domain pores between two parallel clay sheets (Fig. 8b). Equant-shaped small, clay domain pores are rarely observed below 150 mbsf depth (ε_c>2.4). Crescent-shaped, small, clay domain pores are rare at shallow depth but become abundant with an increase in compactional strain ε_c >2.95 (871.87 mbsf) as the surrounding clay particles are bent (Fig.6). In addition, large clay domain pores in these samples are rarely observed in the vicinity of silt clasts (Fig.6).

Below 100 mbsf (ε_c =2.20), silt-adjacent small pores are dominantly equant shaped, but below 300 mbsf (ε_c >2.5) silt-adjacent small pores are dominantly linear-elongated (Fig. 8e). Crescent-shaped, small, silt-adjacent pores are common in all samples. Large silt-adjacent pores are dominantly equant above 200 mbsf depth (ε_c <2.40) and commonly linear-elongate below 400 mbsf depth (ε_c >2.5) (Fig.8f). It appears that due to an increase in compactional strain, the shape of the silt-adjacent pores changes from equant to linear-elongated (Table S3 in Supplementary data). In samples with more silt, equant-shaped small and large, silt-adjacent pores can persist at greater depths (Fig. 8e and f).

Below 28 mbsf (ε_c >2.0), the number of large silt-adjacent pores in the microstructures decreases. Comparing samples SN-8 (74.07 mbsf and ε_c =2.09) and SN-33 (1299.14 mbsf and ε_c =2.51) illustrates how the number of large, silt-adjacent pores decreases with depth (Fig. 6a, and c) when the clay fraction (Table S2 in Supplementary data) is comparable. This relationship is apparent even in samples separated by a smaller depth difference (SN-49 from 959.14 mbsf and SN-55 from 1433.36 mbsf; Fig. 7b and c). While the number of large pores diminishes, the maximum size of the large silt-adjacent pores remains constant (10^7 nm^2; Figure S9).

It can be observed in Fig.2e that, around 1300 mbsf depth MAD porosity for the sample sets again rapidly increases. However, microstructural observations of the sample from this horizon does not exhibit increase in porosity (Fig. 6c). Hence, the increase in MAD porosity in this horizon is attributed to the increase in smectite content (Fig.2a) (Dutilleul et al., 2021). In general, the moisture and density method (MAD) overestimate the measured porosity of the smectite rich sediment because of the inclusion of the interlayer water from smectite during measurement (Brown and Ransom, 1996; Dutilleul et al., 2020).

Variation in the orientation of pores and grains due to compactional strain

We examined the change in orientation of the long axis of pores with increasing compaction strain. For all segmented pores, the angle between the long axis and the bedding plane was determined and plotted in rose diagrams (Supplementary data-15). Samples from the seafloor to 28 mbsf exhibit a weak preferred orientation of the long axis of pores with maxima oriented obliquely to the bedding planes. However, below 28 mbsf the samples have a preferred orientation of the long axis of pores aligned subparallel to the bedding plane. Further, due to an increase in vertical effective stress down section below 28 mbsf in Units II and III, the degree of preferred alignment of the long axis of pores only increases by a small amount (Figure S10).

We determined the angle between the long axis of individual silt grains and the bedding plane for all samples and plotted the angle in a rose diagram (Figure S10). For quartz, feldspar, and calcite the degree of preferred orientation of the long axis of grains changes little with depth. However, the rose diagrams obtained for mica show weak maxima parallel to the bedding plane and several submaxima oriented obliquely to the bedding plane above 28 mbsf. Preferred alignment of the long axis of mica grains increases at 28 mbsf with a strong maximum oriented parallel to bedding plane. Below 28 mbsf, further increase in the degree of preferred alignment is small.

Size distribution of pores

Pore size distributions (Fig. 9) of shallow samples (Unit I) are trimodal. Sample SN-1 has peaks between 10^5 to 10^6 nm^2, 10^6 to 10^7 nm^2, and 10^7 to 10^8 nm^2, and SN-2 has peaks from 10^4 to 10^5 nm^2, 10^5 to 10^6 nm^2, and 10^6 to 10^7 nm^2. These three pore size regimes correspond to the small clay domain and silt-adjacent pores, large clay domain pores, and large silt-adjacent pores. Samples of Units II and III exhibit bimodal pore size distributions (SN-10, SN-26, and SN-33 in Fig. 9). SN-10 has a peak between 10^5 to 10^6 nm^2, corresponding to small clay domain and silt-adjacent pores, and 10^6 to 10^7 nm^2, reflecting large silt-adjacent pores. Large clay domain pores are absent from samples below 28 mbsf depth (Units II and III) based on the pore size distributions combined with image analysis. At shallow depths, the contribution to total porosity by larger silt-adjacent pores is greater compared to the contribution by small clay domain pores (Fig. 9e and g). The contribution of large, silt-adjacent pores to total porosity diminishes with depth. Hence, at greater depth, contribution to total porosity by larger silt adjacent pore is less compared to small clay domain pores (Fig. 9i).

Pore size distributions follow a power-law shown on a double logarithmic graph following the equations (Klaver et al., 2012; 2015; 2016; Hemes et al., 2013; 2015; 2016; Laurich et al., 2014):

$$\frac{N_i}{b_i S_{mosaic}} = C S_{Pore}{}^D \qquad\qquad\qquad\qquad\qquad \text{(Eqn-3)}$$

$$\log\left(\frac{N_i}{b_i S_{mosaic}}\right) = -D . \log(S_{pore}) + Log\ C \qquad\qquad\qquad\qquad \text{(Eqn-4)}$$

Where N_i= number of pores with area S_{pore}, b_i= bin size, S_{mosaic}= surface area of the current mosaic, C=constant, and D= power-law exponent. The resulting power-law exponent (D) varies between 1.70 to 2.00 (Table T2 in Supplementary data).

