## 11 12 **Abstract**

13 Transpressional uplift domains of inverted Pliocene–Pleistocene basin fill along the  
14 San Andreas fault zone in Coachella Valley, southern California (USA), are characterized by  
15 fault linkage and segmentation and deformation partitioning. The Indio Hills wedge-shaped  
16 uplift block is located in between two boundary fault strands, the Indio Hills fault to the  
17 northeast and the main San Andreas fault to the southwest, which merge to the southeast.  
18 Uplift commenced about or later than 0.76 million years ago and involved progressive fold  
19 and faulting stages caused by a change from distributed strain to partly partitioned right-slip  
20 and reverse/thrust displacement on the bounding faults when approaching the fault junction.  
21 Major fold structures in the study area include oblique, right-stepping, partly overturned *en*  
22 *echelon* macro-folds that tighten and bend into parallelism with the Indio Hills fault to the east  
23 and become more open towards the main San Andreas fault to the west, indicating an early  
24 and close relationship of the macro-folds with the Indio Hills fault and a late initiation of the  
25 main San Andreas fault. Sets of strike-slip to reverse step-over and right- and left-lateral cross  
26 faults and conjugate kink bands affect the entire uplifted area, and locally offset the *en*  
27 *echelon* macro-folds. Comparison with the Mecca Hills and Durmid Hills uplifts farther  
28 southeast along strike in Coachella Valley reveals notable similarities, but also differences in  
29 fault architectures, spatial and temporal evolution, and deformation mechanisms. The present  
30 work contributes to better understand the structure and tectonic history of a major fault system  
31 along a transform plate boundary.

32

### 33 **Introduction**

34           This paper describes and evaluates structural patterns of the Indio Hills uplift in the  
35 northwestern part of Coachella Valley along the San Andreas fault zone (SAFZ) in California,  
36 southwestern USA (Fig. 1), where the fold–fault architecture, evolution, and partitioning of  
37 deformation compared to Mecca Hills and Durmid Hills are not well understood (e.g., Keller  
38 et al., 1982, Dibblee and Minch, 2008). The main goal of this study is to analyze internal  
39 macro- and meso-scale folds and related faults and to outline the kinematic evolution in  
40 relation to major SAFZ-related fault strands in the area (Fig. 1: Keller et al., 1982; Guest et  
41 al., 2007). These include the Indio Hills fault in the northeast (Allen, 1957; Tyley, 1974), and  
42 the main San Andreas fault along the southwest flank of the Indio Hills and of the Mecca  
43 Hills, and along the northeast flank of the Durmid Hills (Janecke et al., 2018; Fig. 1). The  
44 progressive tectonic evolution model for the Indio Hills uplift is then compared and correlated  
45 with other major uplifts and SAFZ-related fault strands along strike in the Mecca Hills and  
46 Durmid Hills (Sylvester and Smith, 1987; McNabb et al., 2017; Janecke et al., 2018; Bergh et  
47 al., 2019). We also discuss briefly the potential northwestward continuation of the Indio Hills  
48 fault into the Eastern California shear zone and its role as possible transfer fault (Dokka and  
49 Travis, 1990a, 1990b; Thatcher et al., 2016). The variable fault and fold architectures and  
50 associated ongoing seismic activity in these uplift areas underline the need for persistent  
51 along-strike studies of the SAFZ to characterize the fundamental geometry, resolve the  
52 kinematic development, and correlate regionally major fault strands (cf. Janecke et al., 2018).  
53 Such studies are essential to explain the observed lateral variations in fold and fault  
54 architectures and to resolve mechanisms of transpression, fault linkage, and areal  
55 segmentation in continental transform settings.

56

### 57 **Geological setting**

58           The Coachella Valley segment of the SAFZ in southern California is expressed as  
59 multiple, right-lateral fault strands, which uplifted blocks in the Indio Hills, Mecca Hills, and  
60 Durmid Hills (Fig. 1; Sylvester, 1988). These domains comprise thick successions of  
61 Pliocene–Pleistocene sedimentary strata uplifted and deformed in Pleistocene–Holocene time  
62 due to oblique convergence of the Pacific and North American plates and movement along the  
63 SAFZ and related faults (e.g., Atwater and Stock, 1998; Spotila et al., 2007; Dorsey et al.,  
64 2011). Recent structural studies in the Mecca Hills (McNabb et al., 2017; Bergh et al., 2019),  
65 and Durmid Hills at the southern termination of the SAFZ (Janecke et al., 2018), show that

66 individual fault strands are linked, and that the deformation splits into abruptly changing fold  
67 and fault geometries (Fuis et al., 2012, 2017). These recent works call for further  
68 characterization of the understudied Indio Hills segment in order to compare its structural  
69 development with other uplifted features along a major transform plate boundary fault zone.  
70 Below we summarize local and regional fault nomenclature, distribution, and fault movement  
71 history (Table 1) throughout the greater Coachella Valley region (Fig. 1), the stratigraphy of  
72 the Indio Hills area, and previous structural work in the main Indio Hills, Mecca Hills, and  
73 Durmid Hills uplift areas.

74

### 75 ***Regional faults***

76 The southeastern Indio Hills are a WNW–ESE–trending tectonic uplift situated in a  
77 small restraining bend northeast of the main San Andreas fault (Figs. 1 and 2 and Supplement  
78 S1). The studied uplift is located along strike about 25–50 kilometers northwest of the Mecca  
79 Hills and Durmid Hills, and to the southeast of the major left bend in the SAFZ trace near San  
80 Gorgonio Pass (Matti et al., 1985, 1992; Matti and Morton, 1993; Dair and Cooke, 2009).

81 The main faults in the southeastern Indio Hills include the Indio Hills fault in the  
82 northeast (Allen, 1957; Tyley, 1974), and the main San Andreas fault in the southwest (we  
83 refrain from using the name “Indio strand” ascribed to this fault by Gold et al., 2015 to avoid  
84 confusion with the Indio Hills fault). Regionally, the Indio Hills fault possibly merges with  
85 the Landers–Mojave Line and the Eastern California shear zone in the north (Dokka and  
86 Travis, 1990a, 1990b; Nur et al., 1993a, 1993b; Thatcher et al., 2016). The Landers–Mojave  
87 Line is believed to be the locus of several recent earthquakes aligned in a NNW–SSE-trend,  
88 including the 1992 Joshua Tree earthquake (Fig. 1b; Nur et al., 1993a, 1993b). These  
89 earthquakes were tentatively ascribed to movement along a through-going NNW–SSE-  
90 striking fault, possibly the west-dipping, Quaternary West Deception Canyon fault (Sieh et  
91 al., 1993; Rymer, 2000). This fault is thought to crosscut the E–W- to ENE–WSW-striking,  
92 left-lateral, Holocene Pinto Mountain fault, which merges with the main strand of the San  
93 Andreas fault in the west at the intersection of the right-lateral Mission Creek and Mill Creek  
94 strands (Allen, 1957; Bryant, 2000; Kendrick et al., 2015; Blisniuk et al., 2021). The former is  
95 thought to correspond to the continuation of the main San Andreas fault to the northwest  
96 (Gold et al., 2015) and may have accommodated ca. 89 km of right slip in the past 4 million  
97 years, whereas the latter accommodated about 8 km right slip at 0.5–0.1 Ma and is offset ca. 1  
98 km by the Pinto Mountain fault (Kendrick et al., 2015).

99           The main San Andreas fault continues to the southeast where it bounds the Mecca  
100 Hills to the southwest. The Painted Canyon fault, a previous (late Miocene?–) Pliocene  
101 southwest-dipping normal fault reactivated as a right-lateral-reverse oblique-slip fault in the  
102 Pleistocene–present-day, bounds the Mecca basin to the northeast (Sylvester and Smith, 1987;  
103 McNabb et al., 2017; Bergh et al., 2019). Farther southeast, the main San Andreas fault  
104 proceeds along the northeast flank of the Durmid Hills opposite the Pleistocene (ca. 1 Ma),  
105 right-lateral East Shoreline fault (Babcock, 1969, 1974; Bürgmann, 1991; Janecke et al.,  
106 2018). There, the main San Andreas fault merges with the Brawley seismic zone (Lin et al.,  
107 2007; Hauksson et al., 2012; Lin, 2013) and, together with the right-lateral San Jacinto fault  
108 zone, they merge into the right-lateral Imperial fault (Rockwell et al., 2011). In the north, the  
109 main San Andreas fault splays into the Banning strand and the Mission Creek fault in the  
110 northwestern part of the Indio Hills (Keller et al., 1982; Gold et al., 2015). The Banning  
111 strand is much younger than the Mission Creek fault and may have accommodated  
112 approximately 3 km of right slip in the past 0.1 million years (Kendrick et al., 2015).

113           Northwest and west of the Coachella Valley, Miocene–Pleistocene sedimentary strata  
114 are structurally bounded by the San Bernardino and San Jacinto fault strands of the SAFZ  
115 (Bilham and Williams, 1985; Matti et al., 1985; Morton and Matti, 1993; Spotila et al., 2007).  
116 To the southwest, Miocene–Pleistocene strata are bounded by the West Salton Detachment  
117 fault (Dorsey et al., 2011). The San Jacinto fault is typically believed to have slipped ca. 25  
118 km right-laterally in the past 1.5 million years (Matti and Morton, 1993; Kendrick et al.,  
119 2015), whereas the West Salton Detachment fault is a low-angle normal fault that  
120 accumulated ca. 8–10 km of normal-oblique movement starting in the mid Miocene and is  
121 related to the opening of the Gulf of California (Prante et al., 2014 and references therein).

122

### 123 *Stratigraphy of the Indio Hills and adjacent areas*

124           The Indio Hills uplift is an inverted Pliocene–Pleistocene sedimentary basin lying  
125 upon Mesozoic granitic basement rocks, which we regard as an analog to the inverted Mecca  
126 basin farther southeast (Keller et al., 1982; Damte, 1997; McNabb et al., 2017; Bergh et al.,  
127 2019). In the Mecca basin, alluvial, fluvial and lacustrine deposits of the Mecca and Palm  
128 Spring formations are truncated unconformably by the mid to upper Pleistocene Ocotillo  
129 Formation (Dibblee, 1954; Sylvester and Smith, 1976, 1987; Boley et al., 1994; Rymer, 1994;  
130 Sheridan et al., 1994; Sheridan and Weldon, 1994; Winker and Kidwell, 1996; Kirby et al.,  
131 2007; McNabb et al., 2017; Table 1). Similar uplifted strata at Durmid Hills (Fig. 1) belong to  
132 the Pliocene–Pleistocene Borrego Formation, and are overlain by mid to upper Pleistocene

133 deposits of the Brawley and Ocotillo formations (Dibblee, 1997; Herzig et al., 1988; Lutz et  
134 al., 2006; Kirby et al., 2007; Dibblee and Minch, 2008).

135         Leuco-granitic rocks crop out near gently SW-dipping conglomerates along the  
136 northeastern flank of the Indio Hills, near the trace of the Indio Hills fault (Fig. 2). Despite  
137 proximity of the conglomerates with segmented granite outcrops, the contact itself is not  
138 exposed. The conglomerates are the lowermost stratigraphic unit exposed in the Indio Hills  
139 and are characterized by a succession of meter-thick beds of very coarse, poorly sorted blocks  
140 of gneissic and granitic rocks more than a meter in size. Previous mapping in the area  
141 (Dibblee, 1954; Lancaster et al., 2012) considered the conglomerates as stratigraphic  
142 equivalents to the mid to upper Pliocene Mecca Formation in the Mecca Hills (Sylvester and  
143 Smith, 1987; McNabb et al., 2017; Bergh et al., 2019) and that at least part of the clasts are  
144 from the leuco-granitic rocks, which must correspond to basement rocks of the inverted Indio  
145 Hills basin. Up-section toward the southwest the conglomerate gradually is succeeded by  
146 coarse-grained sandstone, which defines the transition from the Mecca Formation to the lower  
147 Palm Spring Formation.