Effect of texture on porosity, pore morphology, and orientation of pores

We analyzed six samples (SN-7, SN-9, SN-17, SN-28, SN-29, and SN-31) that are enriched in silt content compared to the rest of the mud samples (Table T2 in Supplementary data)). Silt content has a positive correlation to the total SEM porosity. For example, sample SN-29 (1172.88 mbsf) exhibits a BIB-SEM porosity of 14% whereas other samples from a similar depth with less silt exhibit an average BIB-SEM porosity of 12% (Table T2 in Supplementary data)) at 20000x magnification. The samples with greater silt content are also enriched in equant-shaped silt-adjacent larger pores (Fig.10a). We also estimated the orientation of the long axis of pores for these three samples and plotted the obtained results as rose diagrams (Fig.10b). The obtained results exhibit a relatively weak preferred alignment of the long axis of pores with respect to the bedding planes (Fig.10b).

Discussions

Effective stress vs porosity: A comparison with experimental study

To understand the consolidation mechanisms of the Sumatra sediments, we estimated vertical effective stress following the steps proposed by Hüpers et al. (2015). Following Terzaghi and Peck (1948), vertical effective stress (σ_v') is expressed as:

$$\sigma_v' = \sigma_v - P_f \tag{Eqn-5}$$

Here σ_v = total vertical stress caused by the overburden load, and P_f = fluid pressure. To compute vertical effective stress of a layered sediment, we use Eqn 6:

$$\sigma_v' = \sum(\boldsymbol{\rho_s} - \boldsymbol{\rho_w}) \cdot \mathbf{g} \cdot \Delta\mathbf{z} \tag{Eqn-6}$$

where $\boldsymbol{\rho_s}$ = bulk density of the sediment, $\boldsymbol{\rho_w}$ = density of the pore water, $\Delta\boldsymbol{z}$ = depth interval, and g = gravitational acceleration. Although small offset strike-slip faults are evident at the seafloor and in seismic reflection profiles (McNeill et al., 2017a), the amount of strain attributed to these fault offsets supports the idea that the maximum horizontal stress is comparable to the vertical stress; there is no evidence in seismic reflection data or from core microstructures for thrust or reverse faults associated with a vertical least principal stress. On this basis, we assume that vertical stress is the maximum principal stress, and that pore pressure is hydrostatic. Bulk density of the sediment $\boldsymbol{\rho_s}$ was acquired from MAD data set obtained from IODP website (McNeill et al., 2017a), and $\boldsymbol{\rho_w}$ was considered as the density of seawater i.e. 1025 kg/m^3 (Hüpers et al., 2015).

We plotted vertical effective stress against MAD porosity for 55 mud samples (Fig.11). Fawad et al. (2010) experimentally studied the consolidation behavior of mud with varied proportions of silt and clay. While Sumatra samples follow trends like those defined by Fawad et al. (2010), the experimental samples are more compacted than natural Sumatra samples for the same silt content.

13

Clay mineralogy has a significant effect on the compaction behavior of mudstone (Mondol et al., 2007). Mondol et al. (2007) performed compaction experiments using pure smectite and pure kaolinite clay particle packs because they represent two end members compared to other clay minerals (illite and chlorite) in terms of grain size and surface area. Smectite is the more fine-grained clay with the largest surface area while kaolinite is coarser and has a smaller surface area than other clay mineral types (Meade, 1964; Mesri and Olson, 1971; Rieke and Chilingarian, 1974). Kaolinite is more compressible than smectite, and clay compaction gradually decreases with increasing the proportion of small size clay particles in the sample (Mondol et al, 2007).

Fawad et al., (2010) used clay mixtures of 81% kaolinite, 14% mica, and 5% microcline grains, whereas Sumatra mud samples are composed of 50%-79% illite and 5%-30% smectite, with only 8-20% undifferentiated chlorite and kaolinite and 5-10% quartz particles. Therefore, due to higher illite and smectite content, Sumatra muds appeared to be less compacted than the experimental samples used by Fawad et al. (2010).

BIB-SEM porosity vs MAD porosity

We note that BIB-SEM porosity is lower than the porosity found from shipboard MAD data, however the two measurements correlate along a line through the origin. (Fig.3b). The reason for this difference is that MAD porosity measures the total amount of moisture in a much larger sample and accounts for pores much below the PPR. Rare large pores are also under-represented in the 1 mm^2 BIB section. Earlier studies also documented and discussed mismatches between MAD and BIB-SEM measurements (Hemes et al., 2013; Houben et al., 2014; Nole et al., 2016; Oelker et al., 2019). They concluded that the mismatch could be due to several factors; i) BIB-SEM porosity largely depends on the magnification and resolution of images, ii) variation in sample sizes, and iii) MAD porosity takes into account the pores whose sizes are much lower than PPR, whereas BIB-SEM technique detects only the pores larger than PPR. We plotted estimated BIB-SEM porosity and MAD porosity data from earlier studies on Boom clay (Hemes et al., 2013; Oelker et al., 2019); Opalinus clay (Houben et al., 2014) and samples from the Nankai trough (Nole et al., 2016). The data for Boom clay and Opalinus clay follow a similar trend to the Sumatra samples, whereas clay samples from the Nankai trough shows a different trend. This difference may be attributed to differences in magnification of Nankai trough samples.

In addition, we plotted clay content against the difference between the two porosities in Fig.12a. We performed regression analysis using the data set for the 33 mud samples analyzed at Aachen (Fig.12b) for BIB-SEM porosity versus MAD porosity (following Eqn-7) but also incorporating the effect of clay content (following the Eqn-8).

BIB-SEM porosity=a*MAD porosity + c   (Eqn-7)

BIB-SEM porosity =a*MAD porosity + b*clay content + c   (Eqn-8)

The coefficient of determinations (R^2) for Eqn-7 and Eqn-8 are 0.7126 and 0.9262 respectively. These results suggest that the ratio in porosity depends on depth and clay content.

For all samples, the BIB-SEM pore size distribution follows a power-law over an interval of three orders of magnitude. We may extrapolate this below the practical pore resolution (PPR; Klaver et al., 2012; Kuila and

477   Prasad, 2013; Wang et al., 2019). Extrapolating our data set down to 3 nm pore diameter, the BIB-SEM porosity

478   increases only up to 20%~25%. A mismatch of 15% to 20% between the MAD porosity and extrapolated BIB-

479   SEM porosity remains. The fall -off from the normal trend in log-log pore size distribution plots (Fig.9b) for the

480   shallow depth (Unit-I) samples suggest that also large pores are also under-counted in the data set. The mud

481   samples from Unit-I contains forams that are rare or absent in the deeper section (Figure S11 a, b, c, and d in

482   Supplementary data), and part of missing pore volume can be attributed to the intact forams that may be missed

483   due to the small size of the BIB SEM sample.

484   Another factor that can create a mismatch between data sets is drying artefacts. In the past, Desbois et al. (2014)

485   performed a detailed study on drying artefacts of mudstone samples using Cryogenic BIB-SEM technique. They

486   identified four types of drying damages (Type-I, II, III and IV) that can develop during drying of a mudstone.

487   Type-I and type-II drying damage develops at clay/clay particle interfaces with tip to long axis contact, and at

488   clay/clast interfaces. Heterogeneous deformational behavior or shrinkage strain of clay and/or non-clay mineral

489   grains can cause a build-up in stress at the boundary between particles during drying. Type-III drying artefacts are

490   large cracks that develops within the clay matrix itself. Type-IV drying artefacts are the small damages that modify

491   pore morphology during drying. Among all of them, Type-II and III are the most spectacular and large enough to

492   modify microstructure significantly. The morphology of the type-II and III drying artefacts are characterized by

493   large irregular shaped very elongated pores with serrated pore boundaries. However, in the present study, the large

494   clay domains and silt-adjacent pores in all samples potentially show smooth edges and rounded pore tip-end, which

495   are incompatible with the typical morphologies of the drying artefacts (Fig. 5, 6 and 7). Hence, drying artefacts

496   appear to be less important for reconciling a mismatch between MAD and BIB-SEM porosity.

497   Shallow samples from Unit-I are richer in smectite content than deeper samples, although a few samples from 400

498   to 1000 mbsf have similar smectite abundances as Unit I. The moisture and density method (MAD) may

499   overestimate the measured porosity of the sediment if interlayer water from smectite is included in the

500   measurement (Brown and Ransom, 1996; Dutilleul et al., 2020). Greater smectite content in the shallow samples

501   (Unit-I) may have contributed to an overestimation of the MAD porosity in the study. This is also consistent with

502   the observation that the difference between the measurements getting larger as porosity increases.

Micromechanical model for porosity reduction

Sharp reduction in porosity at the shallow depth from the seafloor to 28 mbsf

505   High porosity (80% MAD; 32% BIB-SEM) in the shallowest sediments is attributed to large pores in the samples

506   created by abundant EE and EF particle contacts (Fig. 5a and 7a). These contacts are unstable and collapse under

507   low effective stress to form FF contacts, resulting in a rapid porosity decrease within the first 28m of burial

508   (Supplementary data-11). This deformation is apparent from the reduction of large clay domain pores observed

509   over this interval (Fig. 8; Supplementary data-10). Collapse of pores surrounded by EE and EF contacts is further

510   recognized by the progressive alignment of clay particles into the bedding plane, which promotes an increase in

511   the number of elongated, small, clay domain pores parallel to the bedding plane. Each of these observations is

512   consistent with rotation of clay particles into the bedding plane as these large clay-domain pores collapse.

Mechanism of porosity reduction from 28 mbsf to 1500 mbsf

Below 28 mbsf to >1500 mbsf, porosity continues to decrease from 52-30% (MAD) but at a reduced pace. SEM observations suggest that this porosity decline results from the progressive loss of silt-adjacent pores with large silt-adjacent pores lost before small ones (Fig. 8), although they remain present in common abundance to 1200 mbsf. Small clay domain pores are abundant throughout the section, and the large clay domain pores are lost between the seafloor and 28 mbsf.

Within the population of silt-adjacent pores, the large, equant pores are most susceptible to collapse (Fig. 8). Large, elongate pores persist in abundance, both in linear and crescent geometries. While it seems plausible that large, equant pores collapse to form large, elongate pores, no corresponding increase in the elongate pore population is observed. Large, elongate pores may collapse further and become small silt-adjacent pores. Microstructural evidence supports the idea that large equant pores collapse as surrounding clay particles within clay-rich domains bend and shrink the size of the remaining pore (Fig.13), and that the collapse results in an increasing aspect ratio of the pore.