148         The Palm Spring Formation in the Indio Hills consists of moderately- to well-  
149 consolidated alluvial fan deposits (Dibblee and Minch, 2008), with some interbedded gypsum  
150 layers and red-colored calcareous mudstone, as in the Mecca Hills (Sylvester and Smith,  
151 1987). The main rock types include beds of light-colored, medium- to coarse-grained  
152 sandstone, gray–brown silty sandstone, and dark biotite-rich mudstone. The southwestwards  
153 increase in silt–clay toward the main San Andreas fault (also recorded in the Mecca Hills;  
154 Bergh et al., 2019) may indicate a gradual transition from the lower to the upper member of  
155 the Palm Spring Formation. By contrast, the transition between the lower and upper members  
156 of the Palm Spring Formation in the Mecca Hills is marked by two angular unconformities  
157 that signal further steps in uplift and inversion of the Mecca basin (Table 1; McNabb et al.,  
158 2017; Bergh et al., 2019).

159         Ages of 3.0–2.3 Ma (latest Pliocene–early Pleistocene) and 2.6–0.76 Ma (earliest  
160 Pleistocene to earliest late Pleistocene), were obtained respectively for the lower and upper  
161 member of the Palm Spring Formation in the Mecca Hills based on reversed magnetic polarity  
162 data (Chang et al., 1987; Boley et al., 1994; McNabb, 2013; McNabb et al., 2017; Table 1).  
163 We infer a similar age range for the Palm Spring Formation in the southern Indio Hills.

164         In contrast to other uplift areas in Coachella Valley, the Ocotillo Formation has not  
165 been mapped in the Indio Hills in the present study. However, based on the occurrence of the  
166 Bishop Ash at the northwestern edge of the study area and on the occurrence of the volcanic

167 deposit within the uppermost Palm Spring Formation or at the base of the overlying Ocotillo  
168 Formation in the Mecca Hills, it is likely that the Ocotillo Formation is present just northwest  
169 of the area mapped (Fig. 2). In addition, it is deposited on the flank northeast of the Indio  
170 Hills fault, and southwest of the main San Andreas fault (Figs. 1 and 2), indicating that this  
171 unit was either not deposited or eroded in the area that recorded the most uplift in Indio Hills.

172 Additional dating constraints on transpressional uplift in the Coachella Valley include  
173 tephrochronology of the 0.765 million year old Bishop Ash layer (Sarna-Wojcicki et al., 2000;  
174 Zeeden et al., 2014; Table 1). This volcanic deposit is found within the upper member of the  
175 Palm Spring Formation (which is unconformably overlain by the Ocotillo Formation) in the  
176 hanging wall of the Painted Canyon fault away from the fault, and within the base of the  
177 Ocotillo Formation in the hanging wall of the Painted Canyon fault near the fault (Ocotillo  
178 and uppermost Palm Spring formations interfingering near the fault) and in the footwall of the  
179 fault (McNabb et al., 2017; Bergh et al. 2019). The unconformable contact between the Palm  
180 Spring and Ocotillo formations away from the Painted Canyon fault towards the southwest  
181 and their interfingering relationship near the fault suggest that uplift had already initiated prior  
182 to deposition of the Ocotillo Formation (i.e., before 0.76 Ma, in the mid Pleistocene), possibly  
183 during the formation of the lower unconformity between the lower and upper members of the  
184 Palm Spring Formation (McNabb et al., 2017; Table 1). Complementarily, the involvement of  
185 the Bishop Ash in deformation suggest that deformation continued past 0.76 Ma (in the late  
186 Pleistocene).

187

## 188 ***Major tectonic uplifts in the Coachella Valley***

### 189 *Indio Hills*

190 The southeastern end of the Indio Hills is an uplifted domain of deformed strata of the  
191 Mecca and Palm Spring formations situated in between the main San Andreas and Indio Hills  
192 fault (Fig. 2). The main San Andreas fault corresponds to a major oblique strike-slip fault  
193 segment at the eastern end of San Gorgonio Pass (Matti et al., 1985; Morton et al, 1987). It is  
194 easily traced to Indio Hills (Figs. 1 and 2) since its main trace provides preferential pathways  
195 for ground water flow and growth of wild palm trees along strike.

196 The Indio Hills fault was mapped north of the study area (Dibblee and Minch, 2008)  
197 extending into the Landers–Mojave Line (Nur et al., 1993a, 1993b), a NNW–SSE-striking  
198 right-lateral fault system extending hundreds of kilometers northward from the southeastern  
199 Indio Hills into the Eastern California shear zone and related fault segments such as the  
200 Calico and Camp Rock faults (Fig. 1; Dokka et al., 1990a; Nur et al. 1993b). The Indio Hills

201 fault may correspond to a major fault splay of the SAFZ (Dokka and Travis, 1990a, 1990b;  
202 Thatcher et al., 2016). Southeast of the Indio Hills, however, the geometry of the Indio Hills  
203 fault remains elusive, and the fault either dies out or merges with structures like the main San  
204 Andreas fault, the Skeleton Canyon fault, and/or the Painted Canyon fault in the Mecca Hills  
205 (Fig.1).

206 The transpressional character of the Indio Hills uplift was suggested by Sylvester and  
207 Smith (1987). However, detailed structural analyses documenting this hypothesis for the uplift  
208 as a whole have not been conducted. Gold et al. (2015) explore tectonogeomorphic evidence  
209 for dextral-oblique uplift and Keller et al. (1982) and Blisniuk et al. (2021) focus on landscape  
210 evolution near the intersection of the Banning strand and Mission Creek fault (northwest of  
211 the study area), which merge into the main San Andreas fault (Fig. 1). In addition to  
212 investigating soil profiles, offset drainage systems, and recent (a few thousand years old)  
213 displacement along the SAFZ, Keller et al. (1982) called attention to a strong dominance of  
214 gently plunging and upright macro-folds in bedrock strata along the Mission Creek fault and  
215 at the southeastern end of the Banning strand where these faults merge. Their study showed  
216 that bends and steps along the main fault traces were consistently located near brittle fault  
217 segments and zones of uplift. The study also showed that drainage systems were offset  
218 recently (at ca. 0.03–0.02 Ma) and indicate relatively high slip rates along the Mission Creek  
219 fault in the order of 23–35 cm.y<sup>-1</sup>, i.e., comparable to the more recent c. 23 cm.y<sup>-1</sup> estimate by  
220 Blisniuk et al. (2021).

### 221 *Mecca Hills*

222 Farther south, the Mecca Hills uplift was previously defined as a classic flower-  
223 structure (Sylvester and Smith, 1976, 1987; Sylvester, 1988), in which all folds and faults  
224 formed synchronously and merged at depth. Recent analyses (Bergh et al., 2014, 2019)  
225 indicate that a modified flower-like structure, consisting of a steep SAFZ fault core zone to  
226 the southwest, a surrounding approximately one–two kilometers wide damage zone expressed  
227 by *en echelon* folds and faults oblique to the SAFZ (including left-slip cross faults), steeply  
228 plunging folds, and SAFZ-parallel fold and thrust belt features (including right- and left-slip  
229 and oblique-reverse faults) formed in kinematic succession. In addition to the steep shallow  
230 portion of the SAFZ (Fuis et al., 2012, 2017), two other, major NW–SE-striking faults occur  
231 in the Mecca Hills (Fig. 1). One is the Skeleton Canyon fault, which initiated as a steep  
232 SAFZ-parallel strike-slip fault and was reactivated as a reverse fault dipping gently  
233 northeastwards in the late kinematic stages (Sylvester and Smith, 1976, 1979, 1987; Bergh et  
234 al., 2019). The other is the Painted Canyon fault, which is a former Miocene–Pliocene basin-

235 bounding normal fault (McNabb et al., 2017) and is now reactivated as a NE-directed thrust  
236 fault with dip to the southwest (Bergh et al., 2019; Table 1). The polyphase evolution and  
237 reactivation of internal oblique, step-over faults, and SAFZ-parallel faults, were explained by  
238 a series of successive–overlapping events involving a change from distributed, locally  
239 partitioned, into fully partitioned strain in a changing, oblique-plate convergence regime  
240 (Bergh et al., 2019).

#### 241 *Durmid Hills*

242 The Durmid Hills are an elongate ridge that parallels the main strand of the SAFZ at  
243 the south edge of the Salton Sea in Imperial Valley (Fig. 1). Farther south, this deformation  
244 zone and the SAFZ project towards the Brawley seismic zone, an oblique, transtensional rift  
245 area with particularly high seismicity (Lin et al., 2007; Hauksson et al., 2012; Lin, 2013). The  
246 main San Andreas fault (mSAF) is located on the northeast side of the Durmid Hills and has  
247 been thoroughly studied (Dibblee, 1954, 1997; Babcock, 1969, 1974; Bilham and Williams,  
248 1985; Bürgmann, 1991; Sylvester et al., 1993; Lindsey and Fialko, 2013; Janecke et al.,  
249 2018). The rocks southwest of the mSAF consist of highly folded Pliocene–Pleistocene  
250 deposits (Babcock, 1974; Bürgmann, 1991; Markowski, 2016; Janecke et al., 2018) bounded  
251 to the southwest by the subsidiary East Shoreline fault strand of the SAFZ. Northeast of the  
252 mSAF, the formations are much less deformed (Janecke et al., 2018). The overall structure  
253 (Fig. 1) resembles a right-lateral strike-slip duplex (Sylvester, 1988), but the geometry is not  
254 fully consistent with a duplex model due to abundant left-lateral cross faults and internal  
255 block rotations. Instead, the Durmid Hills structure was interpreted as a ladder structure  
256 (Janecke et al., 2018), as defined by Davis (1999) and Schulz and Balasko (2003), where  
257 overlapping, E–W- to NW–SE-striking step-over faults rotated along multiple connecting  
258 cross faults. The one–three kilometers wide Durmid ladder structure consists of multiple  
259 internal, clockwise-rotating blocks bounded by major *en echelon* folds and right- and left-  
260 lateral cross faults in between the right-slip mSAF and East Shoreline fault strand, indicating  
261 a complex termination of the SAFZ around the Brawley Seismic Zone to the southeast  
262 (Fig.1).

263

#### 264 **Methods and data**

265 In our investigation of the Indio Hills, we used Google Earth images and aerial  
266 photographs (© Google Earth 2011) as a basis for detailed field and structural analyses (Fig.  
267 2). We mapped and analyzed individual macro- and meso-scale folds and associated faults in  
268 Miocene–Pliocene strata both in the field and via imagery analysis. Key horizons of light-

269 colored quartz sandstone and carbonate rocks in the Palm Spring Formation provide structural  
270 markers, notably to correlate bed displacement and fault–fold geometries and kinematics. We  
271 address crosscutting relations of the main San Andreas and Indio Hills faults and nearby fold  
272 structures. Structural orientation data are obtained from meso-scale folds and faults and are  
273 integrated between the areal segments to link a prevalent pattern of deformation into a wider  
274 structural architecture (Fig. 2).

275

## 276 **Results**

### 277 *Structural overview of the Indio Hills*

278 The study area comprises three major, SAFZ-oblique, asymmetric, E–W-trending,  
279 moderately west-plunging fold systems having multiple smaller-scale parasitic folds (Fig. 2).  
280 The main folds affect most of the Palm Spring Formation in a zone approximately two  
281 kilometers wide between the main San Andreas and Indio Hills faults (Fig. 2). The  
282 northeastern flank of the Indio Hills is structurally different by consisting of a sub-horizontal,  
283 NW–SE-trending, open, upright anticline, which trends parallel to the Indio Hills fault (Fig.  
284 2). Similarly, close to the main San Andreas fault, tilted strata of the Palm Spring Formation  
285 are folded into a tight, steeply plunging shear fold (folds involving shearing along a plane that  
286 is parallel to subparallel to the fold’s axial plane; Groshong, 1975; Meere et al., 2013; Fig. 2).  
287 At smaller scale, several subsidiary reverse faults and mostly right-slip, step-over faults  
288 having orientations both parallel with (E–W to NW–SE) and perpendicular (NNE–SSW) to  
289 the bounding faults exist within the macro-folded domain. Most of these faults truncate  
290 individual SAFZ-oblique folds.

291

### 292 *SAFZ-oblique macro-folds*

293 SAFZ-oblique macro-folds are consistently asymmetric and mostly south-verging, and  
294 their axial surfaces are arcuate and right-stepping (Fig. 2). Fold geometries change from open  
295 and nearly upright near the main San Andreas fault, to kink/chevron styles in the middle part,  
296 to very tight (isoclinal) and overturned fold styles adjacent to the Indio Hills fault (Fig. 3a–c  
297 and Supplement S2a–c). These changes in geometry correspond to a change in obliquity of  
298 the fold axial surface trace from approximately 60–70° to less than 20° with the Indio Hills  
299 fault (Fig. 2). All three macro-folds have axial trends that bend and partly merge into  
300 parallelism with the Indio Hills fault. In contrast, moderate to steeply WSW-dipping strata of  
301 the Palm Spring Formation are obliquely truncated by the main San Andreas fault. Tighter  
302 fold hinges are mapped in the central macro-fold and on the back-limb (stretched long limb in

303 an overturned fold) of the Z-shaped, southeastern macro-fold (Fig. 2). These folds were not  
304 observed northeast of the Indio Hills fault, nor southwest of the main San Andreas fault.

#### 305 *Northwestern and central macro-folds*

306 The northwestern and central macro-folds define two major, compound and arcuate  
307 fold systems that affect the entire Palm Spring Formation between the main San Andreas and  
308 Indio Hills faults (Fig. 3a–b). They consist of eight subsidiary Z- and S-shaped, south-verging  
309 anticline-syncline pairs, and show fold axes plunging variably but mostly about 30° to the  
310 west (Fig. 2). At large scale, both folds tighten northeastward and display clockwise bend of  
311 axial traces from ENE–WSW near the main San Andreas fault, to E–W and NW–SE as they  
312 approach the Indio Hills fault (Fig. 2 and 3c). Fold hinges in the west are typically symmetric,  
313 concentric, and open (Supplement S3a–b), and become gradually tighter and dominantly Z-  
314 shaped kink folds eastward (Supplement S3c). The folds transform into tight, isoclinal, and  
315 inverted geometries (Supplement S3d–e) when approaching the central macro-fold back-limb  
316 (Fig. 3b), and they potentially merge with the SAFZ-parallel anticline less than 200 meters  
317 from the Indio Hills fault (Fig. 2). From southwest to northeast, the central macro-fold hinge  
318 zone displays a corresponding change in geometry, i.e., from symmetric, to kink/chevron, and  
319 to isoclinal overturned styles (Supplement S4a–b), until the folds of the central macro-fold  
320 flank the back-limb of the southeastern macro-fold (Supplement S4c–d). Bedding surfaces on  
321 the fore-limb (the shortened, inverted limb indicating the direction of tectonic transport in an  
322 overturned fold) of the central macro-fold dip steeply or are inverted, whereas strata on the  
323 back-limb mostly dip gently to the north or northwest, i.e., at a high angle to the bounding  
324 faults, and gradually change to northward dip when approaching the Indio Hills fault (Fig.  
325 3c).

326 Another feature of the central macro-fold is that it is offset by a system of both layer-  
327 parallel and bed-truncating faults (Fig. 3b). Strata east of the fault system are affected by a  
328 large shear fold having thickened hinges and thinned limbs. The next fold to the north-  
329 northeast changes from open to tight, overturned, and locally isoclinal (Supplement S4a–c),  
330 and merges with the inverted, NE-dipping back-limb of the southeastern macro-fold (Fig. 3c).  
331 Notably, the consistent eastward tightening of fold hinges occurs within the lower  
332 stratigraphic parts of the Palm Spring Formation, whereas conglomerates of the underlying  
333 Mecca Formation are only weakly folded (see Southeastern macro-fold section). Furthermore,  
334 beds in tighter folds (especially in relatively weak clayish–silty dark mudstone layers) are  
335 commonly accompanied by disharmonic folds and internal structural unconformities. By  
336 contrast, more rigid, and thicker sandstone beds are more commonly fractured.

337 *Southeastern macro-fold*

338         The southeastern macro-fold is expressed as a kilometer-wide, Z-shaped, open to tight,  
339 south-verging syncline-anticline pair showing moderately west-plunging axes and steeply  
340 north-dipping axial surfaces (Fig. 3c). Most of the Palm Spring Formation strata on the back-  
341 limb trend parallel to the Indio Hills fault and dip about 50–70° to the north, whereas strata in  
342 the hinge and fore-limb dip about 40–70° to the west/southwest (Fig. 3c). Combined with a  
343 relatively narrow hinge zone, these attitudes define the southeastern macro-fold as a chevron  
344 type. The axial trend of the syncline-anticline pair is at a low angle (< 20°) to the Indio Hills  
345 fault but bends into a NE–SW trend westward with a much higher (oblique) angle to the main  
346 San Andreas fault, which cuts off the fore-limb strata (Fig. 2). The southeastern macro-fold is  
347 very tight in the north and east and has several smaller-scale, tight to isoclinal, strongly  
348 attenuated folds on the main back-limb that merge from the central macro-fold, thus  
349 indicating increasing strain intensity northeastward (see discussion). In contrast to the tightly  
350 folded beds of the Palm Spring Formation, bedding surfaces in conglomerates of the  
351 underlying Mecca Formation are only weakly folded northeastward and becomes part of the  
352 open SAFZ-parallel anticline close to the Indio Hills fault.

353         A macro-folded siltstone layer of the lower Palm Spring Formation more than 200  
354 meters southwest of the Indio Hills fault (Fig. 4a) contains centimeter-scale, upright (sub-  
355 horizontal) and disharmonic folds having E–W trend and western plunge (Fig. 4b). These  
356 intra-layer folded strata are cut by low-angle reverse faults yielding a NE-directed sense-of-  
357 shear. The upright geometry and the sub-horizontal fold axes (about 5° plunge) of these intra-  
358 bed minor folds differ from the SAFZ-oblique folds but resemble those of the macro-scale,  
359 SAFZ-parallel NW–SE-trending anticline near the Indio Hills fault. These disharmonic folds  
360 are interpreted as intra-detachment folds (see discussion).

361

362 *SAFZ-parallel macro-folds*

363         About 100–200 meters southwest of the trace of the Indio Hills fault, the  
364 conglomerates of the Mecca Formation are folded into a major open anticline, whose axis is  
365 parallel to slightly oblique (< 20°) to the Indio Hills fault. This macro-fold is traceable  
366 northwestward to where the Indio Hills fault bends northward (Fig. 1). The southwestern limb  
367 of the fold marks the transition from the Mecca Formation conglomerate with the overlying  
368 Palm Spring Formation on the back-limb of the southeastern and central macro-folds (Fig. 2  
369 and Supplement S4c). The conglomerate beds are thicker, nearly unconsolidated, and much  
370 less internally deformed than the strata of the Palm Spring Formation. The major anticline

371 displays an open, symmetric, partly box-shaped, NW–SE-trending, upright geometry with 2–  
372 3° plunge of the fold axis to the northwest. Outcrops on the SW-dipping limb of the anticline  
373 (Fig. 3c) are cut by a SW-dipping reverse fault system that is sub-parallel to the Indio Hills  
374 fault (Supplement S5a). These reverse faults may be linked with the reverse fault in folded  
375 strata of the Palm Spring Formation on the southeastern macro-fold back-limb described  
376 above (Fig. 4). The upright geometry and sub-horizontal NW–SE-trending axes of related  
377 small-scale folds in a mudstone layer (Fig. 4) resembles that of the SAFZ-parallel anticline.

378 A couple of major synclines showing axial traces parallel to the main San Andreas  
379 fault are also well displayed on Google Earth images (Fig. 5 and Supplement S6). These folds  
380 affect WSW-dipping strata of the Palm Spring Formation on the broadened western part of  
381 the northwest and central macro-folds. Fold geometries are tight and asymmetric, with  
382 wavelengths less than 200 meters, and presumably steep NW-plunging axes. The local  
383 appearance and sheared geometry of these folds contrast both with the broad SAFZ-oblique  
384 folds near the main San Andreas fault, and with that of the upright, SAFZ-parallel anticline  
385 near the Indio Hills fault.

386

### 387 *Major and minor faults*

388 Fold-related brittle faults exist both in granitic basement and in sedimentary rocks of  
389 the Mecca and Palm Spring formations in the study area. Such faults display narrow damage  
390 zones less than one meter wide and are geometrically either related to SAFZ-oblique or  
391 SAFZ-parallel macro- and meso-scale folds, or are orthogonal to the SAFZ and related faults.  
392 With exception of the main San Andreas and Indio Hills faults, brittle faults are generally  
393 difficult to trace laterally but, where preserved, they display centimeter- to meter-scale strike-  
394 slip and/or reverse dip-slip displacement. Macro-scale fault orientations and kinematics in  
395 sedimentary rocks are more variable than in basement rocks, but strike commonly WNW–  
396 ESE to N–S and show moderate–steep dips to the northeast (Fig. 2). Subsidiary meso-scale  
397 faults include high-angle SW- and SE-dipping strike-slip faults, and low-angle SW-dipping  
398 thrust faults. We describe the Indio Hills and main San Andreas faults, strike-slip faults, and  
399 thrust faults in sedimentary strata, and fractures in basement rocks northeast of the Indio Hills  
400 fault.

### 401 *Indio Hills and main San Andreas faults*

402 Along the Indio Hills fault, poor exposures make it difficult to measure fault strike and  
403 dip directly, but Google Earth images suggest a rectilinear geometry in map view relative to  
404 the uplifted sedimentary strata to the southwest (Fig. 2). The fault strikes mainly NW–SE and

405 is subparallel to the northeastern flank of the Indio Hills. Farther southeast, it probably merges  
406 with the main San Andreas fault (Fig. 1; Tyler, 1974). In the southeastern part of the study  
407 area (Fig. 2), the Indio Hills fault is most likely located between an outcrop of basement  
408 granite and the first outcrops of overlying strata of the Palm Spring Formation. The granite  
409 there is highly fractured and cut by vein and joint networks (see description below), as may be  
410 expected in the damage zone of a major brittle fault.