Frequently, bent clay particles are observed on the top of larger silt-adjacent pores. In the clay microstructure, large silt-adjacent pores act as a zone of heterogeneous strain localization. Clay particles can bend and collapse into large silt-adjacent pores more readily than the smaller pores in the clay matrix (Fig.13a to f). With increasing vertical effective stress two situations can arise which are demonstrated in the model shown in Fig.13g. First, with an increase in effective stress, the bent clay particles can lose frictional resistance from the sidewall (Fig.13a and b), can continue to bend, and slide down to fill the larger silt-adjacent pore space (Fig.13g-(iii)). Second, with an increase in vertical effective stress, bent clay particles may develop fractures (red lines in Fig.13g-(iv)) and subsequently collapse into the larger silt-adjacent pore space to reduce the porosity of samples (Fig.13g-(v)). Fig.13a represents fractured bent clay on the top of the larger silt adjacent pore (shown by white arrow). Similarly, two small clay particles appear to have fallen into the larger silt adjacent pore space (Fig.13e) while another bent clay particle (shown by white arrow) covers the pore. Fig.13f represents a bent clay particle wrapping across the top of two quartz particles, and four small clay platelets fill the space between two quartz particles, suggesting an older, larger silt-adjacent pore filled by fractured clay platelets. Occurring within the pore space between two equant quartz grains (Fig.13f), four small clay particles appear to have developed due to the fracturing of two large bent clay particles. Hence, it appears that the collapse of larger silt-adjacent pores in these mud samples is governed by the bending of clay particles and subsequent fracturing due to an increase in vertical effective stress. While these processes are defined within individual pores, the observed deformation is interpreted to result from an imposed force chain that acts on specific pores in a progressive manner as the force chain evolves and as adjacent pores deform.

Small silt-adjacent pores also become less abundant with burial, but the transition occurs deeper than the large pores, and small, silt-adjacent pores remain common throughout the section (Fig. 8; Supplementary data-11). Small equant pores are lost like the large pores, and elongate pores remain abundant within this population subset throughout. There is a loose correspondence between the loss of small, equant pores and an increase in elongate

549   pores, suggesting that pore flattening is part of the pore collapse history. The pore collapse evolution outlined for
550   large pores (Fig.13g) appears to also hold for small pores, even though observations are more challenging.

551   Small, clay domain pores appear to remain resilient throughout the compaction history (Fig. 8), even though some
552   of these pores must become lost to account for porosity loss. Small, equant pores are lost between 100-200 m, and
553   this loss appears to be accommodated by an increase in elongate pores (Fig. 8). Elongate crescent pores increase
554   in abundance around 800 mbsf, and we interpret this to reflect folding of abundant linear elongate pores as the
555   overall system compacts.

556   Large equant pores in the clay domain are lost within the first few 10's of meters of burial. Elongate pores appear
557   to form at the expense of equant pores, and there may be a reduction in pore size associated with this shape change.
558   Most of the pores remaining after 1500 m of burial are small, elongate pores found both in clay domain and silt-
559   adjacent pores.

560   The presence of silt particles locally redistributes the force chain of load to retain undeformed, silt-adjacent, large
561   pores (Schneider et al., 2011). The samples with greater silt content are also enriched in equant-shaped silt-adjacent
562   larger pores (Fig.10) in the microstructure. Hence, as a result, they display greater porosity compared to other
563   samples from similar depth intervals (Fig.10).

564   Previous studies report contrasting ideas on the development of phyllosilicate fabric strength due to mechanical
565   compaction. Some studies suggest that mechanical compaction creates a phyllosilicate fabric in mud (Bowles et
566   al., 1969; Oertel and Curtis, 1972; Vasseur et al., 1995), whereas other studies conclude that vertical effective
567   stress has limited impact on phyllosilicate fabric development (Ho et al., 1999; Aplin et al., 2006; Day-Stirrat et
568   al., 2008; 2011). Here, we consider the preferred orientation of pores as a proxy for the alignment of phyllosilicate
569   (Hemes et al., 2013). At shallow depth (Unit-I), a weak preferred alignment of the long axis of pores with maxima
570   oriented obliquely to the bedding planes is formed (Supplementary data-15), and at greater depth (Unit-II and III)
571   the long axes of pores become aligned subparallel to the bedding plane. Increase in vertical effective stress below
572   28 mbsf depth creates only a small increase in the preferred orientation of the long axis of pores. Hence, we found
573   only a limited change in phyllosilicate fabric strength with increasing vertical stress..

574   Previous authors also document the evolution of pore size distribution in mud with an increase in consolidation
575   stress using laboratory experiments and merury-intrusion porosimetry (Griffiths and Joshi, 1989; 1990). They
576   conclude that the pore size distribution appears to be bi-modal, and the distribution curve shifts toward smaller
577   pore sizes with an increase in applied consolidation stress (Griffiths and Joshi, 1989). We observe an initial
578   transition from tri-modal to bi-modal pore size distribution around 28 mbsf depth due to rapid collapse of large
579   clay domain pores by compactional strain. With an increase in depth below 28 mbsf, the bi-modal pore size
580   distribution persists and tends to shift toward small pore sizes as the number of larger silt-adjacent pores
581   diminishes.

582   Laboratory studies have emphasized the importance of clay particle rotation as a dominant mechanism for
583   mechanical compaction in mudstone (Bennett et al., 1981, 1991; Vasseur et al., 1995; Aplin et al., 2006; Day-
584   Stirrat et al., 2008; 2011). We observe particle rotation only in the shallowest samples where unstable EE and EF

585 particle contacts are present. Clay particle bending and sliding/fracturing are considered more important for most
586 of the section studied.