411 Like the Indio Hills fault, fault-plane dip and strike of the main San Andreas fault  
412 must be inferred indirectly. The main San Andreas fault in the study area strikes WNW–ESE  
413 and is sub-vertical based on its consistent rectilinear surficial trace, and because it truncates  
414 both back- and fore-limb strata on most of the SAFZ-oblique macro-folds (Fig. 2). Thus, the  
415 main San Andreas fault does not seem to have had major impact on the initial geometry and  
416 development of the macro-folds in the Indio Hills. However, notable exceptions include  
417 displacement by the main San Andreas fault of the two shear folds on the southern flank of  
418 the macro-folds (Fig. 5), and a consistent anticlockwise bend of most axial traces of the  
419 macro-folds (Fig. 2).

#### 420 *Strike-slip faults in folded sedimentary strata*

421 One major brittle fault set striking NW–SE and dipping steeply to the northeast has  
422 developed on the central macro-fold (Figs. 3b and 6). The faults splay out from a bedding-  
423 parallel core zone subparallel to steeply SW-dipping mudstone–siltstone layers on the  
424 southern limb of the central macro-fold, and then proceed to truncate NW-dipping  
425 sedimentary strata and offset the hinge of a macro-fold by c. 70 meters right-laterally before  
426 dying out (Supplement S7a–b). The fault damage zone is traceable for more than one  
427 kilometer along strike as a right-slip fault which displaces the hinge of a major, tight,  
428 asymmetric, shear-like (similar style) fold (Fig. 6 and Supplement S8). The shear-folded  
429 sedimentary strata bend clockwise toward the main fault, thus supporting dominant right-  
430 lateral slip (Fig. 6). Minor faults branch out from the fault core zone and either die out in the  
431 macro-fold hinge, and/or persist as bedding-parallel faults for some distance on the southern  
432 limb of the macro-fold (Fig. 6).

433 At smaller scale, the folded and tilted strata of the Palm Spring Formation are  
434 commonly truncated by sets of steep NW–SE-striking right-lateral and NNE–SSW-striking  
435 left-lateral faults, displaying meter- to centimeter-scale offsets (Supplement S7b–d). These  
436 minor faults generally dip steeply to the northeast to east-northeast, i.e., opposite to most  
437 bedding surfaces, which dip southwest (Fig. 3b), and, in places, develop reddish fault gouge  
438 along strike. Furthermore, these minor faults typically cut sandstone beds and flatten, and/or

439 die out within, mudstone beds, which restricts their lateral extent to a few decimeters–meters.  
440 Kinematic indicators, such as offset of bedding surfaces and fold axial surfaces, yield mostly  
441 right-slip displacements, in places with minor reverse components. In some localities, on fold  
442 limbs within thick and competent sandstone beds, such minor right- and left-slip faults appear  
443 to form conjugate sets (Supplement S7b and d) that may have developed simultaneously. In  
444 addition, NNE–SSW-striking, ESE-dipping faults and/or semi-brittle kink bands sub-  
445 orthogonal to the SAFZ are well displayed in the southeastern macro-fold (Fig. 3c and  
446 Supplement S7e) and cut bedding surfaces at high angles with left-slip displacement,  
447 therefore potentially representing cross faults between segments/splays of the SAFZ system.

#### 448 *Reverse and thrust faults in folded sedimentary strata*

449 Reverse and thrust faults are common and traceable on the back-limb of the central  
450 and southeastern macro-folds near the SAFZ-parallel anticline and the Indio Hills fault, but  
451 not recorded in areas close to the main San Andreas fault. Reverse faults strike mainly NW–  
452 SE and dip gently to the southwest, although subsidiary gently NE-dipping faults exist. An  
453 example is the low-angle reverse fault that propagates out-of-the syncline on the southeastern  
454 macro-fold (Fig. 4) and yields a NE-directed sense-of-shear. This thrust fault may continue  
455 westward into the central macro-fold (Fig. 3b), where reverse offset of SW-dipping strata of  
456 the Palm Spring Formation constrains vertical displacement from about 10–15 meters  
457 (Supplement S5a), though offset is only of a few centimeters in the southeast (Fig. 4). This  
458 fault system has a listric geometry, and internal splay faults die out in thick silt- to mud-stone  
459 layers. The low-angle faults seem to develop almost consistently near major fold hinge zones  
460 and propagate northeastward as out-of-the syncline thrusts (Fig. 4 and Supplement S5a).

461 In sandstone beds on the north-dipping limb of the major syncline, minor-scale thrust  
462 faults, offset asymmetric fold hinges (Supplement S7c) and yield down-to-the-north (normal)  
463 sense of shear if the strata are rotated to a horizontal position (Supplement S9). An opposite  
464 effect is apparent for a conjugate set of minor normal faults in a small-scale graben structure  
465 on the steep, north-dipping layer, which defines a set of reverse faults when rotating the  
466 sedimentary strata to horizontal (Supplements S7d and S9).

#### 467 *Fractures and faults in basement rocks north of the Indio Hills fault*

468 Basement-rock exposures in the Indio Hills are limited to a single, approximately 50-  
469 m long chain of outcrops located in the southeasternmost part of the study area (Fig. 2). These  
470 outcrops of massive granite are heavily fractured with mostly steep to sub-vertical sets that  
471 strike dominantly NE–SW to ENE–WSW and subsidiary NW–SE to NNW–SSE (see  
472 stereoplot in Fig. 2). Kinematic indicators are generally lacking, but in highly fractured areas,

473 centimeter-thick lenses of unconsolidated reddish gouge are present, comparable to fault  
474 rocks observed in Palm Spring Formation sedimentary rocks and corresponding to similar  
475 small-scale strike-slip and reverse faults in the basement granite. The fault sets in granitic  
476 basement rocks trend parallel to fault sets in sedimentary strata southeast of the Indio Hills  
477 fault (see stereoplots in Figure 2) and are therefore suggested to have formed due to similarly  
478 oriented stress.

479

## 480 **Discussion**

### 481 *Structural evolution of SAFZ-oblique folds*

482 We mapped and analyzed three macro-scale fold systems between the Indio Hills and  
483 main San Andreas faults. In map view (Fig. 2), the folds are right-stepping, and each fold set  
484 is increasingly asymmetric (Z-shaped) and sigmoidal towards the Indio Hills fault in the  
485 northeast. Based on these properties, we interpret the fold sets as modified SAFZ-oblique *en*  
486 *echelon* macro-folds. Various investigators (Babcock, 1974; Miller, 1998; Titus et al., 2007;  
487 Janecke et al., 2018; Bergh et al., 2019) describe similar fold geometries in sedimentary strata  
488 from many other segments of the SAFZ and are interpreted as structures formed by right-  
489 lateral displacement between two major fault strands. However, the present fold-orientation  
490 data in the Indio Hills (Fig. 2) do not correspond with a uniform simple shear model in  
491 between two active strike slip faults because the long axis of the strain ellipse is not  
492 consistently about 45° to the shear zone as expected (Sanderson and Marchini, 1984;  
493 Sylvester, 1988). Instead, fold geometries vary both across and along strike, e.g., axial surface  
494 traces of dying-out macro-fold hinges are at high obliquity angles (> 50–65°) in the  
495 southwest, whereas they are at much lower angles (< 20–30°) and merge with sigmoidal-  
496 shaped patterns against the Indio Hills fault (Fig. 2). Thus, we propose that the SAFZ-oblique  
497 macro-folds in Indio Hills rather evolved from a single boundary fault (Indio Hills fault)  
498 being progressively more active through time. For example, a model in which the folds  
499 initially splayed out from an early active Indio Hills fault through right-lateral distributed  
500 displacement (compare with Titus et al., 2007) is consistent with fold hinges extending  
501 outward south of the Indio Hills fault and dying out (broadening) away from the fault in a  
502 several kilometer-wide damage zone (Fig. 2). Fold propagation outward from the Indio Hills  
503 fault is supported by the increased structural complexity of the fold geometries towards the  
504 Indio Hills fault. Furthermore, the initial upright, *en echelon* folding clearly occurred after  
505 deposition of the entire Palm Spring Formation because of the involvement in folding of the  
506 Bishop Ash and of adjacent strata possibly of the Ocotillo Formation (i.e., maximum age of

507 0.76 Ma – earliest late Pleistocene; Fig. 2 and Table 1). Should the whole Ocotillo Formation  
508 be folded in the Indio Hills, the maximum age constraints could be narrowed to < 0.6–0.5 Ma  
509 based on magnetostratigraphic ages for the upper part of the Ocotillo Formation (Kirby et al.,  
510 2007). By contrast, the main San Andreas fault truncates both limbs of the open-style, *en*  
511 *echelon* folds (Fig. 2), which therefore indicates younger deformation along this fault.

512 The moderate–steep westward plunge of all three macro-folds ( $\geq 30^\circ$ ), however,  
513 shows that the presumed initial horizontal fold hinges rotated into a steeper plunge. Such  
514 steepening may be due to, e.g., progressive shortening above a deep-seated fault, a hidden  
515 splay of the Indio Hills fault, or to an evolving stage of distributed shortening (folding)  
516 adjacent to the master strike-slip faults (e.g., Bergh et al., 2019), with gradually changing  
517 stress–strain orientation through time, and/or due to structural tilting in the hanging wall of  
518 the Indio Hills fault. This kind of fold reworking favors a situation where the northwestern  
519 and central macro-folds were pushed up and sideways (right-laterally), following the  
520 topography and geometry of an evolving transpressional uplift wedge (i.e., a contractional  
521 uplift formed synchronously with successively with simple shear transpression to balance  
522 internal forces in a crustal-scale critical taper; Dahlen, 1990). The corresponding eastward-  
523 tightening, enhanced shear folding, and recurrent SW-directed overturned geometries of the  
524 central macro-fold on the back-limb of the southeastern macro-fold near the Indio Hills fault  
525 (Fig. 3b) support this idea.

526 We propose a progressive model that changes from distributed (*en echelon* folding) to  
527 partly partitioned, i.e., pure shear (shortening) plus simple shear (strike-slip) deformation  
528 (Fig. 7), as inferred for other parts of the SAFZ, e.g., in the Mecca Hills (Bergh et al., 2019).  
529 In this model, the tight to isoclinal fold geometries to the northeast (Fig. 3b) may account for  
530 progressively more intense shortening near the Indio Hills fault, whereas coeval strike-slip  
531 faulting affected the already folded and steeply dipping strata of the lower Palm Spring  
532 Formation (Fig. 6). This model would favor shortening to have evolved synchronously with  
533 renewed strike-slip shearing adjacent to the Indio Hills fault, and/or on a blind fault below the  
534 contact between the Mecca Formation and overlying Palm Spring Formation, because the  
535 Mecca Formation is much less deformed (Fig. 3c). Alternatively, the more mildly deformed  
536 character of the Mecca Formation conglomerate may arise from its homogeneity, which  
537 contrasts with alternating successions of mudstone–siltstone and sandstone of the Palm Spring  
538 Formation prone to accommodating large amounts of deformation and to strain partitioning.  
539 Regardless, such reshaping of *en echelon* folds is supported by analog modelling (McClay et  
540 al., 2004; Leever et al., 2011a, 2011b) suggesting that partly partitioned strain may lead to a

541 narrowing of fold systems near a major strike-slip fault (i.e., Indio Hills fault), whereas  
542 widening away from the fault indicates still ongoing distributed deformation. Partly  
543 partitioned deformation is supported by the tight to isoclinal and consistent Z-like geometry of  
544 smaller-scale folds present on the back-limb of the central and southeastern macro-folds (Fig.  
545 3b–c), indicating that they are all parasitic folds and related to the same partly partitioned  
546 shear-folding event. Where S- and Z-like fold geometries are present, these minor folds may  
547 have formed by buckling in an early stage of *en echelon* folding. An alternative interpretation  
548 is that the tight, reshaped parasitic folds are temporally linked to the SAFZ-parallel macro-  
549 fold south of the Indio Hills fault (Fig. 3c; see next section).

550

### 551 ***Structural evolution of SAFZ-parallel folds***

552 The SAFZ-parallel anticline differs significantly in geometry from the *en echelon*  
553 macro-folds and associated parasitic folds by having an upright and symmetric geometry <  
554 20° oblique to the Indio Hills fault. Thus, it resembles that of a fault-propagation fold in a  
555 more advanced partitioned transpressional segment of the SAFZ (e.g., Titus et al., 2007;  
556 Bergh et al., 2019). We suggest that this fold formed by dominant NE–SW-oriented  
557 horizontal shortening, i.e., at high obliquity to the main Indio Hills fault (near-orthogonal pure  
558 shear), and/or as a fault-related fold above a buried, major reverse (SW-dipping) oblique-slip  
559 splay of the Indio Hills fault at depth (e.g., Suppe and Medwedeff, 1990). The timing might  
560 be after the tight reworking of *en echelon* folds in the late Pleistocene. The idea of a late-  
561 stage, highly oblique pure-shear overprint onto the macro-folds is supported by small-scale  
562 upright folds located within the tight *en echelon* syncline on the back-limb of the modified  
563 central macro-fold system (Fig. 4). The NW–SE trend, upright style, and negligible plunge of  
564 the fold axes indicate that these folds may be superimposed on the steeper plunging and  
565 reshaped *en echelon* folds, and/or that they formed in progression to an increased component  
566 of NE–SW shortening on the Indio Hills fault. Nonetheless, these folds may have formed  
567 simultaneously with the *en echelon* macro-folds in the (earliest?) late Pleistocene (Table 1)  
568 due to uncertain (not fully understood) crosscutting relationships.

569 Progressive NE–SW-oriented contraction may have triggered formation of the upright  
570 SAFZ-parallel anticline adjacent to the Indio Hills fault (Fig. 2 and 3c). The fault then acted  
571 as a SW-dipping thrust fault with top-NE displacement. The oblique shortening then led to a  
572 certain amount of uplift near the Indio Hills fault, and possibly also accomplished the  
573 overturning of folds on the northeastern back-limb of the central and southeastern macro-fold.  
574 A similar mode of advanced partitioned shortening was proposed for SAFZ-parallel fold

575 structures in central and southern California (Mount and Suppe, 1987; Titus et al., 2007;  
576 Bergh et al., 2019). Our results are supported by stress orientation data acquired by Hardebeck  
577 and Hauksson (1999) along a NE–SW-trending profile across the Indio Hills. They recorded  
578 an abrupt change in the maximum horizontal stress direction from about 40° oblique to the  
579 SAFZ around the main San Andreas fault, to about 70° oblique (i.e., sub-orthogonal) farther  
580 northeast, near the Indio Hills fault, which supports the change in attitude and shape of macro-  
581 fold geometries that we have outlined. Shortening and strike-slip partitioning, however, would  
582 require synchronous right slip on another major fault strand, e.g., the main San Andreas fault,  
583 a hypothesis that is supported by the recorded late-stage (i.e., late Pleistocene) shear folding  
584 there (Fig. 5).

585

### 586 *Fold and fault interaction, evolution, and relative timing*

587 In this section we use the geometry and kinematics of folds and faults in the southern  
588 Indio Hills to reconstruct the tectonic history of the area, not only of the inverted late  
589 Cenozoic basin but also about strike-slip and dip-slip faults that bound the basin. Essential  
590 tectonic events include (1) extensional normal faulting along the Indio Hills fault in the mid-  
591 Miocene–Pliocene (ca. 15–3.0 Ma), (2) reactivation of the Indio Hills fault as a right-lateral to  
592 oblique-reverse fault in the (earliest?) late Pleistocene to present-day (< 0.76 Ma), and (3)  
593 right-lateral movement along the main San Andreas fault in the late Pleistocene to present-day  
594 (< 0.76 Ma; Table 1).

595 Prior to inversion and uplift of the Indio Hills, the Indio Hills fault most likely acted as  
596 a SW-dipping, extensional, basin-bounding normal fault. Indications of an early-stage episode  
597 of extension are shown by micro-fault grabens in steeply dipping layers (Supplements S5d  
598 and S6), by the deposition and preservation of sedimentary strata of the Palm Spring and  
599 Mecca formations southwest of the Indio Hills, whereas they were eroded or never deposited  
600 northeast of the fault, and by fining upwards of the stratigraphic units from conglomerates in  
601 the Mecca Formation to coarse-grained sandstone in the lower parts of the Palm Spring  
602 Formation. In addition, the flat geometry of micro thrust faults (e.g., Supplements S5b–c)  
603 suggests that they were rotated during macro-folding. Restoration of all micro faults in their  
604 initial position prior to macro-folding shows that some of these faults exhibit normal  
605 kinematics with associated syn-tectonic growth strata (Supplements S5d and S9).

606 Alternatively, the Indio Hills fault dips northeast and uplifted the granitic basement rocks in  
607 the hanging wall to the northeast, followed by erosion of the overlying Mecca, Palm Spring  
608 and Ocotillo formations there (Fig. 1). We favor a basin geometry and formation similar to

609 that of the Mecca Hills, where down-SW slip along the Painted Canyon fault was inferred in  
610 the (Miocene?–) Pliocene (McNabb et al., 2017), and of the transtensional Ridge Basin  
611 though having opposite vergence (Crowell, 1982; Ehman et al., 2000) with a steep, SW-  
612 dipping normal fault that was progressively reactivated as an oblique-slip reverse/thrust fault  
613 during basin inversion. Formation of the Indio Hills fault as a normal fault probably occurred  
614 in mid-Miocene times during extension related to the opening of the Gulf of California (Stock  
615 and Hodges, 1989; Stock and Lee, 1994) as proposed for the Salton Trough (Dorsey et al.,  
616 2011 and references therein).

617 Right-lateral to right-lateral-reverse movement along the Indio Hills fault that led to  
618 the formation of the SAFZ-oblique *en echelon* macro-folds also supports a steeply dipping  
619 character for the precursory Indio Hills fault. The change to a right-lateral-reverse fault is  
620 further supported by the presence of both meso-scale strike-slip and thrust faults having  
621 similar NW–SE strikes (Fig. 4, and Supplements S4c and S5a). The increased reverse (and  
622 decreasing right-lateral) component of faulting may have triggered rotation of the *en echelon*  
623 macro-fold axes to a steeper plunge, reshaped the open asymmetric folds into tight overturned  
624 folds, and caused gentle buckling of strata in the nearby SAFZ-parallel anticline. Hence, the  
625 Indio Hills fault ultimately functioned as an oblique-slip thrust oblique to the transform plate  
626 boundary in the late Pleistocene, which is supported by oblique maximum horizontal stress  
627 near the Indio Hills fault (c. 70°; Hardebeck and Hauksson, 1999), while the main San  
628 Andreas fault simultaneously accommodated right slip during this period.

629 By contrast, the last episode of movement along the main San Andreas fault clearly  
630 postdates *en echelon* folding, from its truncating attitude (Fig. 2). In addition, the  
631 anticlockwise bending of the axial traces into an ENE–WSW trend towards the southwest  
632 suggests that a distributed component of off-fault deformation affected the area around the  
633 main San Andreas fault in its early kinematic stages in the late Pleistocene. The refolding of  
634 the southwest limb of the central macro-fold near the main San Andreas fault (Fig. 5) also  
635 favors a late-stage activation of this fault in the late Pleistocene (i.e., after the initial  
636 transpressional slip events along the Indio Hills fault in the – earliest? – late Pleistocene).  
637 Possibly as a consequence of a longer period of activity, and as suggested by relatively higher  
638 topographic relief and more intensely folded sedimentary strata in the vicinity of and along  
639 the Indio Hills fault than along the main San Andreas fault, the former probably  
640 accommodated significantly larger amounts of uplift than the latter. This implies a southwest-  
641 tilted geometry for the Indio Hills uplift.

642 Minor faults in the Indio Hills provide additional input to resolve the spatial, temporal  
643 and kinematic relations between macro-fold and fault interaction. We analyzed minor fault-  
644 related folds (Supplement S5c), which, in their current position on steep north-dipping beds,  
645 define down-to-the north displacement. However, when rotating the sedimentary strata to  
646 horizontal (Supplement S9), the fault-related folds define a low-angle fold-and-thrust system.  
647 These geometric relationships suggest that the minor folds and faults (other than right-slip  
648 faults) pre-date (or were coeval with) the SAFZ-oblique macro-folding event, and that they  
649 formed initially as internal fractures due to N–S-oriented shortening when the sedimentary  
650 strata were still horizontal. This implies that some partitioning (e.g., SAFZ-parallel small-  
651 scale thrust faults) occurred simultaneously with distributed deformation (e.g., SAFZ-oblique  
652 *en echelon* macro-folds).

653 Further, our field data suggest that minor right-slip faults evolved synchronously and  
654 parallel with the E–W-trending *en echelon* fold limbs, propagating through rheologically  
655 weaker mudstone beds that flowed plastically and acted as slip surfaces during distributed  
656 deformation. Later or simultaneously, these faults escaped from the mudstone beds and  
657 propagated as NW–SE-striking right-slip faults adjacent to tightened shear folds during partly  
658 partitioned deformation, and finally ended up with truncation of the SAFZ-oblique folds (Fig.  
659 6 and Supplement S7a–c).

660 The presence of out-of-the syncline reverse/thrust faults relative to the reshaped and  
661 tightened SAFZ-oblique macro-folds (Fig. 4 and Supplement S5a and d), where SW-dipping  
662 thrust faults formed (sub-) parallel to the Indio Hills fault, and the related upright anticline  
663 (Fig. 3c) suggest successive distributed and partly partitioned strain in the study area. The  
664 proximity and superimposed nature of reverse/thrust faults relative to the reshaped *en echelon*  
665 folds suggest that they utilized modified fold hinges and steeply tilted limbs as preexisting  
666 zones of weakness. Despite the uncertainty around the crosscutting relationship between the  
667 SAFZ-parallel anticline and the SAFZ-oblique *en echelon* macro-folds, the low-angle thrust  
668 and intra-detachment folds in the southeastern macro-fold (Fig. 4) indicate that such thrust  
669 detachments may have already formed during (early?) distributed deformation, i.e., that  
670 distributed and partitioned deformation occurred simultaneously and/or progressively (see  
671 phases 1 and 2 in Table 1).

672 The conjugate WNW–ESE- to NNW–SSE-striking right-slip and NNE–SSW-striking  
673 left-slip faults and kink band features truncate strata on both macro-fold limbs (Fig. 3b–c)  
674 with an acute angle perpendicular to the macro-folded and tilted Palm Spring Formation strata

675 (e.g., Supplement S7e). Thus, they formed together with or after the *en echelon* macro-folding  
676 (< 0.76 Ma).