Mechanical compaction of marine sediment: a conceptual model

588 According to earlier studies (Delage and Lefebvre, 1984; Griffiths and Joshi, 1989; 1990; Emmanuel and Day-
589 Stirrat 2012), the reduction of pores in sedimentary rocks during compaction is size-dependent - larger pores
590 deform much readily than smaller pores. According to their model, larger pores rapidly decrease in size during
591 compaction to reduce the overall porosity of the sample. However, microstructural analysis of Sumatra samples
592 suggests that porosity reduction is accomplished by compaction of all pore sizes. Moreover, the maximum size of
593 pores remains almost constant irrespective of increasing vertical effective stress/depth (Supplementary data-8)
594 with little difference observed for the maximum pore size in samples from 98.25 mbsf and 1299.31 mbsf. The
595 preservation of a constant ratio between MAD and BIB-SEM porosity measurements (Fig. 3b) suggests that
596 porosity loss is distributed across all pore sizes. We infer that all pore sizes are available for compaction for every
597 increment of applied stress but acknowledge that pore size reduction in different size classes may proceed at
598 different rates.

599 We propose a new model for the reduction in porosity in which all pores within the force chain of load take part
600 in the reduction of porosity during compaction irrespective of their size. At shallow depth up to 28mbsf, larger
601 clay-domain pores are the most susceptible to early response during an increase in compactional strain, because of
602 two reasons: 1) the 'domains' defined by the clay particles are weaker compared to the larger, rigid silt grains, and
603 2) due to higher relative proportion of clay-rich regions within the mud, the force chain of load dominantly passes
604 through the clay domains. The dispersed nature of the silt-size particles and the high proportion of phyllosilicates
605 in the mud samples indicate that soft clay particles act as the principal load-bearing framework. Hence, larger clay
606 domain pores are more unstable compared to silt-adjacent pores in the mud microstructure. Similarly, below
607 28mbsf depth, under an increase in vertical effective stress, both the larger silt-adjacent pores and smaller pores in
608 the clay matrix that come within the force chain of load collapse. Hence, the ratio between BIB-SEM porosity vs
609 MAD porosity remains almost constant irrespective of the depth. All larger silt-adjacent pores do not come within
610 the force chain of load at the same time. Hence, some of the larger silt-adjacent pores remained undeformed to the
611 maximum depth of 1500mbsf depth. Therefore, the maximum size of the larger silt-adjacent pores remains almost
612 constant irrespective of the depth/vertical effective stress.

613 In this study, we investigated how systematically pore types evolve with increasing depth in naturally compacted
614 samples. However, tracking the pore evolution through additional size categories would elucidate the pore
615 evolution in more detail. Preliminary pore size distribution data (Fig.9) indicate that 4 size bins exist in these
616 samples. Developing this approach requires improved image analysis techniques to tie all the pore attributes
617 together on a pore-by-pore basis for a huge number of pores.

Compaction strain accommodation and grain-scale deformation

619 Deformation of clay-rich sedimentary rocks involves four possible mechanisms: 1) Particulate flow; (Morgenstern
620 and Tchalenko, 1967; Borradaile et al., 1981); 2) Cataclasis; (Ukar and Cloos, 2019) 3) Diffusive mass transfer;

18

621 (Blenkinsop, 2007; Fossen, 2016); 4) Intercrystalline plasticity (Blenkinsop, 2007; Fossen, 2016). Intensity and
622 occurrence of a particular deformation mechanism in a mudstone depend on several parameters, such as effective
623 stress, water content, cementation, temperature (Desbois et al., 2017; Den Hartog and Spiers, 2014).

624 All our samples show evidence of particulate flow controlled by friction between grains. At shallow depths, illite
625 platelets contacted at EE and EF junctions lose these weak bonds, and particles rotate into bedding-parallel
626 orientation. Once FF contacts dominate, large-scale rotations are reduced, and inter-particle slip becomes
627 important. This is best evidenced in collapse of large, silt-adjacent pores where bent clay particles overlay pores
628 (Fig.14a to f). In deforming granular foam material, bending was reported as the dominant deformation mechanism
629 for the reduction in porosity and developing preferred alignment of the long axis of pores perpendicular to the
630 applied stress (Elliott et al., 2002, Zhou et al., 2004; Samsudin et al., 2017; Zakaria et al., 2018) (review of these
631 earlier studies on the experimental deformation of granular foam is described in document S2). Friction adheres
632 clay particles to the edge of pores while the middle of particles drops into the pore, resulting in bending by intra-
633 particle slip. A cartoon (Fig.14g) illustrates the compaction mechanism associated with the bending of clay
634 particles. With increasing compaction strain, clay particles undergo bending, and as a result, pore area reduces,
635 and the orientation of the pores tends to align perpendicular to the applied effective stress (Fig.14g). At shallow
636 depths (Unit-I), particles get enough free space for rotation to align parallel to the bedding plane because of higher
637 porosity (Figure S12a and b). However, at greater depth where porosity decreases, space problems limit particle
638 deformation to bending and fracturing as increase in compactional strain increases (Figure S12c and d).

Compaction of Sumatra input section: generalized implication for rock property evolution

641 The overall compaction curve obtained for Sumatra muds is comparable with the experimental study by Fawad et
642 al., 2010 in the context of compactional range (Fig.8). The curve shows a mono-exponential decrease in porosity
643 with an increase in vertical effective stress, which is evidence of normal consolidation (Fawad et al., 2010;
644 Dutilleul et al., 2020).