677

### 678 ***Tectonic model***

679 In this section we use detailed structural analysis of folds and faults in the southeastern  
680 Indio Hills to outline the structural history of the tectonic uplift itself, evaluate it in terms of  
681 what is known about strain budgets within the southern San Andreas fault system, link it to  
682 nearby structures (Eastern California shear zone and Landers–Mojave Line), and integrate the  
683 local structural history into a structural synthesis for the southern San Andreas fault zone in  
684 the past 4 Myr.

685 Our field and structural data support inversion and uplift of the Indio Hills involving  
686 progressive or stepwise stages of folding and faulting, incorporating a switch from distributed  
687 to partly partitioned transpression (Fig. 7). Prior to inversion in late Pleistocene time, the  
688 Indio Hills fault may have been a steep, SW-dipping normal fault that downthrew (Miocene?–  
689 ) Pliocene sedimentary strata against granitic basement rocks in its footwall to the northeast.  
690 These basement rocks were partly eroded in the footwall of the fault. In the hanging wall of  
691 the fault, strata of the Mecca Formation were deposited in the Pliocene, most likely at 3.7–3.0  
692 Ma, and the lower and upper members of the Palm Spring Formation respectively at 3.0–2.3  
693 Ma and 2.6–0.76 Ma, as suggested from paleomagnetic studies in the Mecca Hills (Chang et  
694 al., 1987; Boley et al., 1994; McNabb et al., 2017).

695 Early inversion involved distributed transpressional strain triggered by right-lateral  
696 slip along the Indio Hills fault (Fig. 7a). Three macro-scale, upright *en echelon* folds and  
697 associated parasitic folds formed in loosely consolidated sedimentary rocks of the Mecca and  
698 Palm Spring formations after the latter was deposited (< 0.76 Ma), i.e., probably in earliest  
699 late Pleistocene time (Table 1). The fold set evolved oblique to the main strand of the SAFZ  
700 and formed a right-stepping pattern of E–W-oriented axial surfaces that trend at a high angle  
701 (45°) to the bounding Indio Hills fault due to uniform simple shear (e.g., Sanderson and  
702 Marchini, 1984; Sylvester, 1988). This is notably observed in the less deformed southwestern  
703 part of the study area (Fig. 2) near the main San Andreas fault, where the macro-folds still  
704 display their initial non-plunging geometries. Bed-internal minor fold and fault systems in  
705 weak mudstone beds (Fig. 4 and Supplement S5a) may have formed parallel to the E–W-  
706 trending *en echelon* fold traces, either as thrust detachments due to oblique N–S shortening  
707 when strata were horizontal, and/or as strike-slip faults on the fold limbs. In addition, minor

708 (bed-internal) SAFZ-parallel thrusts and folds formed prior to or together with the *en echelon*  
709 macro-folds (Supplements S4b–c and S9a–b), thus suggesting minor strain partitioning.

710 Further deformation in the late Pleistocene led to gradual change from mostly  
711 distributed with minor partitioned deformation to partly partitioned shortening and right-  
712 lateral faulting and folding (Fig. 7b), probably since the Indio Hills fault started to  
713 accommodate an increasing amount of reverse slip, thus acting as an oblique-slip right-lateral-  
714 reverse fault, and where the main San Andreas fault did not yet play a major role. The main  
715 result was tightening of the macro-folds toward the Indio Hills fault and clockwise rotation of  
716 fold axes to a steeper westerly plunge due to increased shear folding, whereas *en echelon*  
717 upright folding continued in the southwest (Fig. 7b). Increased shortening and shearing  
718 reshaped the macro-folds and their back-limb folds to tight, isoclinal, and partly overturned  
719 folds with consistent Z-style and sigmoidal axial-surface traces near the Indio Hills fault (Fig.  
720 7b). The sigmoidal pattern of the WNW–ESE-trending *en echelon* macro-folds formed at a  
721 much lower angle with the Indio Hills fault ( $< 20\text{--}30^\circ$ ) than farther southwest ( $60\text{--}70^\circ$ ).  
722 Furthermore, the incremental component of lateral strain is recorded as progressively  
723 crosscutting NW–SE-striking, strike-slip shear faults terminating with local truncation of the  
724 central macro-fold (see Fig. 7c and section below). Uplift of the Indio Hills in the late  
725 Pleistocene (because the earliest late Pleistocene 0.765 Ma Bishop Ash is involved in folding;  
726 Sarna-Wojcicki et al., 2000; Zeeden et al., 2014) was marked by a gradual switch to more  
727 kinematically evolved transpressional strain partitioning, where the dominant shortening  
728 component was accommodated by right-lateral-oblique, top-NE thrusting along the Indio  
729 Hills fault and major strike-slip movement along the main San Andreas fault (Fig. 7c and  
730 phase 3 in Table 1). NE-directed oblique thrusting on the Indio Hills fault and related minor,  
731 reverse, out-of-the syncline faults led to uplift, which resulted in formation of a major  
732 anticline parallel to the Indio Hills fault in sediments of the Mecca Formation (see anticline  
733 closest to Indio Hills fault in Fig. 3c and 7c). With increasing partitioning, slip parallel to the  
734 transform plate boundary was accommodated by right slip along the linear main San Andreas  
735 fault, where sub-vertical folds formed locally, and presumed antithetic conjugate kink band  
736 sets of right- and left-slip cross faults affected the entire uplifted area.

737 We favor a progressive evolution from distributed to partly partitioned deformation as  
738 presented in Fig. 7a–c, although overlapping and synchronous formation of various structures  
739 may have occurred (overlapping of phases 1 and 2 in Table 1), at least locally (except for the  
740 late-stage main San Andreas fault and related shear folds; phase 3 in Table 1). The  
741 overlapping and synchronous formation of structures is based on uncertainties in our field

742 data, e.g., variable cross-cutting relations of early, bedding-parallel strike-slip and thrust faults  
743 and *en echelon* macro-folds (Figs. 4 and 6, and Supplements S5c–d and S7), and from the  
744 spatial variations in the direction of maximum horizontal stress across the Indio Hills at  
745 present, from 40° oblique to the boundary faults near the main San Andreas fault to 70°  
746 oblique near the Indio Hills fault (Hardebeck and Hauksson, 1999).

747 Our observations of mostly lateral movement along the main San Andreas fault (i.e.,  
748 southeastern continuation of the Mission Creek fault) and the proposed late Pleistocene to  
749 present-day age for deformation in the southeastern Indio Hills are consistent with work by  
750 Keller et al. (1982). A major difference between the northwestern and southeastern Indio Hills  
751 is the relatively tighter macro-folding over a narrower area and more intense character of  
752 deformation in between the two bounding faults in the southeastern Indio Hills (Figs. 2 and 3;  
753 Keller et al., 1982; Lancaster et al., 2012).

754 The right-lateral-reverse character of the Indio Hills fault and its role in our kinematic  
755 model for basin inversion in the southern Indio Hills are further supported by the relationship  
756 of the Indio Hills fault with the Eastern California shear zone, which merge together north of  
757 the study area where the Indio Hills fault bends into a NNW–SSE strike along the Landers–  
758 Mojave Line (Dokka and Travis, 1990a, 1990b; Nur et al., 1993a, 1993b; Thatcher et al.,  
759 2016). Recent activity along the Landers–Mojave Line recorded as six–seven earthquakes  
760 with  $M > 5$  between 1947 and 1999 (Fig. 1; Nur et al., 1993a, 1993b; Du and Aydin, 1996;  
761 Spinler et al., 2010) indicates that a through-going NNW–SSE-striking fault crosscuts the  
762 Pinto Mountain fault (Nur et al., 1993a, 1993b; Rymer, 2000). Notably, the 1992 Joshua Tree  
763 earthquake occurred along the NNW–SSE-striking, west-dipping West Deception Canyon  
764 fault (Rymer, 2000 and references therein), which merges with the (probably southwest-  
765 dipping) Indio Hills fault in the south (see figure 1 in Rymer, 2000). Therefore, we propose  
766 that the Indio Hills fault, may be one of several faults to transfer displacement from  
767 unsuitably oriented, NW–SE-striking right-slip faults in the north, such as the Calico and  
768 Camp Rock faults, to the main SAFZ strand in the south (Fig. 1).

769 Farther southeast along strike, the Indio Hills and main San Andreas faults merge  
770 along a dextral freeway junction, i.e., a junction of three dextral fault branches (sensu Platt  
771 and Passchier, 2016 and Passchier and Platt, 2017), which may have enhanced wedge-shaped  
772 transpressional uplift of the Indio Hills after the late formation of the main San Andreas fault  
773 in the late Pleistocene (Fig. 8a–c and Table 1). However, anticlockwise rotation of the Indio  
774 Hills block and related structures in map view as predicted in a dextral freeway junction (Platt  
775 and Passchier, 2016; Passchier and Platt, 2017) was not recorded by our field data (except

776 along the main San Andreas fault due to localized right-slip along the fault; cf. sub-vertical  
777 shear fold in Fig. 5). This may be due in part to the late formation of the main San Andreas  
778 fault (< 0.76 Ma, i.e., late Pleistocene), i.e., clockwise rotation (in map view) of the fold and  
779 fault structures due to right-lateral slip along the Indio Hills fault, and to the oblique-slip  
780 character of the Indio Hills fault. Thus, the dextral freeway junction in the Indio Hills may be  
781 more of a transitional nature. Instead of major anticlockwise rotation of the Indio Hills block  
782 in map view, the accretion of material toward the fault junction due to right slip along the  
783 main San Andreas fault is probably partly accommodated by the dominant vertical slip  
784 component along the Indio Hills fault, leading to further uplift near the junction (i.e.,  
785 clockwise rotation in cross section).

786

### 787 ***Regional comparison and implications***

788 The proposed progressive tectonic model for the Indio Hills uplift has wide  
789 implications when compared and correlated with other fault strands of the SAFZ bounding  
790 uplifted domains along strike in the Coachella and Imperial valleys (Fig. 8a–c), and in  
791 explaining lateral variations in fault architectures, kinematic evolution and timing,  
792 deformation mechanisms and areal segmentation (Sylvester and Smith 1987; McNabb et al.,  
793 2017; Janecke et al., 2018; Bergh et al., 2019). Here we compare and contrast the structural  
794 evolution of the southeastern Indio Hills with that of nearby tectonic uplifts (Mecca Hills and  
795 Durmid Hills).

#### 796 *Comparison with the Mecca Hills*

797 Previous studies of SAFZ-related uplifts between the Indio Hills and Durmid Hills in  
798 Coachella Valley suggest that the Indio Hills and main San Andreas faults link up in the  
799 southeasternmost Indio Hills and proceed as the main San Andreas fault in the Mecca Hills  
800 (Fig. 8c) which then, together with the subsidiary Skeleton Canyon and Painted Canyon  
801 faults, bounds a much wider flower-like uplift area than in the Indio Hills (Fig. 8c; Sylvester  
802 and Smith, 1976, 1987; Sylvester, 1988; McNabb et al., 2017; Bergh et al., 2019). In contrast  
803 to the Indio Hills fault, however, the main San Andreas fault in Mecca Hills has an  
804 anastomosing geometry with thick (10–500 m), red-stained fault gouge. Regardless, we  
805 consider these faults to be correlative and infer the lack of fault gouge along the Indio Hills  
806 fault to be due to more localized strain on the Indio Hills fault than on the SAFZ in Mecca  
807 Hills. This is supported by a more rectilinear geometry and lack of fold–fault linkage in Indio  
808 Hills, which may have allowed initial lubrication of the fault surface in basement rocks with  
809 high contrasting rheology (e.g., Di Toro et al., 2011; Fagereng and Beall, 2021), and which

810 hampered fluid circulation and extensive cataclasis. Another possible explanation may be the  
811 presence of coarse-grained deposits of the Mecca Formation, which may have  
812 partitioned/decoupled deformation along the Indio Hills fault from that in overlying Palm  
813 Spring sedimentary strata.