645 The larger silt-adjacent pores seen in the deepest of these samples (1500 m burial) suggest these muds retain
646 considerable potential for additional mechanical compaction with deeper burial. As this marine sediment
647 progressively approaches greater burial closer to the accretionary prism, it will undergo further change in physical
648 and deformational properties (Bray and Karig, 1985). Despite the substantial compactional strain, the relatively
649 high porosity of the deepest sample and the survival of larger and mechanically unstable silt-margin pores suggests
650 that compactional stabilization has yet to be reached because such IGVs and pore types are not generally observed
651 in older and lithified mudrocks. Based on the current understanding of subduction zone deformation behavior and
652 mudrock properties, it seems likely that mechanical compaction will continue to dominate the pore loss in deeper
653 burial.

654 The general absence of early cementation and the corresponding dominance of mechanical compaction in the total
655 pore loss is consistent with observations of other siliciclastic-dominated muds (Milliken, 2014; 2019). The trends
656 for intergranular volume change observed from the seafloor and 1500 mbsf place useful constraints on the

maximum cement volumes that theoretically could be emplaced at this depth range in sediments containing a more reactive grain assemblage. At the depths of burial attained at the deformation front, any cementation of the Sumatra input sediments will be limited to <30% of the rock volume, or possibly much less, as mechanical compaction is expected to continue up to the burial temperatures that initiate grain reactions and associated cementation.

Conclusions

Pores are classified by size and microstructural position, resulting in a multi-modal contribution to the total porosity. Shallow samples (seafloor to 28 mbsf) display a sharp reduction in porosity from 80% to 52% as large clay domain/matrix pores collapse. Deeper samples (28 mbsf to 1500 mbsf) exhibit a smaller reduction in porosity from 50% to 32% due to the collapse of silt-adjacent pores by bending and subsequent fracturing/sliding of clay particles.

The class of large pores next to silt-sized grains (between 10^4 and 10^6 nm^2) remains common to >1 km burial, irrespective of the mineralogy of the silt-sized grains, but their size decreases with depth. Small, equant pores next to silt particles are abundant in the first 100 m of burial and remain common over the entire depth range.

Small pores in clay domains are almost all elongated, and abundant over all observed depths. Small, crescent-shaped elongate pores increase in abundance with depth as clay particles become folded by compactional processes.

The size-independence of pore loss arises because the force chain driving pore collapse is localized primarily within the volumetrically dominant and weaker clay-rich domains; larger pores around isolated silt particles enter into the force chain somewhat randomly and asynchronously and do not contribute preferentially to pore loss over the depth range studied.

An increase in effective stress up to 18 MPa (~1500 mbsf) causes the development of weakly aligned phyllosilicate fabric (defined by mica and illite clay particles) in the microstructure.

Compaction processes in our samples are dominated by granular flow (rotation and frictional sliding of illite clay particles) at shallow depths. With increasing depth, compaction is additionally accommodated by bending of clay particles.

Data availability

High resolution SE2 and BSE images of all samples are available online at:
https://figshare.com/s/cbaada517b0b1409d575

Authors contributions

SL and KLM performed sample preparation and BIB-SEM microscopy. SL analysed the data. JLU and GD acquired funding. JLU managed the project. PV, KLM and JLU significantly contributed to interpret the data. SL

688 wrote the first draft of the manuscript. PV, KLM and JLU contributed for the correction and improvement of the
689 manuscript.

Fig.1: (a) Satellite image of Sumatra subduction zone and location of U1480 and U1481 drilling sites (created from © Google Maps). (b) Schematic diagram showing location of primary drilling site and deepest drill hole (Hole G) at site U1480 in sectional view (adapted from seismic profile from SW to NE after Hüpers et al., 2017). Location and extension of the seismic profile is represented by red line in (a). (c) Lithostratigraphic units encountered at Site U1480 (adapted after McNeill et al., 2017a). (d) Representative tube sample received from IODP repository, Japan. Red-colored line on tube surface represents notch used to denote orientation of samples collected from drill core. (e) Representative BIB cross-section polished perpendicular to bedding plane.

1013
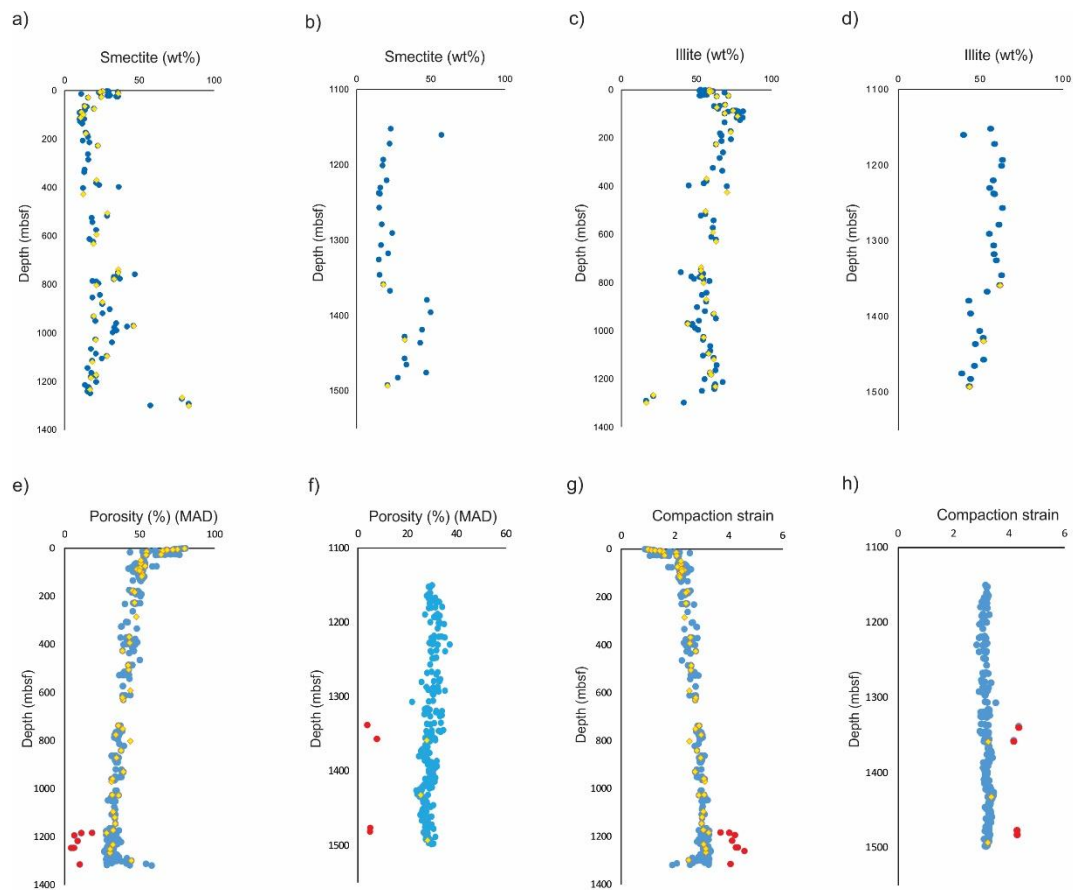

Fig.2: Depth profiles of smectite content (wt%; clay fraction) for Sites U1480 (a) and U1481 (b) (blue symbol). Depth profiles of illite content (wt%; clay fraction) for Sites U1480 (a) and U1481 (b) (blue symbol). Yellow symbols indicate samples analyzed by SEM imaging. (e) and (f) Shipboard MAD (Moisture and density) porosity profiles for mudstone samples recovered from Sites U1480 and U1481 (blue symbol). (g) and (h) Calculated compaction strain profiles for Sites U1480 and U1481 (blue symbols). Red-colored points are cemented (concretion) samples. Clay mineralogy data plotted from Rosenberger et al. (2020), and MAD data extracted from McNeill et al. (2017b).
Fig.3: Porosity data for Units I (green dots), II (orange dots), and IIIA (blue dots). (a) BIB-SEM porosity - depth plot, (b) BIB-SEM porosity vs MAD porosity. Note: linear relationship that intersects origin. Data reported by Hemes et al. (2013); Houben et al. (2014); and Oelker et al. (2019) follow similar trend. However, data estimated from Nole et al. (2016) deviates from trend.

Fig.4: Classification scheme adopted to demonstrate pore reduction mechanics with increasing compactional strain. Dashed lines indicate rare pore types.

34
Fig.5: Microstructural overview (BIB-SEM) of samples SN-1 (a and b), SN-2 (c and d), and SN-6 (e and f). Green color represents segmented pores of the corresponding microstructure of sample. i = Equant large clay domain pores, ii = elongated large clay domain pores, iii = Crescent-shaped large clay domain pores, iv = equant small clay domain pores, v = Crescent-shaped small clay domain pores, vi = elongated small clay domain pores, vii = Equant large silt-adjacent pores, viii = elongated large silt-adjacent pores, ix = Crescent-shaped large silt-adjacent pores, x =equant small silt-adjacent pores, xi = Crescent-shaped small silt-adjacent pores, xii = elongated small silt-adjacent pores. EE= Edge to edge contact, EF=Edge to face contact, and FF=Face to face contact.
Fig.6: Microstructural overview (BIB-SEM) of samples SN-8 (a and b), SN-16 (c and d), and SN-33 (e and f). Green color represents segmented pores of the corresponding microstructure of sample. i = Equant large clay domain pores, ii = elongated large clay domain pores, iii = Crescent-shaped large clay domain pores, iv = equant small clay domain pores, v = Crescent-shaped small clay domain pores, vi = elongated small clay domain pores, vii = Equant large silt-adjacent pores, viii = elongated large silt-adjacent pores, ix = Crescent-shaped large silt-adjacent pores, x =equant small silt-adjacent pores, xi = Crescent-shaped small silt-adjacent pores, xii = elongated small silt-adjacent pores. FF= Face to face contact, EF= Edge to face contact.