814 Both the Indio Hills and Mecca Hills uplift areas are bounded to the northeast by a  
815 presumed Miocene–Pliocene, SW-dipping normal fault (Fig. 8a), which later acted as major  
816 SAFZ-parallel oblique-reverse faults, and which significantly contributed to the uplift of these  
817 areas in (late) Pleistocene time (Sylvester and Smith, 1976, 1987; McNabb et al., 2017; Bergh  
818 et al., 2019). In the Mecca Hills (Fig. 8c), the Painted Canyon fault is flanked in the hanging-  
819 wall to the southwest by a basement-cored, macro-fold (Mecca anticline), which is similar to  
820 the upright anticline that parallels the Indio Hills fault and adjacent minor thrust faults (Figure  
821 2 & Figure 3c and Supplement S5a). Similar folds appear adjacent to the Hidden Springs–  
822 Grotto Hills fault (Sheridan et al., 1994; Nicholson et al., 2010), a NW–SE-striking, now  
823 reverse splay fault of the main SAFZ between the Mecca Hills and Durmid Hills (Fig. 8c). It  
824 is, however, unlikely that these marginal faults link up directly along strike. Rather, they  
825 merge or splay with the SAFZ and SAFZ-oblique faults.

826 The inversion and main uplift history of the Mecca Hills segment of the SAFZ (Bergh  
827 et al., 2019) initiated with right-lateral slip on a steep SAFZ, from where SAFZ-oblique *en*  
828 *echelon* folds and dominantly right-slip faults splayed out in a one–two kilometers wide  
829 damage zone on either side of the SAFZ (Fig. 8a). The subsidiary Skeleton Canyon fault  
830 initiated as a steep right-lateral and SAFZ-parallel strike-slip fault along a small restraining  
831 bend (Fig. 8b). Successive lateral shearing reshaped the *en echelon* folds into steeply plunging  
832 folds with axial traces parallel to the SAFZ. The final kinematic stage generated SW-verging  
833 fold and thrust structures parallel to the SAFZ (Fig. 8c), which truncated the *en echelon* folds  
834 and the NE-dipping Skeleton Canyon fault. The resulting wedge-like flower structure thus  
835 records a polyphase kinematic evolution from distributed, through locally partitioned, to fully  
836 partitioned strain (Bergh et al., 2019).

837 Based on the geometric similarities, we consider that the *en echelon* macro-folds in  
838 both Indio Hills and Mecca Hills formed coevally, but not on the same regional right-lateral  
839 fault strand (Fig. 8a). In both areas, the *en echelon* folds and faults are strongly reworked and  
840 tightened into sigmoidal shapes where they merge with the Indio Hills and Skeleton Canyon  
841 faults respectively (Fig. 8b; Bergh et al., 2019), and SAFZ-parallel thrust faults formed early  
842 (i.e., prior to macro-folding) both in the Indio Hills (Supplement S5c–d) and in the Mecca  
843 Hills (Rymer, 1994), thus supporting continuous, partly partitioned strain field in both areas.

844 Strain partitioning caused major uplift of the Mecca Hills block along the Skeleton Canyon,  
845 Painted Canyon, and Hidden Springs–Grotto Hills faults (Fig. 8c), all acting as SAFZ-parallel  
846 oblique-slip thrust faults (Sheridan et al., 1994; Bergh et al., 2019). The partitioned right-slip  
847 component was partly transferred to the main San Andreas fault in Indio Hills, and/or to an  
848 unknown hidden fault southwest of the SAFZ (e.g., in Mecca Hills; Hernandez Flores, 2015;  
849 Fuis et al., 2017), possibly the East Shoreline fault (Janecke et al., 2018).

850         Based on paleomagnetic and structural field studies, uplift of the SAFZ-related Mecca  
851 basin started at ca. 2.6–0.76 Ma (i.e., earliest to mid Pleistocene) with partial and local erosion  
852 of the Palm Spring Formation (see lower and upper unconformities in McNabb et al., 2017)  
853 and culminated after 0.76 Ma (see unconformity between the uppermost Palm Spring  
854 Formation and base of the Ocotillo Formation southwest of the Painted Canyon fault in  
855 McNabb et al., 2017), i.e., after deposition of the whole Palm Spring Formation (McNabb et  
856 al., 2017; Janecke et al., 2018). Uplift is still ongoing at present (Fattaruso et al., 2014;  
857 Janecke et al., 2018). Fault activity and tectonic uplift of the Mecca Hills therefore most likely  
858 initiated earlier (earliest Pleistocene) than in the Indio Hills (earliest late Pleistocene; Table  
859 1), where the transition from the lower to the upper member of the Palm Spring Formation is  
860 gradual and does not show any major unconformity.

#### 861 *Comparison with Durmid Hills*

862         The Durmid ladder structure along the southern 30 kilometers of the SAFZ in Imperial  
863 Valley defines a similar but oppositely merging, one–three kilometers wide wedge-shaped  
864 uplift as in Indio Hills, bounded by the right-lateral and reverse East Shoreline fault to the  
865 southwest and the main SAFZ to the northeast (Fig. 8c; Janecke et al., 2018). Internally, the  
866 ladder structure comprises *en echelon* folds (Babcock, 1974; Bürgmann, 1991) that merge in a  
867 sigmoidal pattern with the main SAF, and subsidiary sets of conjugate SAFZ-parallel right-  
868 lateral and SAFZ-oblique E–W-striking, left-slip cross faults, which accommodated clockwise  
869 rotation of internal blocks (Janecke et al., 2018). The *en echelon* folds formed at a comparable  
870 time, i.e., < 0.76 Ma in the Indio Hills and at ca. 0.5 Ma in the Durmid Hills (Table 1). By  
871 assuming a northwest continuation of the main SAFZ with the SAFZ in Mecca Hills, the East  
872 Shoreline fault has no exposed correlative fault in the Mecca Hills and Indio Hills (Fig. 8c;  
873 Damte, 1997; Bergh et al., 2019). Nevertheless, the East Shoreline fault may continue at depth  
874 southwest of the main San Andreas fault (Janecke et al., 2018).

875         A significant difference between the Indio Hills–Mecca Hills and the Durmid Hills,  
876 however, is the large number of cross faults in the Durmid ladder structure. Such faults are  
877 interpreted as early-stage (ca. 1 Ma – early/mid Pleistocene), NE–SW-striking, left-lateral,

878 faults (Fig. 8a), which were rotated clockwise by progressive right-lateral motion into  
879 sigmoidal parallelism with the SAFZ and East Shoreline fault (Fig. 8b–c; Janecke et al. 2018).  
880 In contrast, cross faults in Indio Hills are much less common and, where present, probably  
881 formed late, but prior to the main San Andreas fault (i.e., in the earliest or middle part of the  
882 late Pleistocene). Thus, in the Indio Hills, there is no evidence of clockwise rotation of early-  
883 stage cross faults as in the Durmid Hills, but rather clockwise rotation of fold axial traces is  
884 common, which may be a first step in the formation of ladder-like fault blocks (e.g., Davis,  
885 1999; Schultz and Balasko, 2003).

886 A major outcome of the comparison with Durmid Hills is that the wedge-shaped uplift  
887 block between the Indio Hills and main San Andreas faults may represent a failed uplift  
888 and/or the early stage of formation of a ladder structure. This idea is supported by presence of  
889 similar master faults and structures with comparable kinematics in both the Indio Hills and  
890 Durmid Hills, including oblique *en echelon* macro-folds, strike-slip faults acting as step-over  
891 faults, and reverse faults. Younger, non-rotated, conjugate cross faults exist in the Indio Hills  
892 but not in the Durmid Hills where such faults are more evolved features due to larger strain  
893 and more advanced stage of ladder structure formation. From these observations, one should  
894 expect to find ladder structures operating at different evolution stages among the many, yet  
895 unexplored uplifts in Coachella Valley.

896

## 897 **Conclusions**

- 898 1) The Indio Hills fault likely initiated as a SW-dipping, basement-seated normal fault  
899 during the opening of the Gulf of California in the mid Miocene, and was later  
900 inverted as a right-lateral reverse, oblique-slip fault in the (earliest?–) late Pleistocene  
901 due to transpression along the transform plate boundary, whereas the main San  
902 Andreas fault initiated probably as a dominantly right-slip fault during the later stages  
903 of uplift in the late Pleistocene.
- 904 2) The Indio Hills segment of the SAFZ in Coachella Valley, southern California evolved  
905 as a wedge-shaped uplift block between two major SAFZ-related fault strands, the  
906 Indio Hills and main San Andreas faults, which merge in a dextral freeway junction of  
907 a transitional nature to the southeast.
- 908
- 909 3) Transpressive deformation triggered uplift and inversion of the Indio Hills through a  
910 progressive change from distributed *en echelon* folding to partly partitioned right-slip  
911 thrusting. We favor a progressive rather than stepwise model in which the main uplift

912 was related to late shortening at the freeway junction where the Indio Hills and main  
913 San Andreas faults merge.

914 4) The Indio Hills fault is a splay fault of the SAFZ that merges to the north with the  
915 Landers–Mojave Line and contributes to transfer slip from unsuitably oriented faults  
916 of the Eastern California shear zone to the main San Andreas fault in the southeast.

917 5) A significant difference of the Indio Hills with the Durmid Hills is that left-lateral  
918 step-over and cross faults in the Durmid Hills rotated subparallel with the mSAF,  
919 whereas in Indio Hills, all cross faults are oblique with the SAFZ and, thus, may  
920 reflect an earlier stage of a still evolving ladder structure.

921 6) The initiation of right-lateral to right-lateral-reverse slip along major SAFZ-parallel  
922 faults and the main San Andreas fault in the Coachella Valley is younger towards the  
923 northwest (Pliocene in the Durmid Hills, early Pleistocene in the Mecca Hills and late  
924 Pleistocene in the Indio Hills). The onset of uplift, however, appears to be coeval in all  
925 tectonic uplifts (late to latest) Pleistocene.

926

#### 927 **Data availability**

928 The structural dataset and field photographs used in the present study are available on  
929 DataverseNO (Open Access repository) at <https://doi.org/10.18710/TM18UZ>. Satellite and  
930 aerial images are from Google Earth (© Google Earth 2011).

931

#### 932 **Authors contribution**

933 All authors contributed to collect structural measurements in the Indio Hills. JBPK  
934 wrote the first draft of the manuscript and designed half the figures and supplements  
935 (workload: 35%). Prof. SGB made major revision to the initial draft and designed half the  
936 figures and supplements (workload: 35%). Prof. AGS also revised the manuscript and  
937 provided major input about the local geology (workload: 30%).