Fig.7: Microstructural overview (Field Emission SEM) of samples SN-34, SN-49, and SN-55. i = Equant large clay domain pores, ii =elongated large clay domain pores, iii = Crescent-shaped large clay domain pores, iv = equant small clay domain pores, v = Crescent-shaped small clay domain pores, vi = elongated small clay domain pores, vii = Equant large silt-adjacent pores, viii = elongated large silt-adjacent pores, ix = Crescent-shaped large silt-adjacent pores, x =equant small silt-adjacent pores, xi = Crescent-shaped small silt-adjacent pores, xii = elongated small silt-adjacent pores. FF= Face to face contact, EF= Edge to face contact.
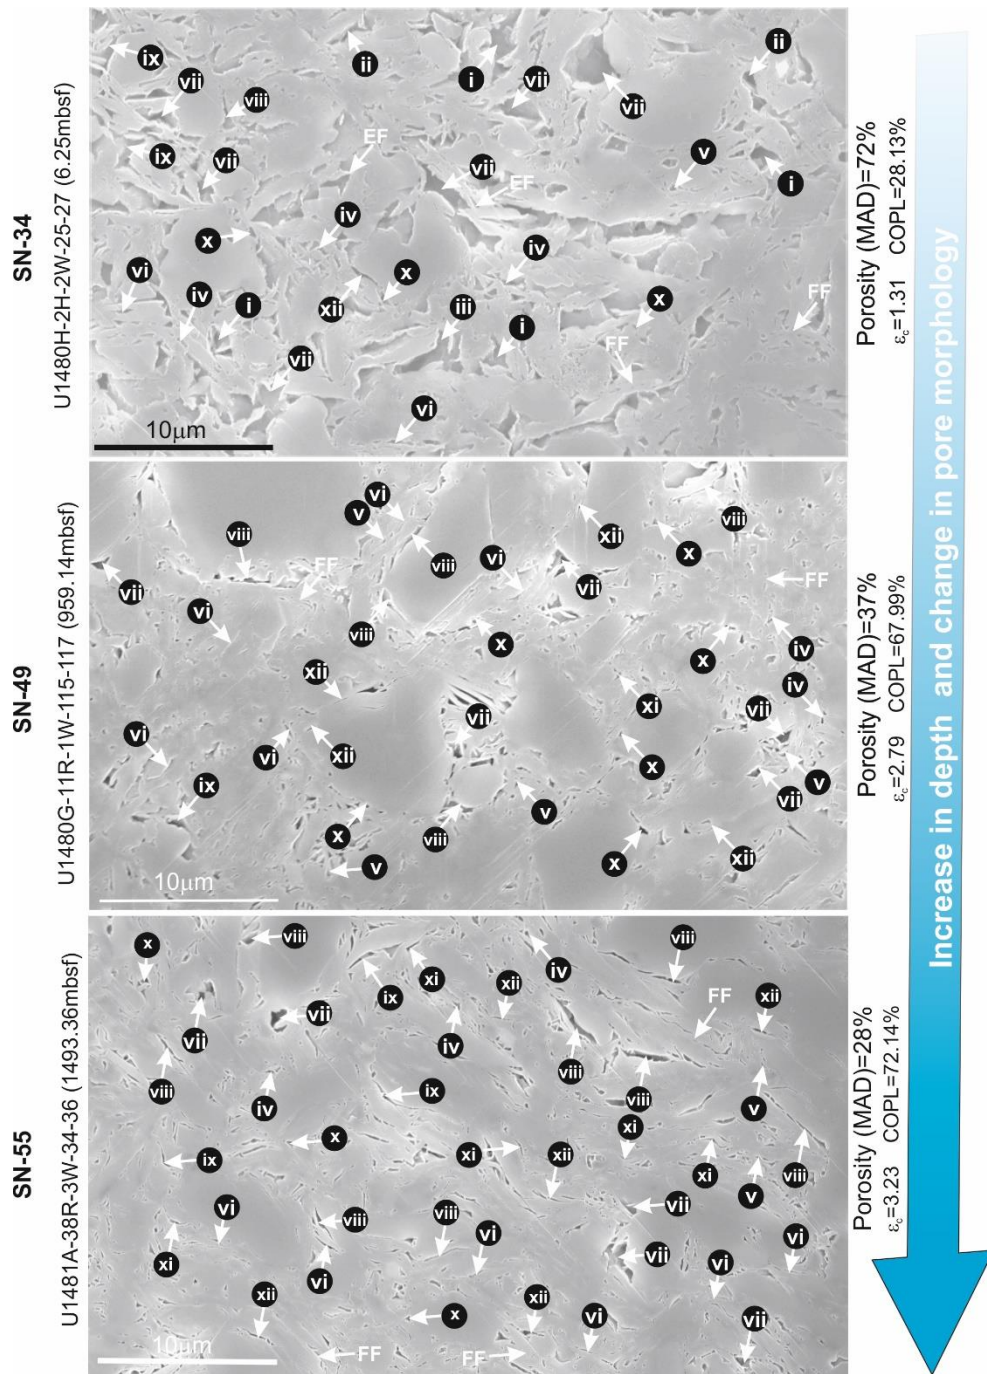

Fig.8: Pore type summary for clay domain (a-c) and silt-adjacent (d-f) pore types. (a) abundance of small and large clay domain pores; (b) and (c) depth progression of small and large clay domain pore morphologies; (d) abundance of small and large silt-adjacent pores; (e) and (f) depth progression of small and large clay domain pore morphologies. Abundant = >25% pores, common = 2%-25% pores, rare = 0-2% pores, absent = not observed.

1098
Fig.9: Pore size distribution defined by pore area. Left column: normalized frequency (blue) and contribution to total porosity (orange). Right column: pore size-frequency log-log distribution. Power-law between PPR and maximum pore size interpreted as black line with corresponding regression parameters. Sample number, depth, and compactional strain defined along right side of diagram

Fig.14: a-f: examples of clay aggregate bending (white arrows). (g) Conceptual diagram tracing porosity reduction and increase in preferred alignment of the long axes of pores by bending of clay perpendicular to applied vertical stress.

Table 1: Core description, bulk mineralogy (McNeill et al., 2017b) and clay composition (Rosenberger et al., 2020) of the analysed samples. <mark>Bulk measurements were done shipboard on Expedition 362 (McNeil et al., 2017a; Underwood, 2020). Additional clay mineralogical analysis was done on the <2μm particle fraction onshore using a different instrument and methodology (Rosenberger et al., 2020). Here, Plag= Plagioclase feldspar, Smec= Smectite*, Chl= Chlorite, Kaol= kaolinite, Calc= Calcite.</mark>