938

#### 939 **Competing interests**

940 The authors declare that they have no known competing interests.

941

#### 942 **Acknowledgments**

943 The staff at the University of California–Santa Barbara and San Diego State  
944 University provided great hospitality during Steffen Bergh’s sabbatical leaves in 2011–2012  
945 and 2016–2017 while working with the San Andreas fault. We thank all the persons from

946 these institutions that were involved in this project. The authors thank Prof. Emeritus Arild  
947 Andresen (University of Oslo) and Prof. Holger Stunitz (UiT) for helpful comments and Jack  
948 Brown (San Diego State University) for fieldwork collaboration. Prof. Susanne Janecke (Utah  
949 State University) and Dr. Miles Kenney (Kenney Geoscience) provided fruitful discussion.  
950 We thank the reviewers (Dr. Jonathan Matti and an anonymous reviewer) for their extended  
951 helpful comments on the manuscript.

952

### 953 **Financial support**

954 The present study is part of the CEED (Centre for Earth Evolution and Dynamics) and  
955 ARCEX projects (Research Centre for Arctic Petroleum Exploration), which are funded by  
956 grants from UiT The Arctic University of Norway in Tromsø and the Research Council of  
957 Norway (grant numbers 223272 and 228107) together with eight academic and six industry  
958 partners.

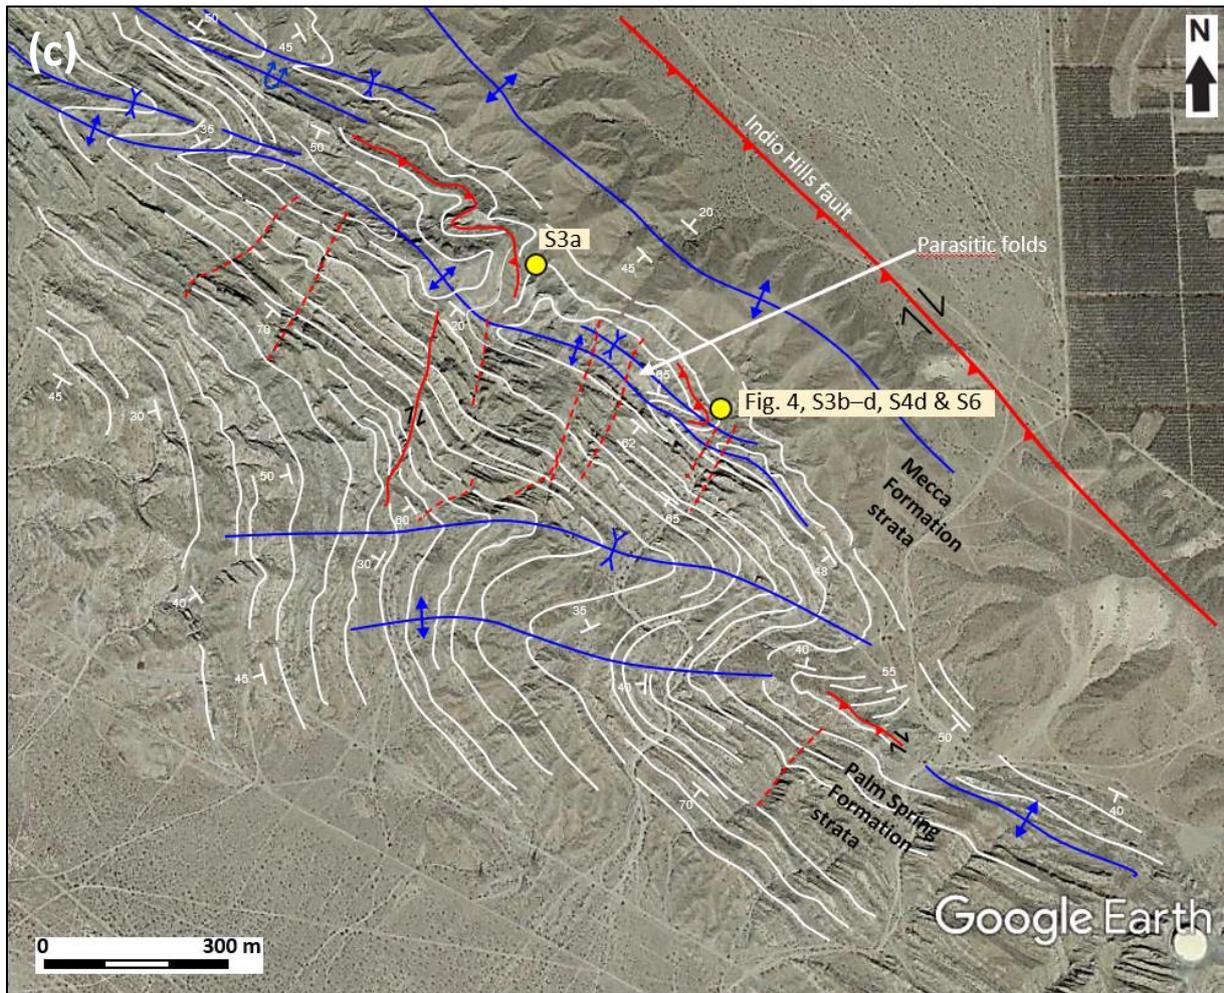

**Figure 2: Interpreted Google Earth image in the southeastern part of the Indio Hills uplift area. Three main SAFZ-oblique macro-folds (northwestern, central, southeastern) are mapped in between the bounding Indio Hills and main San Andreas faults, whereas one SAFZ-parallel anticline is present close to the Indio Hills fault. More detailed figures are numbered and framed. Structural datasets are plotted in lower hemisphere Schmidt stereonets via the Orient software (Vollmer, 2015). Note that faults are also included as fractures in the stereonets. Bedding surfaces are shown as pole to plane with frequency contour lines, with average  $\pi$ S great circle (red great circles), fold axial surface (blue great circles) and fold axis (red dots). Brittle fractures in sedimentary strata and basement rocks are plotted as great circles. Source: Google Earth historical imagery 09-2011. Uninterpreted version of the image available as Supplement S1. © Google Earth 2011.**

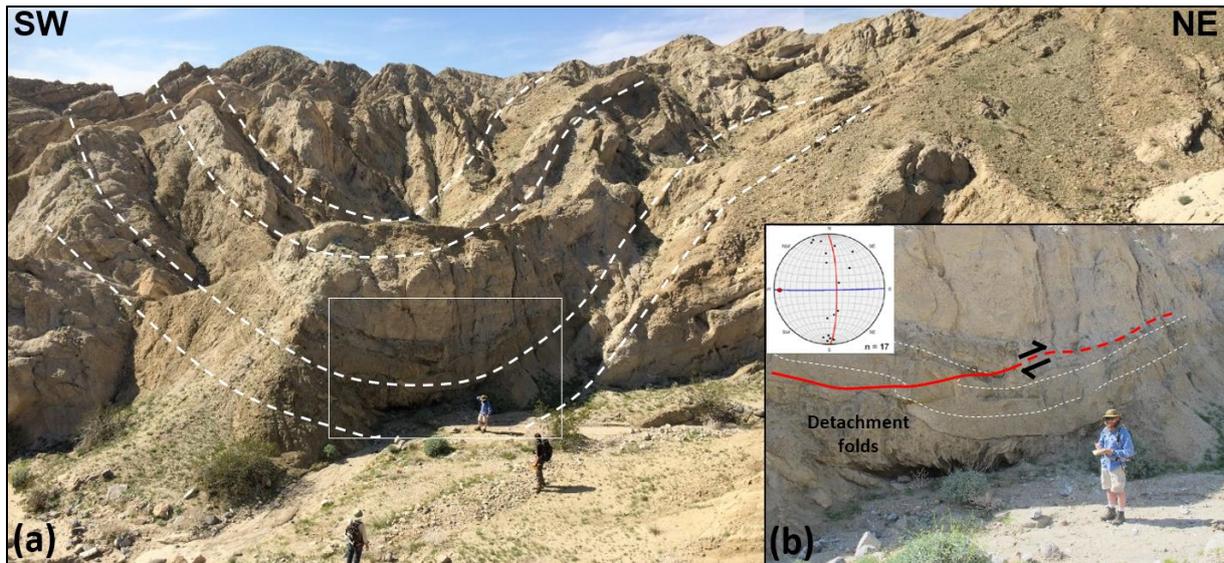

1251

1252

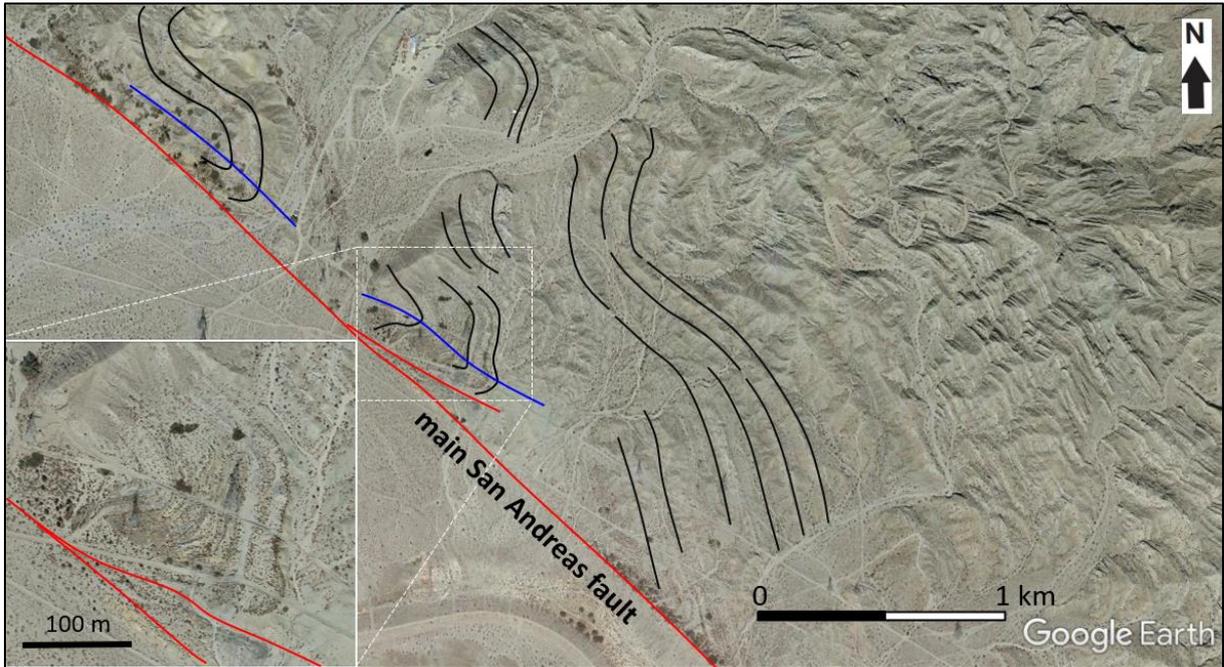

1253  
 1254 **Figure 3: Detailed structural maps showing the architecture and outline of anticline-**  
 1255 **syncline pairs, traces of bedding and strike and dip orientation, axial surface traces, and**  
 1256 **fold-related faults in (a) the northwestern, (b) central, and (c) southeastern macro-folds.**  
 1257 **Note tighter and consistently asymmetric (Z-shaped) geometries of the macro-folds to**  
 1258 **the east, whereas folds to the west are more open and symmetric. Traces and orientation**  
 1259 **of bedding show a back-limb composed of attenuated shear folds merging from the**  
 1260 **central macro-fold in the north, whereas the fore-limb is much shorter and more**  
 1261 **regularly folded. The yellow dots show the location of field photographs. See fig. 2 for**  
 1262 **legend and location. Uninterpreted version of the images available as Supplement S2a–c.**
